THE FEMALE REPRODUCTIVE SYSTEM

By JOHN C. BURCH, M.D., ROBERT L. CHALFANT, M.D.,
and HORACE T. LAVELY, JR., M.D.

JOHN CHRISTOPHER BURCH, a Tennessean, was educated at Vanderbilt University, where he is now Professor of Gynecology. He received an extensive surgical training before pursuing his specialty of gynecology. Doctor Burch is a proponent of the view that there is a close interrelationship between abdominal surgery and gynecology, and that diseases do not respect the boundaries of surgical specialties. For this reason, he believes the surgeon must be grounded in gynecology and the gynecologist in surgery.

ROBERT LEE CHALFANT received his medical education at the University of Tennessee and completed his training in obstetrics and gynecology at Vanderbilt University. He is associated in the practice and teaching of gynecology with Doctor Burch.

HORACE THOMAS LAVELY, JR., graduated in medicine from the University of Pennsylvania and holds an appointment on the Gynecological Teaching Staff of Vanderbilt University.

Individualization of the Patient. This presentation of the diseases of the female reproductive system follows a clinical plan. It starts with the individualization of the patient according to her needs for her various functions. The guiding principle is the conservation of useful function. This is the cardinal rule of the physiologic approach to pelvic surgery. Its mastery is the distinguishing characteristic of those surgeons whose

patients are happy and satisfied with their treatment.

A little story illustrates this type of individualization of the patient. Three uteri are on the pathologist's table. They are almost identical. Several myomas of golf-ball size distort the regularity of their contour. Each weighs about 175 gm. The first came from a young woman thirty-two years of age. This patient came to her physician for

amount of blood is so slight as not to produce discoloration. In such circumstances, the discharge appears whitish. A leukorrheal discharge may become bloody and a bloody discharge leukorrheal.

The principal conditions causing leukorrhea are trichomoniasis, endocervicitis, neisserian infection or gonorrhea, endocrine changes, thrush and cancer. When arranged in this order they spell the key word TENETC.

In making a differential diagnosis of the cause of leukorrhea, the starting point is the history. From a good history, a fairly accurate diagnosis can often be made. The first point to settle is whether the patient really does have an abnormal discharge. The appearance of a little mucus at ovulation, or a slightly increased moisture preceding or following menstruation, is physiologic. If the discharge is noticeable at all times or is of sufficient amount to stain the underclothes, it must be considered abnormal. Some idea can be obtained as to the amount of the discharge by inquiring if it is necessary to wear a napkin, or by finding out how many times a day it is necessary to change the underclothes. If it is not necessary for the patient to change her underclothes, knowing the size of the spot on them may be helpful.

Circumstances surrounding the onset of the symptoms give some help. Trichomoniasis, for example, seldom occurs before puberty, but is common after puberty. Moniliasis may occur at any age and is especially common during pregnancy. It occurs frequently in association with diabetes and following the use of antibiotics. It is a clinical rule to always think of the gonococcus as a cause of discharge before puberty.

TRICHOMONIASIS

The patient complains of either discharge or some form of irritation such as itching, burning or stinging. In consistency, the discharge is thin and its amount is variable. The color is yellowish green; little bubbles contained within the discharge give it a foamy appearance. The odor is disagreeable and somewhat characteristic. Dyspareunia is not voluntarily mentioned by the patient but is frequent. On physical examination, the findings vary according to the severity of the infection. In the acute stage, there is marked vulvitis and vaginitis. Multiple red, punctate spots occur throughout the upper vagina, especially in the fornices. When marked, these produce a characteristic ap-

pearance referred to as "strawberry vagina." Small erosions occur on the exocervix. An eccentric erosion, not touching the os, is rather characteristic. Changes in the hydrogen ion concentration of the vagina are suggestive. Usually the pH reading is 5 or above, using Nitrazine paper as an indicator. The diagnosis depends upon finding trichomonads in the secretion. If present, they are easily identified by placing a little of the discharge on a slide, mixing it with a drop or two of saline solution, and covering the mixture with a coverglass and examining it under a microscope.

Donné first described *Trichomonas vaginalis* in 1836. Not until quite recently was its importance as a cause of vaginitis appreciated. Recent inoculation experiments, made possible by the development of pure cultures of the organism, clearly establish it as a cause of vaginitis. However, there are still some who believe that the associated organisms, especially streptococci, are of greater importance in the production of symptoms. The *Trichomonas vaginalis* is a distinct species, different culturally and morphologically from the *Trichomonas buccalis* and the *Trichomonas fecalis*.

The *Trichomonas vaginalis* inhabits the male and female urogenital tracts. In the male, its habitat is the preputial sac and prostate, in the female, the bladder, urethra, urethral glands, ducts of Bartholin's glands and the vagina. Trichomonads do not invade the endocervix. There is increased evidence that sexual intercourse is a factor in the transmission. However, in an individual case the explanation of the infection is often difficult. Formerly, a good deal of attention was directed toward the rectum and rectal contamination was thought to be one of the chief factors in transmission. Recent studies do not support this view. Contaminations from infected instruments, bath water, douche nozzles, towels and hands are, of course, possibilities. Many women harbor the organisms and yet never have any of the symptoms of vaginitis. However, if the biochemical balance of the carrier's vagina becomes disturbed, infection may result. Alkaline douches, profuse alkaline cervical discharges and infections which disturb the normal vaginal flora are all precipitating causes.

In the treatment of trichomoniasis, the first step is to restore the normal acidity of the vagina. This is accomplished by reducing the amount of alkaline discharge from the cervix and by increasing the acidity of the

a premarital examination. The tumor was found and the uterus removed. The next was from a woman, aged forty-two years, who was the mother of four children. She was anemic from excessive menstruation. The last was found in a woman of sixty-five years who sought examination because of a fear of cancer. She had no symptoms.

In the first woman, the useful function of reproduction could have been conserved by myomectomy or, perhaps, simply by observation. As a result of the loss of this function, the operation has changed the course of her life from normal to abnormal. To her the operation was a tragedy. The second patient probably had no further use for her reproductive functions. She had a disabling condition and to her the operation is a blessing. In the third woman, there is little justification for the operation, because small, asymptomatic fibroids in a postmenopausal woman generally cause no trouble. Their malignant potential is hardly as great as the mortality of the operation.

Now each of these women had an obviously diseased uterus—of sufficient degree, perhaps, to satisfy an exacting tissue committee. Yet one operation was an unnecessary mutilation, another just plain unnecessary and the third, thoroughly justified. The story proves that the surgeon must select a plan of treatment which is suitable for the pathologic process and for the needs of a particular woman. Now, how is this done? Is there a method of reasoning which can be applied to all problems involving the female reproductive system?

There is such a method and in its simplest form it consists of four steps.

1. Consider the pathologic condition in relation to its effect on function. Function is a broad term and includes, specifically, the general functions of life and health (both mental and physical) and the pelvic functions of sex, reproduction, ovarian activity, menstruation and support.

2. Define the needs of the particular patient for each of these functions.

3. Determine the effect of all proposed forms of treatment in terms of these functions.

4. Lastly, put the data together and make the best possible deal, in regard to the pathologic process, for the particular patient.

Those who use this approach study disease from the functional standpoint. In that which follows, the effect of the pathologic condition on function is emphasized so that it can be compared with the effects of the

various forms of treatment. In studying patients, attention should be given to the need of the individual patient for her functions.

Clinical Approach to Gynecology. In the diseases of the female reproductive system, there are three main symptoms and one outstanding physical sign. Discharge, pain and bleeding are the symptoms. The presence of a mass is the physical sign. When a symptom or sign is encountered, the first step in diagnosis is the enumeration of its possible causes. To illustrate this process, consider abnormal vaginal bleeding. The five common causes of this bleeding are cancer, abortion, fibroid tumor, ectopic pregnancy and endocrine dysfunction. The first letters of these disorders are C-A-F-E-E. Although the word "cafee" is not in the dictionary, it is nevertheless useful as a key word or mnemonic. The student thinks of a bleeding problem as a "cafee" problem and this immediately sets up the differential diagnosis. A good many hundreds of students have used the "cafee" scheme in the diagnosis of abnormal vaginal bleeding, and it has been so helpful and practical that key words and a key sentence are now used for discharge, pain, bleeding and mass. The key sentence is "TENETC COPS CAFEE PREMIO". True, the sentence is a little odd, but its oddness makes an impression which serves to better stamp it on the memory.

DISCHARGE

Leukorrhea means any whitish discharge from the female genitalia. It is commonly known among women as the "whites". Normally there is a secretion from the uterus, the vagina and Bartholin's glands, but these secretions are not enough to call the attention of the patient to their presence. Under conditions of sexual excitement, the secretions may be marked in amount. Just before and immediately following the menstrual period, a slight increase in secretions may be noticed. This is physiologic. The whitish discharge may contain a small amount of blood and this gives it a brownish character. In conditions producing a bloody discharge, there may be periods in which the

* Translated, TENETC means trichomoniasis, endocervicitis, neisserian infection, endocrine disorder, thrush and cancer. COPS refers to pain of cerebral, organic, peritoneal and somatic origin. CAFEE represents bleeding due to cancer, abortion, fibroid tumor, ectopic pregnancy and endocrine causes. PREMIO is the mnemonic for masses. These are pregnancy, retroversion, enlargement undiagnosed, myoma, inflammatory disease, ectopic pregnancy and ovarian masses.

As the discharge becomes less, the squamous epithelium pushes back toward the os and blocks off the openings of the glands, with the subsequent formation of the familiar nabothian cysts of the cervix. A flare-up of the endocervicitis leads to a renewal of the process and the erosion cycle repeats itself many times. The histologic pictures in such a cervix are often bizarre. The pathologist must exercise the greatest care in differentiating them from early intraepithelial carcinomatous changes. One of the important features of an erosion is that the histologic changes may be very significant in the subsequent development of cancer.

An area of erosion is often seen in virgins and is congenital in origin. In the normal process of development, the squamous and columnar epithelium meet at the external os, but sometimes the squamocolumnar junction is well beyond the os. The chance of cancer development in congenital erosion is less than in acquired erosion.

A cervical laceration of some degree always follows childbirth. Inevitably, infection occurs in the fresh laceration and healing is by granulation. A well-healed laceration is of little significance. Persistence of the endocervicitis, however, causes poor healing and erosion. A widening of the os allows the endocervix to roll out on the external surface; this is ectropion. It occurs frequently in association with large bilateral tears. The importance of lacerations is in their causal relationship to endocervicitis and to erosion of the cervix. A laceration has the same clinical significance as endocervicitis and erosion unless it involves the internal os and so predisposes to abortion.

Stricture of the cervix is not uncommon in endocervicitis. It may result from the disease, or scarring from treatment by cauterization, conization or radium application. It causes insufficient cervical drainage and the stasis within the canal inevitably leads to infection.

Leukorrhea is the principal symptom in chronic endocervicitis. Its characteristics vary according to the stage of the disease and the amount of infection. It bears a similarity to the nasal discharge of the common cold. First, the discharge is watery, then thick and purulent and, lastly, clear with a high degree of mucus. When the concentration of mucus is high, the discharge is viscous. It emerges from the vaginal orifice, not as an even flow, but at irregular times in the form of masses or globs. The degree to which it is colored yellow depends upon

the amount of pus. Generally the discharge is nonirritating. However, as previously noted, its alkalinity changes the biochemical composition of the vagina and predisposes to trichomoniasis. In mixed infections in which *Trichomonas* is one of the organisms responsible, the discharge has the irritating characteristics of that due to trichomoniasis.

Dyspareunia and pain on manipulation of the uterus occur if the infection extends into the parametrial tissues. Unless this extension takes place, local symptoms such as low abdominal pain and low backache are more often coincidental to rather than caused by the endocervicitis. Extragenital symptoms which might be related to a focal infection are not generally relieved by the treatment of endocervicitis, except in the cases of systemic gonorrhea and chronic posterior urethritis. Many urologists believe that endocervicitis has a causal relationship to chronic posterior urethritis.

In treating endocervicitis, it is necessary to remember that the endocervix has two important physiologic functions. Its mucus serves as a medium for migration of the sperm and its sphincteric action prevents the premature onset of labor. If the sphincter is destroyed by high amputation, a condition is produced which prohibits a woman from carrying a pregnancy to full term. If the source of a normal amount of cervical mucus is destroyed, an impediment to conception occurs.

As in most conditions, the treatment of endocervicitis is both medical and surgical. The specific endocervicitis of gonorrheal origin responds dramatically to penicillin therapy. Dill has recently described an interesting nonsurgical method for the treatment of nonspecific endocervicitis. At the time of ovulation, the patient is started on a regimen of 1 mg. of stilbestrol daily. This increases the mucous flow from the cervix. At the same time, 1 gm. of sulfadiazine is given three times a day. This treatment is continued for fifteen days.

The surgical treatment of endocervicitis consists of a variety of procedures, ranging from simple cauterization to the use of total hysterectomy in exceptional cases. Local treatment is contraindicated when the disease is acute, in the presence of chronic gonorrhea, and until the possibility of cancer is excluded. In treating endocervicitis, it is necessary to remember that the associated erosion is a result of the endocervicitis and it cannot be cured permanently until the endocervicitis is cured. Generally this is best

vagina. One of the most commonly employed methods of increasing the acidity of the vagina is a mild acid douche. Vinegar, in the proportion of 1 ounce to a quart of water, is often used. Perhaps, 1 teaspoonful of lactic acid to a quart of water is preferable. Most of the suppositories now in use contain lactose, which is readily converted to lactic acid by the Doderlein bacillus.

Among the various trichomonacides, none is absolutely specific. Perhaps the most commonly used is Floraquin, which contains diodoquin, boric acid and carbohydrates. One suppository inserted night and morning, with the use of an occasional acid douche, is a very satisfactory form of treatment. Devegan contains acetarsone, boric acid and hydrolyzed carbohydrates. The recommended dose is two to four tablets inserted daily. Sulfa creams have a wide range of applicability and are fairly effective. Picric acid preparations in the form of suppositories of silver picrate have found favor with many clinicians. Milibis is the newest of the trichomonacides and, while expensive, it seems to be highly potent. Vioborm is a very useful and well-tolerated preparation. All of the trichomonacides must be used for a period of several weeks and should be continued during the menstrual period. The oral administration of Tritheon, one tablet three times daily for ten days, has been helpful in the resistant cases.

Recurrences are common and should stimulate a search for the focus of infection. Most commonly this focus is in the paraurethral glands, the bladder or in the urogenital tract of the husband. The best treatment for the infected paraurethral glands is to destroy them by electrocoagulation.

ENDOCERVICITIS

Cervicitis can involve the entire cervix, the endocervix or the external cervix. Endocervicitis is the important lesion, however, because it serves to maintain the disease on the external cervix. Since the etiologic basis of all three types of cervicitis is the same, and since the endocervicitis is usually the solution to the problem of discharge, it seems appropriate to emphasize this by considering the other forms of cervicitis largely as subsidiary diseases.

Endocervicitis may be caused by any of the pathogenic bacteria which may be in the vagina; childbirth infections with or without lacerations, secondary infections occurring after cervical trauma from any cause, such as surgery or the insertion of a stem pes-

sary, gonorrheal infection; syphilis; tuberculosis.

Acute Endocervicitis. In the acute stage of endocervicitis, the tissues are red and edematous. Microscopic examination shows the familiar picture of acute inflammation. The discharge causes maceration and degeneration of squamous epithelium around the external os. In endocervicitis following childbirth, there is danger of a lateral spread to the parametrium by way of the lymphatics. Ultimately such infection can spread to the pelvic peritoneum, tubes and ovaries in gonorrheal infection, the spread is upward to the tubes. Syphilis of the cervix is largely a disease of the exocervix. The cervix is often the site of the primary lesion. However, a typical chancre rarely occurs. Usually the lesion is insignificant and frequently missed. Secondary lesions of the cervix are frequent. The ulcers are grayish white with a yellow base. If there is a zone of normal tissue between the os and the cervix, it adds to the suspicion. Tuberculosis of the cervix is rare, but when it occurs infection is almost always present in the endometrium and the tubes.

Usually the symptoms of acute endocervicitis are minimal, except when they are overshadowed by the symptoms of the spread of the disease. Then they may be violent, but most of the time there is only mild pelvic discomfort, fever, low backache and some malaise. There is always a purulent mucoid discharge in variable amounts.

The diagnosis is easy and is made by finding the signs of acute inflammation. Especially characteristic is pointing of the cervix and the presence of an acute mucopurulent discharge. Unless there is another obvious cause of the infection, gonorrhea is always a possibility. To overlook it invite a crippling spread of the disease to the tubes.

Since the advent of the antibiotics, treatment is easy and effective. Penicillin is the agent of choice.

Chronic Endocervicitis. In chronic endocervicitis, there is often a red, granular appearance of the tissue surrounding the external os. This is an erosion and it is a significant lesion. The alkaline secretions from the site of chronic endocervicitis bathe the epithelium surrounding the external os. Maceration of the squamous epithelium results and this allows the columnar epithelium of the endocervix to replace the squamous epithelium of the exocervix. The endocervical epithelium in the area of erosion forms glands and, in the course of time,

the vulva, dysuria and slight leukorrhea are the principal symptoms. These are not uncommon among women and may disappear in three to four days. Many women ignore these symptoms. Others seek advice. When they do, it is important for the physician to make the diagnosis before the disease spreads to the tubes. This occurs most generally at the time of the period.

In the acute phase, the vulva is hyperemic. Swelling and edema of the urethral mucous membrane everts the tissue so that the orifice appears red and pouting. The periurethral glands are red and prominent. The ducts of Bartholin's glands appear as red macules (Sanger's macules). A thick, mucopurulent discharge exudes from the inflamed cervix. Palpation of the urethra may reveal thickening. Stripping the urethra from above downward expresses pus from the urethral orifice. Closer inspection reveals infection in the glands on the floor of the urethra. The ducts of the two largest glands (Skene's glands) open just inside the orifice. Infection in Bartholin's glands causes swelling and tenderness. A normal Bartholin gland is hard to palpate, but the infected gland is thickened and hard. When abscess is present, the pain is intense and there is marked swelling and tenderness of the affected side of the vulva. The cervical os is reddened and congested, and this redness and congestion blends gradually into the normal cervical tissue. The exudate is thick and purulent. Tenderness on manipulation may be present and variable in degree.

As the infection subsides, the disease becomes chronic. The urethra may be permanently affected and some describe the feel of the chronically infected Skene's glands as bristle-like. Dilatation of the urethral orifice affords visualization of their reddened openings. Both Bartholin's glands may be enlarged. Cysts of the glands are common. The redness around the cervical os subsides, but frequently evidence of infection persists in the form of a mucopurulent discharge from the cervix.

The absolute diagnosis of gonorrhea is possible only by identifying the organism from smears and cultures. Even with this method, it is oftentimes impossible to find the organism in patients with known cases. In a recent series of 538 women named as sex contacts by men with acute gonorrhea, it was possible to confirm the diagnosis by smear and culture in only 20.6 per cent. A presumptive diagnosis is warranted following exposure if the clinical picture of acute

or chronic gonorrhea develops. It is almost certain if there has been salpingitis.

Success in the treatment of gonorrhea in the female depends upon eliminating infection in the sexual partner. To do this often requires extreme tact. Gonorrhea responds to the sulfas and antibiotics. In the adult, the dosage of sulfadiazine is 1 gm. given four times a day for five days. Penicillin, Aureomycin, Terramycin and streptomycin are effective. Of these, penicillin is generally preferred. A single dose of 300,000 units given intramuscularly for three days, or Aureomycin or Terramycin, 250 mg., given orally four times a day for five days, usually effects a cure. All forms of therapy should be repeated until the patient is asymptomatic. The criterion for cure is to obtain three negative smears and cultures, taken at weekly intervals. In children over ten years of age, penicillin therapy is the same as for adults. For younger children, the dosage may be reduced proportionately.

Abscesses will not respond to the above therapy and must be incised. The most common abscess is that of Bartholin's gland. In opening these abscesses, it is best to make the incision just inside the mucocutaneous border. In a cyst of Bartholin's gland, excision or marsupialization is generally necessary. To the uninitiated it is tempting to carry out the treatment in the office with the patient under local anesthesia. Of course this can be done, but it is far better to do it in the operating room with the patient under general anesthesia, as the large venous sinuses of the vulva bleed copiously. Infected Skene's glands and paraurethral crypts are easily destroyed by inserting a small wire and touching it with the electrocoagulating unit. An ordinary cautery serves nicely if the duct will admit a probe.

ENDOCRINE DISORDERS

Endocrine Vaginitis (Senile Vaginitis). Estrogen causes marked changes in the vaginal mucosa by increasing the blood supply and stimulating the epithelium to an orderly proliferation and cornification. As a result, the vagina becomes resistant to infection and trauma. When the estrogen secretion ceases, the epithelium becomes thin and prone to infection. Frequently, little petechial-like areas with superficial ulceration form. They resemble somewhat the strawberry lesions in *Trichomonas vaginalis* vaginitis. Scrubbing the vagina, as in preoperative preparation, makes them especially prominent. In the course of time, marked

accomplished by surgical means. There are five methods for the removal of the endocervix: cauterization, electrocoagulation, high frequency conization, surgical conization of the endocervix, cervical amputation.

The nasal-tip cautery is excellent for destroying the infected endocervix and the associated erosion. After exposing and cleansing the endocervix, the hot cautery incises the mucous membrane from the internal os to the external os and continues out over the erosion to the normal mucous membrane. Several such incisions complete the operation on each lip of the cervix. When nabothian cysts occur, the cautery punctures them. Too vigorous treatment causes pain and as the tissues slough annoying bleeding can occur. Strictures may form from the agglutination of opposing raw surfaces. For these reasons, it is best to carry out the procedure in stages, allowing the incisions in one lip to heal before making new ones opposite them.

Electrocoagulation overcomes many of the disadvantages of the cautery. The construction of the endocervical electrode prevents any damage to the opposite side of the canal. This is important in avoiding strictures. If the individual treatments cover less than half the circumference of the canal, strictures cannot form. After cessation of the endocervical discharge, the erosion will heal when cauterized.

The high-frequency cutting current excises the endocervix in a thorough fashion. A special electrode removes the infected endocervix and the erosion in one cone-shaped piece. The wound remains open and healing occurs by granulation. Bleeding, which sometimes is annoying, occurs during the healing period in a small percentage of patients. Often strictures form unless prevented by dilation. A plastic procedure, similar to the Sturmdorf operation, overcomes some of the disadvantages of the method. Hemiconization at intervals of six weeks is simple and is a more practical procedure for office use. It should be done only by those experienced in the method.

A scalpel can remove as much tissue as does the conization tip. Sturmdorf's technique is best. With a tenaculum grasping the anterior and posterior lips of the cervix within the area of erosion, the incision circumscribes the eroded area and dissects back the vaginocervical mucous membrane for a distance of 2 to 3 cm. Next, the scalpel cones out the entire gland-bearing area of the endocervix. Care is taken to preserve the

musculature. Coning becomes an amputation when too much muscle is removed. Failure occurs when infected glands are left in situ. Finally, a double, inverting suture on each lip pulls the loose vaginocervical cuff into the cavity and covers most of the raw area. The Sturmdorf operation can and does give excellent results. However, it can be difficult and it is not as popular now as it was in the past.

Amputation of the cervix in the treatment of uncomplicated endocervicitis is rare nowadays, as it predisposes to abortion and cervical dystocia. It is mainly reserved for the removal of the prolapsed cervix as part of the Manchester operation.

In very exceptional cases, total hysterectomy is the solution to the problem. Such patients always have other indications for hysterectomy in addition to their endocervicitis.

NEISSERII IN INFECTION (GONORRHEA)

Before the days of the antibiotics, gonorrhea caused more suffering and disability among women than did any other disease. Today, the disease occurs much less frequently. Coitus transmits the infection and the customary incubation period is three to eight days. In adult females, the gonococcus attacks the urethra, periurethral glands, Skene's glands, Bartholin's glands and the cervix. The discharge is purulent and in the acute stage may be loaded with organisms. Abscesses may form in Bartholin's glands. Later, after subsidence or rupture, the gland becomes either fibrosed or cystic. The cervix and urethra are the foci from which the infection spreads. Cystitis is common, but pyelitis is rare. The endometrium readily overcomes the organism, but the tubes usually succumb to the infection with all of the distressing sequelae of salpingitis.

In female children, the disease is very contagious and, until recent times, it was present in most institutions for their care. The vaginal mucous membrane of a child does not resist the infection. Resistance is linked to the changes produced in the mucous membrane by the ovarian hormones at the menarche. In children, vaginitis and cervicitis are the common lesions. Salpingitis rarely occurs. The disease becomes chronic with alternating periods of exacerbation and remission. It finally disappears at the menarche.

Lower genital tract gonorrhea is insidious because the symptoms are few and mild. A little temporary itching, a mild irritation of

the vulva, dysuria and slight leukorrhea are the principal symptoms. These are not uncommon among women and may disappear in three to four days. Many women ignore these symptoms. Others seek advice. When they do, it is important for the physician to make the diagnosis before the disease spreads to the tubes. This occurs most generally at the time of the period.

In the acute phase, the vulva is hyperemic. Swelling and edema of the urethral mucous membrane everts the tissue so that the orifice appears red and pouting. The periurethral glands are red and prominent. The ducts of Bartholin's glands appear as red macules (Sanger's macules). A thick, mucopurulent discharge exudes from the inflamed cervix. Palpation of the urethra may reveal thickening. Stripping the urethra from above downward expresses pus from the urethral orifice. Closer inspection reveals infection in the glands on the floor of the urethra. The ducts of the two largest glands (Skene's glands) open just inside the orifice. Infection in Bartholin's glands causes swelling and tenderness. A normal Bartholin gland is hard to palpate, but the infected gland is thickened and hard. When abscess is present, the pain is intense and there is marked swelling and tenderness of the affected side of the vulva. The cervical os is reddened and congested, and this redness and congestion blends gradually into the normal cervical tissue. The exudate is thick and purulent. Tenderness on manipulation may be present and variable in degree.

As the infection subsides, the disease becomes chronic. The urethra may be permanently affected and some describe the feel of the chronically infected Skene's glands as bristle-like. Dilatation of the urethral orifice affords visualization of their reddened openings. Both Bartholin's glands may be enlarged. Cysts of the glands are common. The redness around the cervical os subsides, but frequently evidence of infection persists in the form of a mucopurulent discharge from the cervix.

The absolute diagnosis of gonorrhea is possible only by identifying the organism from smears and cultures. Even with this method, it is oftentimes impossible to find the organism in patients with known cases. In a recent series of 538 women named as sex contacts by men with acute gonorrhea, it was possible to confirm the diagnosis by smear and culture in only 20.6 per cent. A presumptive diagnosis is warranted following if the clinical picture of acute

or chronic gonorrhea develops. It is almost certain if there has been salpingitis.

Success in the treatment of gonorrhea in the female depends upon eliminating infection in the sexual partner. To do this often requires extreme tact. Gonorrhea responds to the sulfas and antibiotics. In the adult, the dosage of sulfadiazine is 1 gm. given four times a day for five days. Penicillin, Aureomycin, Terramycin and streptomycin are effective. Of these, penicillin is generally preferred. A single dose of 300,000 units given intramuscularly for three days, or Aureomycin or Terramycin, 250 mg., given orally four times a day for five days, usually effects a cure. All forms of therapy should be repeated until the patient is asymptomatic. The criterion for cure is to obtain three negative smears and cultures, taken at weekly intervals. In children over ten years of age, penicillin therapy is the same as for adults. For younger children, the dosage may be reduced proportionately.

Abscesses will not respond to the above therapy and must be incised. The most common abscess is that of Bartholin's gland. In opening these abscesses, it is best to make the incision just inside the mucocutaneous border. In a cyst of Bartholin's gland, excision or marsupialization is generally necessary. To the uninitiated it is tempting to carry out the treatment in the office with the patient under local anesthesia. Of course this can be done, but it is far better to do it in the operating room with the patient under general anesthesia, as the large venous sinuses of the vulva bleed copiously. Infected Skene's glands and paraurethral crypts are easily destroyed by inserting a small wire and touching it with the electrocoagulating unit. An ordinary cautery serves nicely if the duct will admit a probe.

ENDOCRINE DISORDERS

Endocrine Vaginitis (Senile Vaginitis). Estrogen causes marked changes in the vaginal mucosa by increasing the blood supply and stimulating the epithelium to an orderly proliferation and cornification. As a result, the vagina becomes resistant to infection and trauma. When the estrogen secretion ceases, the epithelium becomes thin and prone to infection. Frequently, little pebble-like areas with superficial ulceration form. They resemble somewhat the strawberry lesions in *Trichomonas vaginalis* vaginitis. Scrubbing the vagina, as in preoperative preparation, makes them especially prominent. In the course of time, marked

atrophy and contraction may occur and sometimes the anterior and posterior walls agglutinate, causing complete or partial obliteration of the vagina. The discharge is serous in character and most often brownish in color. Slight bleeding occurs and this must be differentiated from that due to the other causes of postmenopausal bleeding. Burning is common and mild itching not infrequent. Dyspareunia is frequent. The epithelium is thin and flat and the rugae are atrophic to the point of nonrecognition.

Even the severely atrophic mucous membrane responds to estrogen therapy. The dosage required is 0.5 mg of conjugated estrogens given once daily, by mouth, for three to four weeks. Sometimes this treatment confuses the picture by causing bleeding. For this reason, vaginal suppositories are preferable. The dosage for suppositories is 2000 IU estrogens, or 0.5 mg of stilbestrol or benzestrol given daily for a week or ten days. Estrogen in this amount inserted once a week provides a satisfactory maintenance dose. Suppositories, such as Flor-aquim or Devegan, containing a carbohydrate, aid in re-establishing the normal bacterial flora.

Endocrine-Cervical Hypersecretion. Estrogen causes increased secretion from the endocervix and this occurs normally at the time of ovulation. In ovarian failure, there are derangements in ovarian function, causing a continuous high level estrogen secretion. The discharge is colorless, consists of thin mucus and has no odor. Usually it is fluid in consistency but may be a little stringy at times. It is nonirritating. Many times an associated *Trichomonas vaginalis* infection masks the character of the discharge. Symptoms are few, the main ones being a sense of wetness and the presence of a discharge on the clothing. Unless the stimulus to an abnormal estrogenic secretion is caused by therapeutic agents, medical treatment is unsatisfactory. To obtain satisfactory cure, a partial obliteration of the hypersecreting glands in the endocervix is required.

THRUSH INFECTIONS

Thrush is a mycotic vaginitis. The responsible organism is usually *Candida albicans*. Pruritus is the chief complaint of most women with thrush. Oftentimes it is distressing to the point of distraction. The patient is in real misery. Dyspareunia and dysuria are frequently present but are rarely mentioned by the patient. The discharge is variable in amount, being scanty more often

than profuse. It is thick in consistency and tends to adhere to the vulva and comes away like tiny bits of cottage cheese. Sometimes it is described as buttermilk-like. The disease can occur at any age and in all classes of women, but it is especially common in the pregnant woman, the diabetic and in those who have recently received antibiotics. In the individual patient, it is practically impossible to state the method of transmission. *Candida albicans* is isolated so frequently from the mouth, skin and stools that infection from these sources is always a possibility. It can occur from coitus or from contamination of the hands, douche nozzles or instruments. Many women who harbor the organisms are asymptomatic. In these women, symptoms develop only when there is a change in hydrogen ion concentration in the vagina resulting in a shift to the acid side. A high intake of sugar, use of acid douches and acid contraceptive jellies and destruction of the normal vaginal flora by antibiotics are all predisposing factors. In severe cases, the entire vulva becomes fiery red. Such an appearance is highly suggestive of underlying diabetes. Lesser degrees of vulvitis are the rule. The vagina is inflamed and contains patches of thickened, whitish exudate. In chronic infections, the mucous membrane of the vulva is thin, dry and glazed. The skin around the vulva is thickened and whitish in appearance. The hydrogen ion concentration tends to the acid side, around 4.5 or lower. Finding the organisms confirms the diagnosis. For this purpose, wet smears are satisfactory. A drop of the discharge is placed on a slide and diluted with two or three drops of 10 per cent sodium hydroxide solution; on examination the organisms are readily found if present.

The first consideration in the treatment of thrush is to eliminate the possibility of diabetes, either frank or latent. It is amazing how many sufferers from this type of infection have been using vinegar douches. These, of course, should be eliminated. The reliable treatment is to swab the vagina with gentian violet. It is supplied in 1 to 2 per cent aqueous solution, but even in such concentration chemical irritation is not unusual. The treatment should not be repeated for three or four days. The newer preparation of Gentia-Jel or Gentials has much to offer to those who rely upon gentian violet. Mild iodine douches have found great favor with many practitioners, 8 cc or 2 teaspoonfuls to half a gallon of water is the

usual prescription. The simplest and easiest form of treatment is the instillation of a mixture of 1 ounce of sodium borate and 4 ounces of glycerin. Two teaspoonfuls of this mixture are instilled into the vagina with a bulb syringe every other night. Most cases will respond to this form of treatment. Propion Gel is an effective agent as an alternative treatment. The most recent therapy is the intravaginal use of the antifungal antibiotic, Mycostatin. One or two tablets inserted daily for seven to fourteen days produce excellent results.

CANCER

Discharge is an early symptom of all forms of genital cancer. At first the discharge is represented simply by a slight increase over the normal secretions and generally the patient overlooks it. When the surface epithelium over the growth sloughs, there is an abrasion and from this exudes a serous discharge. Infection adds to the normal weeping of the tissue. As the growth opens up the smaller blood vessels, the discharge becomes brownish. Frank bleeding occurs as larger vessels are involved. Contact bleeding from examination, coitus, douches or downward displacement of the cervix against the posterior vaginal wall, as in straining, is common at this stage. As the process continues, the mass of sloughing and devitalized tissue increases. The vaginal bacteria attack it and the discharges become putrid. Cancer of the cervix produces a discharge which often follows such a pattern. In cancer of the body of the uterus, the discharge usually remains serosanguineous and relatively nonodorous for a rather long time. A clear, continuous serous discharge from the cervix in a postmenopausal woman always arouses suspicion of cancer of the fallopian tubes.

PAIN

In order to interpret painful symptoms arising from the female reproductive tract, one must understand the mechanisms of pelvic pain. Much ill-advised surgery has been due to a lack of this understanding. For example, one-sixth of all women entering a large clinic had pelvic pain. One-fourth of these had normal pelvic organs and the pelvic pain was not relieved by surgery. All too often the pain is attributed to the ovary. One investigator checked 1320 ovaries removed because of pain and found 993 to be normal.

The interpretation of pelvic pain also requires an appreciation of many varying factors. First, there is its inconstant nature. Then, the threshold for pain varies with different individuals and at different times in the same person. Much of this variation is due to the emotional reaction of the individual. Another difficulty is the various descriptions which patients give of their pain and its characteristics. A good history should include the usual information as to onset, duration, location and quality of the pain and, in addition, should note the relationship of the pain to such functions as menstruation, defecation, urination, coitus and ovulation.

Some understanding of the major causes of pelvic pain is essential to accurate history taking and examination. For this purpose, four different types of pain should be distinguished according to the site of origin. These are cerebral, organic, peritoneal and somatic. The mnemonic for pain, therefore, is COPS. In using this classification, it should be clearly understood that mixtures of the various types of pain are common. In many patients with organic disease, there is a cerebral component. In inflammation of an organ, the peritoneal component may be prominent and at times completely dominant. Understanding comes only when we are able to recognize and evaluate the various components.

CEREBRAL PAIN

Pain in the pelvis is often the result of an emotional conflict. It is common but difficult to interpret. Some psychiatrists believe it may be associated with the presence or absence of some kind of sexual activity, either imaginary or actual. Most of the patients with pain due to emotions also have easily recognized neurotic symptoms. Many times there is a tendency to use the symptoms as an evasion mechanism in a particular situation. Fatigability, palpitation, depression, insomnia, poor appetite and irritability are present either singly or in combination. The causative mechanism of pelvic pain of emotional origin is generally considered to be the result of a contraction of blood vessels in the affected part.

ORGANIC PAIN

In general, there is nothing specifically characteristic about pain from the various pelvic organs. Perhaps the best example of organic pain is the labor pain, but the cir-

circumstances under which it occurs and its time-intensity relationship are its characteristic aspects, rather than its quality.

Pure visceral pain, unassociated with peritonitis, occurs either as poorly localized pain in the region of the diseased viscus or as a more sharply localized pain in some area of the body surface supplied by the same neural segment. When the pain stimulus is severe, adjacent neural segments may be involved. Injection of procaine in the zone of reference will sometimes abolish the pain when the stimulus is mild, but if the stimulus increases this procedure becomes ineffective.

Observations made during operation with the patient under local anesthesia show that the wall of the uterus is rather insensitive. A uterine incision causes little pain. The endometrium is sensitive, especially so in the region just above the internal os. The fallopian tubes are always very sensitive.

Neurosurgical operations for the relief of pelvic pain show the importance of the sacral parasympathetics. Interruption of the sympathetic pathways by resecting the superior hypogastric plexus (presacral neurectomy) relieves uterine pain but has little effect on cervical or bladder pain. Pain impulses from the uterus enter the cord from the twelfth thoracic vertebra to the second lumbar vertebra. The zone of reference is the suprapubic region and the lower back.

The fallopian tubes are always very sensitive, pain from the inner third of the tube utilizes the uterine pathway while that from the outer two-thirds utilizes the ovarian pathway which runs with the ovarian vessels to the aortic plexus. Impulses from the ovary enter the cord over a broad area, from the tenth thoracic vertebra to the first lumbar. Their ordinary zone of reference is the suprapubic region, the loin and thigh. The ovaries are practically insensitive. Pricking them with a needle and handling them with a forceps are almost painless. Distending the capsule of the ovary by injecting saline solution causes only mild pain. Twisting of an elongated mesovarium causes severe pain, referred to the umbilical or subumbilical region.

Clinical localization of the origin of a pain arising from the pelvic viscera cannot be made by the characteristics of the pain or from its zone of reference. Lewis calls attention to the similarity of visceral pain and somatic pain in quality and in segmental distribution. Abdominal wall tenderness and muscular rigidity are not conclusive of vis-

ceral pain. Allowable conclusions can only be based on the consideration of the entire picture of pain, its localization, time-intensity curve, the constitutional reaction, circumstances under which it occurred, its relation to organ functions and the demonstration of visceral disease.

PERITONEAL PAIN

Anatomically the peritoneum has little or no nerve supply. It is very sensitive as a result of the rich innervation of the underlying tissue. Pain impulses from the peritoneum go by way of the intercostal nerves supplying the particular area. Inflammation of the parietal walls causes pain, tenderness and rigidity in the affected area. Hyperalgesia of the skin is frequently present. In diagnosis, it is necessary to look upon pain caused by the irritation of the parietal peritoneum as the surface outcropping of underlying disease. This indicates only the extent to which the disease is in contact with the parietal peritoneum and does not indicate either the extent or degree of the primary disease. An extensive and serious inflammation may be so situated that only a very slight amount of the area involved is in contact with the parietal peritoneum. This is not infrequent in diseases originating in the fallopian tubes or in the sigmoid colon. On the other hand, some disease processes are so intimately related to the parietal peritoneum that the signs rather accurately indicate the extent and degree of the process. Usually preceding the development of the peritoneal phenomena are the signs and symptoms of organic disease. Cramplike pain may be transmitted from a diseased viscus to the umbilicus, subumbilical region and the lower back. The constitutional reaction and the abdominopelvic examination usually supply the information necessary to relate all of the phenomena to the primary disease.

SOMATIC PAIN

Pain in the abdomen should direct attention to a visceral origin. Almost universally the tendency is to overlook other causes, and especially the somatic structures of the abdominal wall, as the basis of pain impulses. In doing so we forget that the parietes have a far richer nerve supply than do the viscera and are far more sensitive. Certainly the seriousness of visceral disease and its potential danger have much to do with this attitude. Everyone realizes that pain can be felt over the abdominal viscera as a

result of herpes zoster and the possibility of basal pleurisy with irritation of the intercostal nerves is excluded in every case of suspected appendicitis. As a matter of fact, somatic pain is far more common than visceral pain. Failure to understand it has led to missed diagnosis resulting in needless surgery and bad results.

In Lewis' studies on pain, he found that the injection of the interspinous ligaments with hypertonic saline solution produces pain similar to the pain of visceral disease. Injection of both recti below the navel produced a pain similar to that of intestinal colic. Carnett stressed the importance of somatic pain many years ago and his views are only now beginning to receive the attention of those interested in the female reproductive system.

According to Judovitch and Bates, the most common and clear-cut type of somatic pain is that of segmental neuralgia. By definition, this is a painful or tender area within one or more sensory skin segments. Etiologically, it results from any disease process, toxic absorption or mechanical disturbance which irritates the roots, ganglia or trunks of the spinal nerves. As a result, its point of origin is in, or close to, the vertebrae. Tenderness of the parietes is a major sign in segmental neuralgia. Pinching and pin-pricking reveal superficial tenderness. Pressure against bony structures or against contracted muscle and bimanual palpation of the abdominal wall reveal deep tenderness. The diagnosis depends upon the demonstration of tenderness in the paravertebral region or along the rib margins corresponding to the level of the tender anterior distribution. Segmental tenderness rarely, if ever, occurs as a result of a disease of the pelvic viscera. Tenderness does occur from pelvic visceral disease as a result of involvement of parietal peritoneum overlying the viscera. But this tenderness is local, not segmental, and usually is associated with local pain and many times with some degree of rigidity.

The severity of the pain of segmental neuralgia varies from mild to severe. Most frequently it is mild and is described as a nagging or aching pain or as a soreness. Pain on motion, radiating from the anterior distribution to the back, has diagnostic significance. On vaginobdominal examination, the tenderness may be so great as to confuse the examiner. To clarify the picture, the pressure of the abdominal hand should be decreased slowly. If the pain diminishes and

the vaginal hand can palpate the viscera without pain, somatic pain should be suspected. The direct pressure of the intravaginal fingers against the sacrum or the side walls of the pelvis is often very painful if the parietes are sore. Palpation of the body of the uterus presses the tender abdominal wall against the uterus supported by the intravaginal fingers and thus causes pain. To determine if the uterus is painful or if the pain is in the overlying abdominal wall, the intravaginal fingers are slipped anterior to the uterus and the overlying structures are palpated bimanually. This maneuver can be utilized to palpate a large area of the lower abdominal wall. When the examiner can be reasonably sure that the bladder and intestines are not between the external and internal fingers, and that peritonitis is absent, this sign is of great value in the diagnosis of somatic pain.

The treatment of segmental neuralgia depends upon finding the cause of the nerve irritation. Many times this is the result of a defect in body posture, such as is present in scoliosis, lordosis and ptosis of the lower abdomen. Occasionally an inequality of leg length is the cause. From time to time, atrophy of the spinal muscles from old poliomyelitis is noted. Unfortunately, in many circumstances it is impossible to find the cause.

In treating the patient for segmental neuralgia, one should remember that most of the time pain is of a mild degree. The emotional reaction resulting from the uncertainty and anxiety as to the cause and origin of the pain is in many instances the real cause of the patient seeking relief. For this reason, explanation and reassurance are often all that are necessary. Simple corrective exercises to strengthen the muscles of the lower abdomen and to improve the body posture are always helpful. In severe cases, procaine injections of the affected nerve often produce surprisingly good results.

DYSMENORRHEA

Dysmenorrhea, or painful menstruation, is one of the most common types of pain confronting the physician. It has been estimated that approximately 30 per cent of menstruating women are subject to either primary or secondary dysmenorrhea. Division of dysmenorrhea into primary and secondary categories is purely an arbitrary one. Primary dysmenorrhea designates painful menstruation unassociated with any demonstrable pelvic pathologic process, in contradistinction

tion to secondary dysmenorrhea which is due to pathologic states within the pelvis, such as endometriosis, pelvic inflammatory disease, fibroids or fixed retroflexion. Obviously the treatment of secondary dysmenorrhea should be directed toward the correction of any existing pelvic disease. The problem of dealing with primary dysmenorrhea is a much more difficult one. Indeed, it presents one of the most challenging problems in the practice of gynecology. To refer back to the mnemonic, the pain of primary dysmenorrhea may be entirely cerebral or entirely organic, or any combination of the two. In most cases, there is a liberal amount of both factors present and each must be handled appropriately.

Characteristically the pain of dysmenorrhea is cramping in nature and usually quite severe—in many respects simulating labor pains. It may precede the onset of menstruation and its duration may be from a few minutes to several days. Frequently there are associated systemic complaints of nausea, vomiting, headache and backache. Generally the pain of dysmenorrhea does not make its appearance for some several months or years after the menarche. This is considered to be due to anovulatory cycles. When the cycles become ovulatory, the dysmenorrhea commences. Following pregnancy, the pain is less severe in the majority of women. Also many women tend to outgrow their cramps. In others they persist in the same or in an intensified degree. The exact etiologic basis of primary dysmenorrhea is unknown. Certainly, abnormal uterine contractions are known to be a factor.

Treatment of dysmenorrhea falls into three categories: psychotherapy, medical management and surgical treatment. It probably is safe to say that nowhere in medicine is the psychologic evaluation of a patient more important to the eventual successful management. Even after this is done, it is sometimes difficult to tell immediately how much of any given patient's pain is functional and how much is organic. It usually requires several interviews and several courses of therapy with various medications to establish the exact relationship. Two important points to include in the psychotherapy of a patient with what is felt to be a fair amount of functional dysmenorrhea are reassurances as to the normalcy of her pelvic organs and careful explanation that uterine contraction is a normal reaction to a physiologic process.

The medical management of dysmenor-

rhea is often effective. If combined with appropriate psychotherapy, probably 70 per cent of patients can be relieved to a point where the dysmenorrhea is tolerable. A variety of analgesics and antispasmodics has been used. A combination of aspirin (5 grains), phenacetin (5 grains) and Propadrine hydrochloride ($\frac{3}{4}$ gram) given at four-hour intervals is helpful. Great discretion should be used in prescribing codeine. Other opiates should not be given. Endocrine therapy also may be used and in many cases is extremely helpful. Perhaps its chief value is the establishment of the organic nature of the pain. It is a well-known fact that if ovulation is suppressed, the bleeding which follows is painless. This is the basis for a regimen which is frequently employed as a diagnostic measure. It consists of the administration of stilbestrol, 1 to 2 mg. daily, beginning on the first day of menstruation and extending for twenty-one to twenty-five days. Stilbestrol suppresses ovulation during the current cycle and the absence of pain establishes the cycle's anovulatory nature. Androgens also have been used in the treatment of dysmenorrhea. The exact mode of their action is uncertain, but here again it probably is related to a change in the mechanism of ovulation or a decreased formation of corpus luteum hormone. An effective method is to administer 10 to 30 mg. of methyltestosterone daily from the seventh to fourteenth day of the cycle.

Surgical methods for relief of dysmenorrhea consist of dilation of the cervix, with or without insertion of a stem pessary, and presacral neurectomy. Dilation of the cervix often produces a remission but rarely cures dysmenorrhea. In our experience, the percentage of success with dilation and curettage has been appreciably increased by the insertion of a coil-spring type of stem pessary. This remains in place for a period of two menstrual cycles. However, stem pessaries are not without danger, and endocervicitis is an absolute contraindication to their use.

The decision to perform presacral neurectomy on any patient for the relief of dysmenorrhea can be arrived at only after a careful evaluation of the patient and the determination that the dysmenorrhea is uterine in origin and disabling in nature. In well-selected patients and with a thorough operation, the cure rate will be satisfactory.

Doyle recently proposed a simplified method of interrupting the sensory parasympathetic fibers to the uterus and the

sensory sympathetic fibers to the fundus. Both sets of fibers run in the terminal 2.5 cm. of the uterosacral ligament. To denervate the uterus, it is only necessary to cut the uterosacral ligament. The method appears to have many advantages, but it still lacks widespread clinical confirmation.

BLEEDING

The analysis of abnormal genital tract bleeding poses many interesting problems. There is much truth in the saying, "He who knows bleeding knows gynecology." The first problem is to determine if the bleeding is really abnormal. Contrary to popular belief, menstruation does not always occur with clock-like regularity. As a matter of fact, many women exhibit a considerable variation from month to month and it is only when these variations exceed rather wide limits that we are justified in labeling the bleeding as abnormal. In taking a history, therefore, it is necessary to consider the normal variability of the process as well as the normal for that particular woman.

Onset. The great majority of women begin to menstruate between the twelfth and fifteenth years of life. The outside limits of normal are from eleven to sixteen years of age.

Interval. The normal intermenstrual interval is twenty-eight days, plus or minus seven days. There is a good deal of variation among different women and from cycle to cycle in the same woman.

Duration. The normal duration of flow is five days, plus or minus three days. In the same woman the length of the period is fairly constant, but it varies among different women.

Amount. The amount of blood lost at each menstrual period also varies widely in different women and in the same woman at different periods. The number of napkins gives a rough idea of the amount of blood lost. During the first two or three days, the flow is usually more profuse and thereafter gradually tapers off.

Character. Under normal conditions, the menstrual discharge is of a dark color and free from clots. When the flow becomes profuse, it is redder and contains clots.

Pain. In 70 per cent of women, menstruation is a painless process, the remainder exhibit some habitual discomfort of a widely varying degree. The onset of pain, or a change in its character, has great diagnostic significance in bleeding problems. In

the early stages of cancer, for example, bleeding is painless. In abortion, the bleeding is definitely painful. If a fibroid tumor is present, there may be gradually increasing pain. In ectopic gestation pain is almost always present, while in the common forms of endocrine bleeding pain is generally absent. Hence, careful attention to the relationship of pain and bleeding may reap a rich diagnostic reward.

Associated Symptoms. There are many symptoms associated with bleeding which will be encountered from time to time. The most constant is a dull heaviness or dragging in the pelvis. Occurring with this may be headache, nausea and vomiting, depression, nervousness and tension states. Usually these symptoms are not disabling. After determining the characteristics of the patient's normal cycle and the date of the last menstrual period, the change in the patient's menstrual flow is noted as regards interval, duration, amount, character and relationship to pain. Often the patient cannot give exact dates, but even without them a fairly accurate picture of the abnormal bleeding can be obtained. In such cases, a calendar is a great help, as the women can readily note thereon the approximate intervals, durations and amounts.

CANCER OF THE CERVIX

Even though the cause of cancer is unknown, much can now be done to control the disease and it is possible that still more can be accomplished in the future. Three-fourths of all genital tract cancer in women occurs in the cervix, a site which is readily accessible for study and examination. Next to cancer of the breast, cancer of the cervix is the most common in the female. It accounts for 10 per cent of the total cancer deaths. Its common occurrence, deadly nature, and ready availability for observation have stimulated an ever-increasing number of fruitful investigations.

Cancer Control. In 1900, the cure rate was practically zero. Today, it ranges from 35 to 45 per cent and tomorrow it could readily be 70 per cent. Cancer control depends on the elimination of predisposing factors and the diagnosis of the disease in its preclinical form. When cervical cancer can be recognized by clinical means, the chances for cure have already begun to diminish.

Life insurance statistics indicate a drop in the death rate of cancer in females. This is

largely due to a marked decline in the death rate from cancer of the female generative tract

Predisposing Factors. The predisposing factors present some interesting points of information. The disease is more common in the lower income group than in the upper income group. Next, it is very rare in virgins and occurs only occasionally in the single. Marriage definitely increases its incidence. Those individuals who marry young are the most susceptible. Multiple marriages seem to be of some significance. Prostitutes have more than their share of the disease. All of this indicates that an active sex life is a factor of importance. This naturally leads to pregnancies and a higher incidence of chronically inflamed and lacerated cervixes. Chronic cervicitis has often been described as the breeding ground of cancer and most gynecologists believe that these cervical lesions are potentially dangerous as a future source of cancer. So far, all of this evidence incriminates sexual intercourse, but this may not be the whole story, as the Jews and Moslems have a very low incidence of the disease. Members of both of these races practice circumcision. Negroes, on the other hand, have a very high incidence of cancer. This may be attributed to poor penile hygiene or to a racial factor.

In our enthusiasm to control the disease, we should not try to eliminate a function which is a biologic and psychologic necessity, but rather we should concentrate on the susceptible individual or groups in our efforts to discover the cause. Needless to say, the elimination of cervical irritation is of great importance, not only in ruling out a potential source of danger, but also in directing the attention of physician and patient to the cervix. The data on circumcision and penile hygiene are suggestive. The wide adoption of circumcision and good penile hygiene can do no harm and may be a step in the right direction.

Histologic Changes and Metastasis. The basal layer of the normal cervical epithelium consists of several layers of deep-staining cells. Squamous cell carcinoma originates from these cells. At first there may be basal cell hyperactivity with an area of proliferation six to ten cells deep. Gradually the process involves the entire epithelium. In well-marked cases, there is complete loss of the normal stratification of the epithelium. The cells vary in size and shape, and mitoses, as well as nuclear irregularities, are present. The cells are identical with malignant cells.

But invasion, the most important characteristic of malignancy, appears to be lacking. To establish the fact that it really is lacking requires a careful examination of many specimens from the cervix. Often this extensive study reveals invasion. Many times, in clear-cut invasive carcinoma, there is an area of preinvasive carcinoma at the margins of the growth. From a therapeutic standpoint, therefore, preinvasive carcinoma must be considered as invasive until proved otherwise.

There have been a number of reported cases in which it was possible to trace the sequence of events from basal cell hyperactivity to frank invasive carcinoma. In one of our cases, described by Jones, the changes extended over a thirteen-year period. The transition to a malignant state may be a slow process. Preinvasive carcinoma reaches the peak of its incidence in women at the age of thirty-eight years, invasive carcinoma in those forty-five years of age. On the other side of the picture, it has not been determined that preinvasive carcinoma always progresses to invasive carcinoma. At times regression occurs and this is especially likely following the termination of a pregnancy. Once the process acquires sufficient growth momentum to become invasive, it loses forever its capacity to undergo spontaneous regression.

Cancer of the cervix spreads by three methods. The first is by continuity or direct extension. This type of spread begins primarily with involvement of the cervix. The growth then extends laterally in any of three main directions—the paracervical tissue, the paravaginal tissue or along the uterosacral ligaments. The second method is by the lymphatic channels. This type of metastasis is embolic in nature. The most common nodes involved in our experience are the obturator, hypogastric, and the external and common iliac nodes. The paraureteral node has not been frequently involved in the earlier cases. As shown by operative results, the lymph node involvement of stage I lesions is approximately 18 to 20 per cent, in stage II lesions 30 to 35 per cent. In the more advanced lesions, the percentage of involvement increases. The third method of spread of carcinoma of the cervix is by the blood stream. This usually is a late occurrence in the disease. Carcinoma of the cervix is restricted within the limits of the pelvis for a relatively long time before distant metastasis by the blood stream occurs.

Classification and Grading. The size of

the tumor is closely related to the degree to which it metastasizes and its curability by radiation or surgery. In order to compare the results of treatment, it is necessary to consider patients in whom the growths are approximately the same size. For these reasons, therefore, it has been necessary to establish a uniform descriptive system. The following has been adopted by the League of Nations' Health Organization and is now used universally. It is sometimes referred to as the International Classification.

Stage 0. Noninvasive carcinoma confined to the epithelial margins of the cervix.

Stage I: The carcinoma is strictly confined to the cervix.

Stage II. The carcinoma infiltrates the parametrium on one or both sides but has not involved the pelvic wall. The carcinoma infiltrates the vagina but does not involve the lower third. The carcinoma involves the endocervix and has spread to the corpus.

Stage III. The carcinomatous infiltration of the parametrium has involved the pelvic wall on one or both sides. On rectal examination, no cancer-free space is found between the tumor and the pelvic wall. The carcinoma involves the lower third of the vagina. Isolated metastases are palpable on the side wall of the pelvis, irrespective of the extent of the primary growth.

Stage IV. The carcinoma involves the bladder, as determined by cystoscopy or by the presence of a vesicovaginal fistula. The carcinoma involves the rectum. The carcinoma has spread outside the true pelvis.

For most practical purposes, adenocarcinoma of the cervix may be considered to behave as does squamous cell carcinoma. Because of its origin within the cervical canal, it presents a little more diagnostic difficulty, and because of its location it is a little more likely to spread laterally early in the disease. In spite of these minor differences, the results of treatment are about the same in the two groups.

Both squamous cell carcinoma and adenocarcinoma of the cervix exhibit marked differences in their histologic characteristics. Some squamous cell carcinomas consist of cells which are very highly differentiated and closely resemble the cells of the normal cervix. In others, the cells are completely anaplastic and have no resemblance to normal cervical cells. As a result of these differences in the appearance of the cells of different tumors, various systems of histologic gradation have come into being. The two classifications in common use are those of

Martzfloff and Broders. Martzfloff used the three cell types of the normal cervical epithelium as the basis of his classification:

1. *Spinal cell type*, representing chiefly the external layer of cells. These are the most benign of the epidermic carcinomas and are classified by Broders as grade I.

2. *Transitional cell type*, consisting of cells resembling the middle layers of the cervical epithelium. These cells are less differentiated than the spinal cells and are more malignant. Broders places tumors consisting of these cells in grade II.

3. *Spindle cell or basal cell tumor.* In this group the cells resemble those from basal layers, the so-called stratum germinativum. These are the most undifferentiated and anaplastic of the cervical cells and are the most malignant type. Broders classifies tumors of this type as grade III or IV.

Transitional cell tumor (grade II) is the most common, with the spinal cell (grade I) next in frequency, and the spindle or basal cell (grade III) the least common.

The cell types are important and are thought by many pathologists to be of significance in the prognosis and selection of treatment. But one should bear in mind that there is a marked variation in all types and in different portions of the same tumor. Rarely does a tumor at any one spot consist entirely of one clear-cut cell, but rather is a mixture of several types, one of which usually predominates. A single biopsy may give an erroneous impression of the tumor as a whole. All of these factors must be considered if histologic grading is to be of any significance.

Symptomatology. Cervical cancer in its curable stage presents few if any symptoms. As the disease progresses to the incurable stage, the classical symptoms of discharge, bleeding and pain make their appearance. Patients, as well as physicians, must learn that to await the appearance of symptoms is to diminish the chances of cure. In the typical case, discharge is usually the first symptom. It is often mild and frequently unnoticed until bleeding occurs. Many times the first bleeding follows intercourse. This postcoital bleeding is a very suggestive symptom and always calls for investigation. Other forms of contact, such as with a douche nozzle, or by the insertion of a diaphragm, or the downward descent of the cervix against the posterior wall of the vagina as a result of straining, may cause bleeding. Bleeding implies a break in the surface covering of the growth and, follow-

ing this, infection occurs with an increase in the amount and character of the discharge. The discharge usually is serous or serosanguineous at this stage and gradually begins to develop an odor which in advanced cases can only be described as stinking. The discharge is in many respects similar to that emanating from a chronic leg ulcer. The amount of odor roughly parallels the degree of slough. As sloughing proceeds, the process opens larger vessels, the bleeding becomes more profuse and often is continuous. In late stages of the disease, it can exsanguinate a patient very rapidly. The bleeding is not related to the normal menstrual cycle, but is superimposed and, depending on circumstances, it can and does mimic all the varieties of abnormal menstruation.

Pain, as such, does not occur in the early stages of the disease, but there is a strange awareness of something not right which patients often describe as occurring early. This is usually labeled as discomfort. Later, as the growth extends and involves the nerves, the pain becomes severe. Especially characteristic is pain in the low back and pelvis with radiation into the back of the upper thighs.

Diagnosis. The first step in examination is to visualize the cervix and take smears from it and the vaginal pool. When these are stained, a competent cytologist can state if cancer is present or absent in a high percentage of cases. This technique, first described by Papanicolaou and Traut, depends on the exfoliative nature of cancer cells and its recognition. Unfortunately, the interpretation of the smear is not so easily learned, is time consuming and requires very experienced personnel. For this reason, it is difficult to use on a routine basis. But where it has been used, the results have been worth while. It is especially valuable in the detection of the preinvasive and the early invasive cases.

The great value of the Papanicolaou technique is that cells from all portions of the cervix and uterus can be examined on a single slide. It is a diffuse test, while biopsy is focused on a few spots. The great promise of the Papanicolaou technique is in the routine detection of early cancer. At the present time, it is best to regard it as purely a screening test. In all patients having a suspicious or positive report, biopsy should be performed. To our way of thinking, the colposcope affords important advantages in selecting the areas for biopsy. With this instrument, it is possible to examine the

cervix with magnifications of $\times 20\times$, and many changes invisible to the naked eye are apparent. Preinvasive carcinoma and invasive carcinoma present well-defined characteristics.

Preinvasive carcinoma may present no recognizable signs on visual examination. In some cases, the bright red color of an erosion changes to a paler saffron-like color. Dilatation of the surface veins over this area is suggestive. Painting the cervix with compound tincture of iodine stains the normal squamous epithelium a mahogany brown. Abnormal areas do not absorb the stain. This is known as Schüller's test. It delineates the abnormal areas and it is from these areas that we must take our biopsy specimens. In early cases, a single biopsy may miss the lesion in perhaps half the subjects. At least four pieces of tissue should be taken from the circumference of a cervix. In taking biopsy specimens, it is helpful to remember that the significant changes are in the epithelium. It is easy to remove the epithelium from the hard, unyielding stroma by taking a superficial bite with the biopsy instrument. The correct technique is somewhat like that which would be used in attempting to take multiple pinch grafts from the cervix. When the disease becomes invasive, the tissue appears friable and granular. It bleeds readily at the slightest touch. A probe passes easily into the growth until it reaches the uninvolved cervical stroma.

Advanced cancer of the cervix is not difficult to recognize. It may be either a cauliflower-like growth, an infiltrating growth or an ulcerated growth. Everted growths form cauliflower-like lesions which are soft, friable and bleed easily. Infiltrating growths grow beneath the mucous membrane and into the stroma. For this reason the cervix is hard and has a suggestion of nodularity. Ulcerating lesions can result from either an infiltrating or a cauliflower growth. The latter is the more frequent cause.

Treatment. Cancer of the cervix yields only to surgery, irradiation or a combination of the two. To use either successfully requires skill and experience with the disease. The selection of patients suitable for each form of treatment varies from clinic to clinic. Ruth Graham believes it possible to mine the response of a given patient to radiation by cytologic study, and thereby to select the appropriate form of treatment. The confirmation and perfection of her method would go a long way toward solving the problems of treatment. That is

each patient must be treated with respect to her functional needs, the stage and grade of the lesion and the abilities and experience of the physician. In this disease, the latter counts as in no other pelvic condition.

Since preinvasive carcinoma occurs in a comparatively young age group, the patients often have greater functional needs than do those suffering from invasive carcinoma. In addition, the long, latent period, and the likelihood that the disease will not explode overnight, make the problem a little less pressing. For these reasons, the physician can assume the calculated risk of observation or local treatment in exceptional cases, provided, of course, he has done all necessary in his judgment to exclude invasion. This can best be accomplished by surgical conization of the cervix. By following a conservative course in these cases, he may allow the patient to satisfy her reproductive desires. Such a course, however, does entail risk and is not to be entered upon lightly. When the patient's desire for reproduction is not so important, the consensus is to proceed immediately with total hysterectomy. In doing this operation, the parametrial clamps should be outside the cervical fascia. In order to place the clamps properly to avoid ureteral injury, it is necessary to expose these structures. A generous portion of the vagina adjacent to the cervix should be removed with the specimen. This operation is considerably more difficult than is routine total hysterectomy. Te Linde describes it as a modified radical hysterectomy. If indicated, the ovaries can be safely conserved.

In our clinic, we use a modified Stockholm technique in radiation therapy for carcinoma of the cervix. Basically it is a combination of treatment with radium and supplementary deep x-ray radiation. More recently we have used cobalt radiation. The application of radium is the most important part of the treatment and usually is given in two applications, separated by a period of three weeks. The radium is applied in the vagina, about the cervix and in the uterine cavity. No radium is placed in the lower 0.5 cm. of the endocervical canal. The vaginal radium is applied by means of three tubes—one in each lateral vault and one posterior to the cervix in a transverse position. These tubes are placed in this position to radiate the areas of direct extension, that is, the paracervical tissue, the paravaginal tissue and the uterosacral ligaments. These tubes are incorporated in a dental compound which holds the three radium containers firmly in position. The intrauterine

radium extends the entire length of the uterine cavity. The dosage varies from 3000 to 4000 mg. hours for each treatment, according to the size of the lesion, the width of the vagina and the length of the uterine cavity.

Deep x-ray or cobalt therapy may precede the use of radium in those patients in whom the lesion is bulky and infected or extends down the vaginal mucosa. Deep therapy through two perineal fields can be helpful in cleaning up the markedly infected lesions. The filtration used in the application of radium is equivalent to 1 mm. of platinum. It is generally accepted that a tumor dose is 5000 r. This technique will deliver approximately 6000 to 7000 gamma r at the point called A, 2 cm. lateral from the center of the cervix and 2 cm. beneath the mucous membrane on the lateral vaginal vault. At the area on the pelvic wall in the region of the obturator nerve, the average dosage is approximately 1200 to 1500 gamma r by this method of application. It is obvious that the majority of the tissue lateral to point A receives an insufficient tumor dose, and deep radiation therapy is necessary to increase the amount of radiation in the parametrium and on the pelvic wall. It is rarely possible, however, to achieve a total dosage of more than 3500 to 4000 r in the typical patient in the region of the obturator fossa. The deep x-ray therapy is given through two anterior and two posterior portals. The total skin dose varies from 3200 to 4000 r to each field. With cobalt therapy, a tumor dose of 3500 to 4500 r can be given to the parametrial and pelvic wall areas. The skin reaction is minimal and nausea and generalized discomfort are less. Heyman and Kottmeier of Stockholm were the originators of this technique. They were pioneers in the development of radiotherapy for carcinoma of the cervix. In their patients treated between 1936 and 1945, at the end of five years they had a relative apparent recovery rate of 69.2 per cent in stage I; 51.4 per cent in stage II, 24.4 per cent in stage III; and 11.3 per cent in stage IV.

In the early 1900's, before the advent of radiotherapy, surgery offered the one hope for cure of cancer of the cervix. True, it was a slim hope, but some patients were cured. At this time, surgery was in its infancy. Anesthesia was poor, transfusions unknown, wound healing not understood and there were no antibiotics. It was also before the days of the early diagnosis of cervical cancer and most of the cases were advanced. In spite of all this, surgeons cured

a fair number of patients with cervical cancer. But there were many disappointments, long hours at the operating table, fearful hemorrhages and shock, convalescence was long and difficult. Fistulae were frequent. In 1904, Abbe, a New York surgeon, began to treat cervical cancer with radium. The results were miraculous. No wonder surgeons turned to the promise of radiotherapy.

Of course, radiotherapy had its disappointments too and they were somewhat similar to those experienced in surgery. But the ease of treatment and the good palliation encouraged even the most skeptical. As soon as the new method was perfected, results would be better. However, in the course of time the cure rate reached a plateau. This was about the time that surgery was really developing. It was only natural that surgeons again interested themselves in cancer of the cervix. In this country, Lynch, Taussig and, above all, Meigs led the surgical revival. So far, the surgical results have been superior and somewhat better than the best from radiotherapy. But comparisons are not valid because the surgical cases represent a selected group. Therefore, the question of the superiority of surgery or radiation is not settled. Probably it cannot be settled for a long time by statistical means. Most agree that surgery is ideal for many early cases. For the rest, radiation is best. To solve the problem we must discover solid indications for each type of treatment.

Our personal reaction to this situation is a double-barreled technique—preliminary radiation followed by radical hysterectomy with bilateral pelvic lymphadenectomy. So far, our results are encouraging to us, but there are not enough cases to warrant positive recommendations to others.

In considering the problem of the treatment of cancer of the cervix, it is easy to see the tree and to overlook the forest. Both radiation and surgery can cure cancer of the cervix. We know that the stage of the lesion influences the cure rate more than does the form of treatment. Of course, perfecting either form of treatment will increase the number of cures. But the best results come from early diagnosis, for with early diagnosis either surgery or radiation can eliminate the mortality of cancer of the cervix.

CARCINOMA OF THE CORPUS UTERI

Today, carcinoma of the corpus uteri is being recognized more frequently than ever

before. It is stated that the ratio of incidence of carcinoma of the corpus to carcinoma of the cervix uteri is approximately 8.1. In our material, this ratio is approximately 3.5. An increase in the life span is an important factor in this increased incidence of the disease.

In America the disease is rare before the age of forty, 25 per cent of cases occur before age fifty, while 75 per cent of cases occur after this age. The peak of the incidence curve is in the mid-fifties. The probability of a woman developing the disease is 15 per thousand at age forty-five, and this decreases to about 7.5 per thousand at between sixty-five and seventy. In any series of cases, the high percentage of nulliparous women is striking, in some series this is as high as 40 per cent. Some surgeons have suggested the presence of prolonged ovarian activity as a factor in the pathogenesis of carcinoma of the corpus.

A hereditary influence seems to occur in a significant number of histories. There are records of the disease occurring in identical twins with an onset at the same approximate time. From an economic standpoint the number of private patients is significantly greater than in cancer of the cervix. Oftentimes the women are large and obese. One authority has described them as burgeoning. In Corseaden's cases, the women with cancer of the endometrium weighed on an average of eighteen pounds more than those with cancer of the cervix. There is more than an ordinarily close relationship with diabetes. Palmer gives the amazing figure of an incidence of 167 times that in women of the same age in the general population.

Novak stresses the relationship between postmenopausal endometrial hyperplasia and the development of carcinoma of the body of the uterus. While this opinion is not unanimous, the evidence is suggestive. Kottmeier puts greater emphasis on the association with endometrial polyps.

Women do not develop cancer of the endometrium, only 8 per cent menstruate beyond age fifty, while in those who do 35 per cent continue their periods beyond the fiftieth year.

The chief symptom of carcinoma of the uterus is usually some form of abnormal uterine bleeding. In women who have not passed the menopause, this is characterized by intermenstrual bleeding. Only a very small percentage of premenopausal bleeding

is due to cancer of the endometrium, but when the common causes of bleeding are eliminated the incidence rises to about 10 per cent. In the postmenopausal woman, the bleeding may vary from a small amount of spotting to an excessive type of flow. Slightly more than a third of all women having bleeding a year or more after the menopause will be found to have carcinoma of the endometrium. An increased vaginal discharge may also be noted. Early in the disease the discharge is odorless, later, as the tissue begins to degenerate, it may be foul. At intervals, this discharge is blood tinged. Pain is not a frequent symptom. However, most patients do complain of a vague lower abdominal or pelvic heaviness or discomfort.

The efficiency of vaginal smears in the diagnosis of this disease is less than in cancer of the cervix. As in cervical cancer, a positive smear must be confirmed by tissue study. For this purpose, as well as in the differential diagnosis of the disease, endometrial biopsy is useful. This is an office procedure and, with experience, one can sample the endometrium almost as thoroughly as with a conventional curettage.

the woman
to the ex-
and curet-
tage is reserved for these women, as well as for those in whom endometrial biopsy does not give a clear-cut answer.

For curettage, Heyman emphasized the fractional technique. It should be done in the following manner: (1) curettage of the area around the external os, (2) curettage of the endocervical canal without passing the internal os, (3) measuring the length of the uterine cavity, (4) careful dilation of the cervix, (5) examination of the fundus of the uterine cavity with polyp forceps, (6) curettage of the fundus and the corpus and examination of the uterine cavity with forceps and the curet. This method of curettage is most important in the differentiation between carcinoma of the body of the uterus and carcinoma of the body of the uterus and endocervix. This differentiation is of significance, both in the prognosis of the disease and in determining the form of therapy.

Carcinoma of the corpus uteri is an adenocarcinoma arising from the endometrial glands. The gross lesion varies from a small circumscribed one to a diffuse polypoid growth which fills the entire uterine cavity.

Microscopically, the tumor also shows much variation. In the well-differentiated lesion, the glandular pattern is still present,

but, as the degree of differentiation becomes less, solid masses of malignant cells replace the glands. Mitotic figures and nuclear changes are prominent.

Hertig was one of the first to investigate the carcinoma-in-situ phase of adenocarcinoma of the corpus uteri. Histologically, he bases his diagnosis on the appearance of endometrial glands composed of large cells with abundant clear eosinophilic cytoplasm. In addition to this, the nuclear membranes are irregular and arranged in irregular palisades. Cellular disorientation, variation in size and stratification are common findings. This contribution is a real step forward in the control of carcinoma of the body of the uterus.

The principles of treatment for carcinoma of the uterus depend upon the clinical characteristics and the method of spread of the disease. When the diagnosis is made by tissue biopsy, we first apply intracavity radium by the multiple packing technique. A total dosage of 1000 to 5000 mg. hours is given, depending on the size of the uterus and the number of applicators used. This technique gives more uniform radiation through the entire uterine cavity. The number of uteri with residual carcinoma has been greatly reduced by this form of therapy. Operation then follows the radiation therapy in approximately six weeks. It is generally believed that age, obesity, hypertension and diabetes often complicate the treatment. Hence, as a matter of necessity, the condition of the patient determines the extent of the operation. Under ideal circumstances, the operation is a radical hysterectomy, bilateral salpingo-oophorectomy and bilateral pelvic lymphadenectomy. If this seems too much of an operation for the patient, the surgeon must do a lesser operation, consisting of a wide extrafascial removal of the uterus and a portion of the upper vagina. Some surgeons speak of an operation of this magnitude as a semiradical hysterectomy. In our hands, it pretty closely approximates the original Wertheim type of operation. It is definitely a more difficult operation than is the ordinary total hysterectomy. This latter operation may occasionally have to suffice in the very old or the very sick, but it is not a sound operation for the removal of any form of uterine malignant lesion.

Of importance is the postoperative use of radium in the vagina. Approximately 5 per cent of the patients will develop recurrences in the vaginal cuff. A lesser per cent will develop metastatic lesions in the peri-

urethral area. The use of prophylactic vaginal radiation postoperatively will reduce the incidence of these complications. This radium application is usually given in the form of a large bomb which fills the vaginal cavity. The dosage varies somewhat according to the size of the vagina. The average dose is 1500 to 1800 mg. hours. We do not use deep x-ray therapy postoperatively except in patients in whom ovarian metastasis or obvious metastatic spread has occurred beyond the limits of the uterus. In these patients, and in those in whom the spread is extensive and surgical treatment is not feasible, x-ray or cobalt therapy is given to two anterior and two posterior portals. In the group in whom operation is not undertaken, the deep therapy is preceded by a relatively large dose of radium applied within the uterus by the packing technique. Application is usually divided into two doses at three- to four-week intervals.

Today, the over-all expected five-year survival rate in all patients with carcinoma of the body of the uterus is 50 to 60 per cent. In patients in whom operation is clinically possible, the five-year apparent survival rate rises as high as 70 to 80 per cent.

It is important to remember that approximately 5 per cent of the malignant lesions of the body of the uterus are sarcomatous in nature and that the majority of these arise in myomas. Sarcoma of the endometrial stroma is seen occasionally. The therapy is primarily surgical, however, preoperative use of radium within the uterus of patients with endometrial sarcomas is of benefit.

Rare cases of carcinosarcoma have been reported in the literature. It is our opinion that many of these lesions turn out to be an undifferentiated type of adenocarcinoma when differential stains are employed.

ABORTIONS

Abortion is one of the five major causes of abnormal uterine bleeding, as designated by the mnemonic C-A-F-E-E. The term "abortion" is defined as the expulsion of the products of conception from their site of implantation before the period of fetal viability. In some areas, the term is applied to fetal loss up to the twenty-eighth week, in other areas, as in Tennessee, the term abortion is applied to fetal loss up to the twentieth week of gestation.

It has been estimated that approximately 18 to 20 per cent of all pregnancies terminate as abortions. This incidence is somewhat higher than the usual hospital incidence of

10 to 15 per cent because of the large number of unreported or unrecognized cases. More than 750,000 abortions occur in the United States each year.

A number of adjectives have been used in order to describe the various phases of an abortion. Abortions may be divided into the following categories: threatened abortion, inevitable abortion, incomplete abortion, complete abortion and missed abortion.

Threatened Abortion. Threatened abortions most often occur in the first trimester of pregnancy. The expected times of the second and third menstrual periods are the periods of danger. The one constant symptom is uterine bleeding. The amount may vary from minimal spotting to a flow that is equal to the flow of a normal menstrual period. The color of the flow may vary from a dark brownish stain to the bright red of fresh bleeding. Frequently a brownish stain will precede the onset of a more profuse flow. The presence of abdominal pain is variable. When pain is present it is of the visceral type characteristic of the contracting uterus. It is intermittent and not constant. This pain must not be confused with the short-lasting, sharp catchlike pains present in both inguinal regions in the first trimester.

In addition to the usual signs of pregnancy, the significant finding is a closed cervix without apparent shortening. The blood in the vagina varies in amount and color, according to the rate and duration of the bleeding. Clots may be present if the flow is profuse.

Inevitable Abortion. This form of the moving abortion picture shows definite evidence that fetal loss is imminent. The bleeding is usually greater in amount and the blood redder than in threatened abortions. Usually the bleeding is constant but varies in amount as fresh pieces of placenta separate. Clots indicate profuse bleeding. Owing to the fact that blood tends to accumulate in the upper vagina, there may be periods in which the uterine bleeding is fairly heavy and the external bleeding only slight. When the patient bears down, as with urination, the vagina is emptied. Patients describe these sudden gushes of blood from the vagina as flooding spells. Lower abdominal cramps are more prominent than in the threatened abortion and are similar to labor pains. These make the patients so extremely uncomfortable that they often refer to an abortion as being more painful than labor.

All the signs and symptoms of pregnancy are present. The uterus is enlarged accord-

ing to the duration of the pregnancy. Cervical effacement is definite. The external os may be dilated and frequently will admit one finger. On inspection, the membranes may be seen to bulge in the dilated os. Sometimes the membranes may be ruptured and the fetus is seen presenting at the os.

Incomplete Abortion. This type of abortion shows a variable picture. The history may be short or long, from a few hours to several months. As pregnancy proceeds, the chorionic villi attach themselves more firmly to the uterine wall. This firm attachment predisposes to incomplete separation of the placenta resulting in an incomplete abortion. Prior to the eighth week, the placenta separates easily, but after the eighth week the attachment is so firm that incomplete separation is the rule.

Pain, bleeding and the passage of the products of conception are the chief symptoms. The pain is often severe and similar to a labor pain in all respects. Bleeding is profuse, sometimes to the point of exsanguination. Transfusions are frequently necessary. The passage of the fetus or portions of the placenta may be masked by the passage of clots. Patients frequently mistake clots for tissue and almost invariably describe them as "like chicken liver." For these reasons, the physician is wise to instruct the patients to save everything passed.

In the chronic cases, there is a history of bleeding and cramping followed by a more or less painless flow which varies in amount from a continuous bloody discharge to a moderately profuse flow. Occasionally the flow will become foul in odor, which indicates degenerating and infected tissue.

The size of the uterus may conform to the duration of the pregnancy, especially if the examination occurs shortly after the onset of signs and symptoms. But as the process continues and as portions of the conceptus pass, the uterus becomes smaller and firmer. Early in the process, the cervix is open and frequently a piece of placenta lodges in the os. Later, the cervix shows a lesser degree of dilatation and no evidence of placental tissue.

Complete Abortion. The uterus has expelled the entire conceptus in complete abortions. Because of the weak attachment of the chorionic villi, complete abortions occur mostly before the eighth week. The history is of cramping, bleeding and the passage of tissue. By the time the physician sees the patient, the cramps have ceased and the bleeding is minimal.

The cervix shows moderate dilatation with no visible tissue. The bleeding has largely ceased and there is a serosanguineous discharge from the os. The uterus is slightly enlarged, contracted and firm.

Missed Abortion. In missed abortion, the conceptus remains in the uterus after the death of the fetus. The history reveals the development of the signs of pregnancy followed by their regression. A most suggestive sign is the involution of the breasts. After the death of the fetus, reactions to pregnancy tests become negative. At times the history is hard to interpret and the diagnosis is difficult.

The physician who is following the patient will note the failure of the uterus to grow. If the patient is seen some time after the death of the fetus, the uterus will be smaller than expected at that particular stage of gestation. It may have a very soft, boggy feeling. The cervix will be closed. A dark-brown discharge may be seen coming from the os. Sometimes the discharge may have a foul odor.

Treatment. In abortions, the choice of treatment is and always has been difficult. The old axiom that an accurate diagnosis is the basis for sound treatment does not always apply in abortions. An examination is not without danger. It may introduce infection or stimulate the contractions of the uterus. It might even cause a threatened abortion to progress to an inevitable abortion. There is a natural reluctance of the physician to hasten or stimulate a threatened abortion or to do anything which a patient might even think caused her to abort. For all these reasons, physicians are inclined to treat expectantly, and without examination, these patients with the symptoms of a threatened abortion. This is a good plan, but it is easy to overdo. If the symptoms do not abate in twenty-four to forty-eight hours, or if they increase in severity, an examination is in order. In making the examination, gentleness and observance of a sterile technique should be practiced.

If the cervix is closed, the abortion is still only threatening and conservative treatment must be continued. On the other hand, if there is a shortening of the cervix with dilatation or a bulging of the amniotic sac, the condition is considered to be an inevitable abortion. In the opinion of many physicians, this diagnosis is justification for the institution of therapy designed to stimulate the uterus. In many hospitals, such treatment would cause severe repercussions. However,

if the physician is convinced of the inevitable nature of the process and the ineffectiveness of his treatment, he may abandon those measures considered useful in threatened abortion and leave the outcome to nature.

As the process proceeds, the uterine contractions rupture the membrane and extrude the fetus and portions of the placenta. Under these circumstances, it is proper to administer drugs to stimulate the process, or, if necessary, to complete the emptying of the uterus by surgical means.

In every patient with a threatened abortion, bed rest is indicated as an initial procedure. To quiet the patient and to stop the contractions, barbiturates and opiates are useful. Care should be given to the bowels so that the patient need not strain unnecessarily during evacuation. Large doses of vitamin C and the flavonoids have been used favorably. The use of hormones is popular but controversial. They will not harm and may be of value. Stilbestrol is the most widely used. The dosage varies according to the severity of the symptoms and the beliefs of the physician. In one plan of treatment, 25 mg of stilbestrol is given hourly until the bleeding is controlled. The administration of progesterone is a rational form of therapy and perhaps useful if the drug is given in a dosage of 100 to 150 mg per day. Very recently Norlutin, 10 to 30 mg daily, has been used with success. There have been some observations indicating an effect of the progesterone-like compounds on the secondary sex characteristics. So far, this suggestion has not been confirmed. Such therapy is, however, very expensive. Chorionic gonadotropins are also being used and are perhaps of value.

In patients who have had incomplete abortions of short duration and with mild symptoms, one may use an intravenous Pitocin drip to stimulate the contractions and complete the abortion. In patients with more severe symptoms, surgical interference is necessary. Often the blood loss is severe and transfusions are lifesaving. Antibiotics are always indicated.

In the operating room after gentle dilation of the cervix, the finger, placental forceps and curet are used to remove the remains of the conceptus. In so doing, the operator may be alarmed by a very brisk hemorrhage. This results from open sinuses in a noncontracted uterus. In such circumstances, uterine massage, a firm pack and the use of Ergotrate and Pitocin will quickly control the bleed-

ing. The pack is removed in twenty-four hours.

In the missed abortion, conservatism is indicated. The use of estrogens over a seven to ten-day period is frequently followed by the passage of the intrauterine contents. This form of therapy may be repeated several times. Practically all patients will empty their uteri if given sufficient time. In the very occasional uterus which does not empty, surgery is necessary.

FIBROIDS

The terms myoma, fibroid, fibromyoma and leiomyoma are used interchangeably. From an anatomic point of view, fibromyoma is preferable.

Fibroids are the most common pelvic tumors and occur in 20 per cent of women over thirty years of age. They are less frequent in those between twenty and thirty years of age but do occur in this group. New growths do not appear after the menopause, but previously existing tumors may rarely increase in size or undergo degenerative processes which make surgical interference necessary. It is well known that Negro women are more susceptible than white women.

In fibroids, the percentage of fibrous and muscle tissue varies. The cut surface is firm and pale when fibrous tissue predominates. A redder or pinkish color indicates an increase in the relative amount of smooth muscle.

All fibroids originate in the myometrium. Traditionally they are described as intramural, subserous and submucous.

Subserous tumors grow out from their original intramural position and come to lie under the visceral peritoneum. As the tumor continues to grow, it may become pedunculated. At times its blood supply may be inadequate and it may develop a secondary blood supply from an omental adhesion. Sometimes the original pedicle spontaneously separates and the tumor's only attachment is to the omentum. Under such conditions, it is known as a wandering fibroid. Pedunculated subserous fibroids may twist on their pedicles and this may require immediate attention. Tumors which grow out between the leaves of the broad ligament are intraligamentary fibroids. Because of their proximity to the uterine arteries, they are well nourished and may grow rapidly. Intraligamentary fibroids push the arteries and veins outward on their surface, at times they may displace the ureter.

A submucous myoma grows toward the uterine cavity and comes to lie under the endometrium. When submucous tumors become pedunculated, they tend to act as a foreign body, causing uterine contractions and dilatation of the cervix. Degenerative changes, infection and bleeding (the latter often marked) are common with these tumors. Tumors which maintain their original intramural position may grow to good size and, in so doing, elongate and distort the endometrial cavity. The growth of such a tumor increases the square area of the endometrial cavity and so increases its menstruating surface. Menorrhagia, therefore, is common.

Mucoid degeneration follows prolonged circulatory inadequacy. Calcification occurs in tumors of long standing. It is especially common after the menopause. Necrosis occurs from interference with the blood supply. Its causes are a twisted pedicle or circulatory changes occurring during pregnancy or during the puerperium. A special form of necrosis (red degeneration) occurs frequently in pregnancy. Its exact cause is unknown. The red color results from hemolysis. Cystic degeneration also results from necrosis. Local liquefaction of tissue causes the appearance of the cystic spaces. The incidence of sarcomatous degeneration varies between 0.41 per cent and 1.02 per cent. A rapidly growing tumor indicates the possibility of a sarcomatous change. Some believe that cancer of the endometrium develops as frequently in the normal as in the fibroid uterus. Others hold that fibroids predispose to adenocarcinoma of the endometrium. Most of the cases in which the two conditions occur are in patients exhibiting postmenopausal bleeding.

Sterility, low fertility and a tendency to abortion and premature labor are common in women with fibroid tumors. Pain resulting from a degeneration or a twisted pedicle can excite uterine contractions and so terminate the pregnancy. At term, the tumors may cause malposition and interfere with the force of the uterine contractions or obstruct the delivery. In the puerperium, there is an increased risk of postpartum hemorrhage and puerperal infection. From a statistical standpoint, fibroid tumors certainly impose an added risk to the pregnancy, but in spite of this the great majority of women with fibroid tumors go through pregnancy and labor satisfactorily. In evaluating the possible effect of a fibroid on a pregnancy, size is the first consideration. With large tumors there may not be enough room in

the abdomen for both the tumor and the baby. The position of the tumor is also of much importance. A small tumor low in the pelvis may block labor, while the same tumor arising from the fundus is of little significance. Pedunculated tumors are very liable to twist during pregnancy.

Most fibroids are asymptomatic and require no treatment. Bleeding is the most troublesome symptom. The mechanism is not always the same. As mentioned, large tumors increase the menstruating surface of the endometrium. Since intramural tumors are just under the endometrium, some believe they cause bleeding as a result of pressure on the veins. A submucous myoma acts as a foreign body within the uterus and bleeding results from pressure necrosis of the uterine endometrium in apposition to the tumor. Usually, however, bleeding occurring in conjunction with fibroid tumors is from none of these causes but is the result of associated ovarian failure. If this fact can be established, it may alter the decision as to the treatment. The possibility of the simultaneous presence of adenocarcinoma and fibroids increases as the patient passes through the menopause. In postmenopausal women with fibroids and bleeding, the chances are that the fibroid is incidental and that some other cause, such as adenocarcinoma of the endometrium, is present. In a small minority of postmenopausal women, fibroids which did not bleed during menstrual life migrate to a submucous position and cause bleeding.

Pain from fibroids may be felt in varying degrees and in many forms. The pain resulting from a twisted pedicle may be severe. Degeneration causes pain and sometimes these pains are severe. Dysmenorrhea is frequent, it increases in severity when it has been present before the advent of the fibroid. When the masses are heavy, there may be a sense of weight in the pelvis. Bladder pain may result from inability of the bladder to expand. Pain from pressure on the rectum is rare. Fibroids can cause dyspareunia, especially if the tumor is impacted in the cul-de-sac. Sometimes large abdominal tumors are painful during intercourse.

Fibroids produce few general symptoms unless the bleeding has been severe. Severe secondary anemia was not uncommon before the days of modern surgery and, in such patients, myocardial degeneration was a frequent occurrence. In patients with large tumors, there is sometimes a diminution of the vital capacity.

In the treatment of any given fibroid, four

courses are open: expectant treatment, radiation therapy, myomectomy and hysterectomy.

Many fibroids require only expectant treatment. Observation should be considered when the tumor is asymptomatic, smaller than the size of a uterus that has been gravid for three months and the diagnosis is clear cut. It must be ascertained that the tumor is a fibroid and not an ovarian cyst. If observation is elected, coexisting malignant disease in the cervix and endometrium must be considered and its possibility eliminated by appropriate examinations. The rationale for observation is greater the nearer the patient is to the menopause.

In fibroids associated with bleeding, expectant treatment is also permissible under the above conditions. But in such cases, the indication for the exclusion of malignant disease is more urgent than in the asymptomatic cases. To exclude the possibility of cancer of the endometrium, it is necessary to make a study of the endometrium from all parts of the endometrial cavity. The classical method is dilation and curettage. A properly performed suction biopsy of the endometrium by the original technique, or one of its many modifications, often yields as much or more endometrium as does the conventional dilation and curettage. It has the advantage of being an office procedure and hence can be applied in a greater number of patients. In doubtful cases, it can always be supplemented by dilation and curettage. If the endometrial study reveals the changes characteristic of an ovarian failure, it certainly is permissible to try hormone therapy before resorting to surgery or radiation.

Radiation destroys the reproductive, ovarian and menstrual functions. It does not abolish sex function but impairs it in the same way as does age. The classical contraindications to irradiation are any fibroid occurring in a woman under forty years of age, unless surgical treatment is contraindicated; if the diagnosis is questionable and the fibroid cannot be differentiated with certainty from an ovarian cyst, if the fibroid is larger than a fetus of three and one-half months; the presence of an old complicating pelvic inflammatory disease, a complicating ovarian neoplasm, a pedunculated submucous fibroid, a submucous fibroid, or a large pedunculated subserous fibroid, when there is a history of rapid growth, when abdominal pain is present, if some other condition requires surgical relief.

Some surgeons appear satisfied with the

results of radiation, but in general the tendency of most is away from radiation because of its failure in the occasional patient and because of its destructive effect on function, as well as the retention of the malignant potential of the uterus. The occurrence of malignant change seems a little higher in those patients having a fibroid in whom bleeding was present. In spite of this tendency, radiation is a valuable method and in a small number of patients can be used to advantage when surgery appears too risky.

Myomectomy is the operation of choice when it is necessary to save the uterus for reproduction, or for sentiment. It is a remarkably successful operation and is applicable to a much higher percentage of patients than is generally believed. It can be practically bloodless by using a catheter as a tourniquet around the cervix and clamping each infundibulopelvic ligament with rubber-shod intestinal clamps. The risk is about the same as for hysterectomy. There is some chance of recurrence. Bonney, in 293 cases, had a recurrence in nine, or 2.3 per cent. He attributed his success to a very thorough removal of all fibroid seedlings. Others report a higher recurrence rate. In Bonney's opinion, the seeds of fibroids are laid down most commonly between the ages of twenty-eight and thirty-three years. In some patients, this occurs much earlier. After the age of thirty-three, the chances of new seedlings diminish, and after thirty-six they are practically nonexistent. In Bonney's series of those women married and desirous of children, 38 per cent conceived after the operation.

In patients requiring surgery in whom the reproductive function is not important, hysterectomy is the treatment of choice. After the operation, ovarian function is about the same as before. The sex function is unchanged and the local condition has been removed. If the operation is restricted to those patients in whom it is properly indicated, it produces the most satisfactory results.

ECTOPIC PREGNANCY

In extrauterine pregnancy, more commonly called ectopic pregnancy, the implantation of the ovum is outside the uterine cavity. The tube is the most common site—most frequently in the ampulla, next, in the isthmus, and, lastly, in the interstitial portion of the tube. In rare cases, the implantation is in the abdominal cavity or on the ovary.

In general, any obstruction to the passage

of the fertilized ovum through the tube favors the development of ectopic pregnancy. Theoretically, the ovum could be too big to pass through the tube. In this connection, an adhering membrana granulosa, rapid cell division and growth of the ovum during external migration (transperitoneal migration of the ovum to the contralateral tube) could be mentioned. Recent reports mention a psychogenic mechanism producing tubal constriction through an autonomic dysfunction. Actually, the common cause is obstruction in the tube and this results from salpingitis. Since the advent of the antibiotics, partially occluded tubes with resulting ectopic pregnancy are the most common causes. Inflammation produces adhesions of tubal folds with pocket formation, strictures and destruction of cilia. External adhesions interfere with peristalsis and produce disturbances of motility. There are also congenital causes, such as double lumina, accessory ostia ending in blind sacs and tortuous infantile tubes. All of these are etiologic factors. Rarely, a fibroid will obstruct or constrict the tube in its interstitial portion.

There is no well-formed decidua in the tube and for this reason the tube is anatomically unsuited for nidation. In ectopic pregnancy, when the ovum comes to rest, it burrows into the tubal mucosa as it does in the endometrium, but, in the absence of a protecting decidua, it comes to rest directly on the muscle layer adjacent to or surrounded by large blood vessels. It quickly erodes into the vessels and hemorrhage occurs. Sooner or later the tube ruptures either internally, producing so-called tubal abortion, or externally, with hemorrhage into the free peritoneal cavity.

By its endocrine action, the growing trophoblast causes the development of a uterine decidua and an enlarged, soft uterus. When trophoblastic activity from the uterus declines, the decidua begins to degenerate with a resulting flow, usually reddish brown in color. Sometimes the decidua separates cleanly as a complete or partial cast of the uterine cavity. In the ovary, the corpus luteum of pregnancy forms and functions throughout the life of the trophoblast. The trophoblast secretes the anterior pituitary-like substance which initiates the above changes and is the basis for the biologic tests for pregnancy. The reactions to these tests remain positive as long as the trophoblast lives and remains in contact with the maternal circulation.

Ectopic pregnancy occurs in the white in

the ratio of one to 190 pregnancies and in the Negro in one to 130. The Negro's higher incidence results from the greater frequency of previous tubal inflammation. Other etiologic factors of importance are a history of abortion, especially induced, and of previous treatment for primary sterility.

The clinical picture of the disease varies greatly. There are two types, the classical, in which the shock is immediate and profound, and the atypical, in which the symptoms develop more slowly.

Making the diagnosis of the classical type of ectopic pregnancy is easy. Typically, the patient is a young woman who has had a delayed or missed period and develops a sudden, severe, lower abdominal pain with moderate vaginal bleeding. She collapses and faints. When examined, she presents a shocklike appearance, is very pale and has a low blood pressure. Such a picture suggests an intra-abdominal hemorrhage, the commonest cause of which is ectopic pregnancy.

In such patients, four symptom groups stand out: the signs and symptoms of pregnancy, the pain; the vaginal bleeding; the evidence of internal bleeding. In the atypical patient, these are not always readily recognizable and a determined search must be made to establish their presence or absence. The common error is to overlook entirely the possibility of ectopic pregnancy in the atypical case. The remembrance of the possibilities embodied in the C-A-F-E-E mnemonic eliminates this. Ectopic pregnancy is a diagnostic possibility which must be considered in all patients manifesting the symptoms of pain and bleeding. Another major difficulty in diagnosis is that the symptoms and signs vary according to the stage of the disease, that is, before, during or after rupture.

Before rupture, the usual signs and symptoms of pregnancy may or may not be present. As many as 30 per cent of the patients may have missed no period. The reaction to the pregnancy test is positive in the majority of the patients. Severe pain is not present. Sometimes, there is unilateral discomfort. Vaginal spotting or scanty bleeding is common. The uterus is slightly enlarged with deep tenderness on the affected side and a tender, soft mass may be present. Sometimes the ovary can be palpated as a structure separate from the mass. Fever and leukocytosis are absent. There are no constitutional signs of hemorrhage.

During rupture, pain is pronounced and is sharp, lancinating and unilateral. When a pain is followed by a period of relief, as in

courses are open: expectant treatment, radiation therapy, myomectomy and hysterectomy.

Many fibroids require only expectant treatment. Observation should be considered when the tumor is asymptomatic, smaller than the size of a uterus that has been gravid for three months and the diagnosis is clear cut. It must be ascertained that the tumor is a fibroid and not an ovarian cyst. If observation is elected, coexisting malignant disease in the cervix and endometrium must be considered and its possibility eliminated by appropriate examinations. The rationale for observation is greater the nearer the patient is to the menopause.

In fibroids associated with bleeding, expectant treatment is also permissible under the above conditions. But in such cases, the indication for the exclusion of malignant disease is more urgent than in the asymptomatic cases. To exclude the possibility of cancer of the endometrium, it is necessary to make a study of the endometrium from all parts of the endometrial cavity. The classical method is dilation and curettage. A properly performed suction biopsy of the endometrium by the original technique, or one of its many modifications, often yields as much or more endometrium as does the conventional dilation and curettage. It has the advantage of being an office procedure and hence can be applied in a greater number of patients. In doubtful cases, it can always be supplemented by dilation and curettage. If the endometrial study reveals the changes characteristic of an ovarian failure, it certainly is permissible to try hormone therapy before resorting to surgery or radiation.

Radiation destroys the reproductive, ovarian and menstrual functions. It does not abolish sex function but impairs it in the same way as does age. The classical contraindications to irradiation are any fibroid occurring in a woman under forty years of age, unless surgical treatment is contraindicated, if the diagnosis is questionable and the fibroid cannot be differentiated with certainty from an ovarian cyst; if the fibroid is larger than a fetus of three and one-half months, the presence of an old complicating pelvic inflammatory disease, a complicating ovarian neoplasm, a pedunculated submucous fibroid, a submucous fibroid, or a large pedunculated subserous fibroid, when there is a history of rapid growth, when abdominal pain is present; if some other condition requires surgical relief.

Some surgeons appear satisfied with the

results of radiation, but in general the tendency of most is away from radiation because of its failure in the occasional patient and because of its destructive effect to function, as well as the retention of the malignant potential of the uterus. The occurrence of malignant change seems a little higher in those patients having a fibroid in whom bleeding was present. In spite of this tendency, radiation is a valuable method and in a small number of patients can be used to advantage when surgery appears too risky.

Myomectomy is the operation of choice when it is necessary to save the uterus for reproduction, or for sentiment. It is a remarkably successful operation and is applicable to a much higher percentage of patients than is generally believed. It can be practically bloodless by using a catheter, a tourniquet around the cervix and clamping each infundibulopelvic ligament with rubber-shod intestinal clamps. The risk is about the same as for hysterectomy. There is some chance of recurrence. Bonney, in 293 cases, had a recurrence in nine, or 2.9 per cent. He attributed his success to a very thorough removal of all fibroid seedlings. Others report a higher recurrence rate. In Bonney's opinion, the seeds of fibroids are laid down most commonly between the ages of twenty-eight and thirty-three years. In some patients, this occurs much earlier. After the age of thirty-three, the chances of new seedlings diminish, and after thirty-six they are practically nonexistent. In Bonney's series of those women married and desirous of children, 38 per cent conceived after the operation.

In patients requiring surgery in whom the reproductive function is not important, hysterectomy is the treatment of choice. After the operation, ovarian function is about the same as before. The sex function is unchanged and the local condition has been removed. If the operation is restricted to those patients in whom it is properly indicated, it produces the most satisfactory results.

ECTOPIC PREGNANCY

In extrauterine pregnancy, more commonly called ectopic pregnancy, the implantation of the ovum is outside the uterine cavity. The tube is the most common site, most frequently in the ampulla; next, in the isthmus, and, lastly, in the interstitial portion of the tube. In rare cases, the implantation is in the abdominal cavity or on the ovary.

In general, any e

to the passage

vives to term, a short, false labor occurs, the placenta degenerates and the fetal circulation ceases. If the condition is recognized in time, an operation may yield a living child.

A definite diagnosis of extrauterine pregnancy calls for operation as soon as possible. Patients who have undergone a serious intra-abdominal hemorrhage present real surgical emergencies. As soon as blood replacement has been instituted, the patient is taken to the operating room. In the absence of an anesthesiologist, ether is the anesthetic of choice in our opinion. A left paramedian incision is made rapidly. The peritoneum is seen to have a darkish color due to the blood underneath and, when it is opened, black blood literally gushes forth from the wound. The operator's hand rapidly explores the pelvis and locates the mass at the point of rupture. A long clamp is used to grasp the uterine end of the tube and utero-ovarian ligament. Within this clamp is held the anastomosis between the uterine and ovarian vessels. Laterally, another clamp is used to grasp the ovarian artery. In very extreme cases, the infundibulopelvic ligament is the most readily accessible site for occluding this artery. However, this means sacrificing the ovary on the affected side. In ordinary circumstances, blunt dissection separates the tubal mass from the ovary and the clamp is placed on the ovarian artery in the mesosalpinx. As the hemorrhage ceases, the patient rapidly improves. The removal of the tube can then proceed leisurely. It is well to remove all of the clotted blood which is readily accessible. In closing the wound, hemostasis receives particular attention.

In an abdominal pregnancy, the placenta poses a special problem. If the child is alive, there must be an active circulation between the mother and the placenta. Since the site of the placental attachment cannot contract as in the uterus, hemorrhage will be severe. To avoid this, the placenta is left in situ. In patients in whom thrombosis of the vessels at the placental site has already occurred, the placenta can be safely removed.

The mortality rate in ectopic pregnancy under modern conditions is about 0.5 per cent in white women and substantially higher in colored women. Following ectopic pregnancy the chance of a second pregnancy in the opposite tube is about one in twenty. The chance of subsequent pregnancy is about even, but a fair number will terminate before viability. The chance of a living child has been given as one in three.

ENDOCRINE DISORDERS DUE TO OVARIAN FAILURE

An endocrine disorder resulting from ovarian failure can cause any type of menstrual disturbance. Two such different symptoms as menorrhoea and menorrhagia often have ovarian failure as a common cause. In order to appreciate either of these symptoms, we must understand the cause—ovarian failure.

The ovary has three known functions—the production of ova, estrin and progesterone. Ovarian failure is the inability to fulfill one or all of these functions in a normal manner.

There are two forms of ovarian failure—intrinsic, or primary, and extrinsic, or secondary. Primary, or intrinsic, ovarian failure results from aplasia, destruction by neoplasms, surgical removal, inflammation and aging. In secondary, or extrinsic, ovarian failure, the primary cause is outside the ovary and is either in the pituitary or mediated through the pituitary. Diseases affecting the ovary indirectly by means of the pituitary are those which affect the thyroid gland, diseases in other endocrine glands such as the pancreas or adrenal, and constitutional diseases, such as tuberculosis, or malnutrition.

Ovarian failure follows a rather constant pattern. First, there is a diminution in progesterone production with normal, or slightly diminished, estrin production. Next, the progesterone production falls with estrin production continuing in a slightly diminished cyclic fashion, or in an acyclic fashion. In the latter, the level of estrin production may never reach a value equal to the top or the bottom values of the normal curve, but continues with only slight fluctuations at some level in between. In such subjects, the monthly excretion of estrin may be greater than in the normal cycle. This is so-called hyperestrogenism. Lastly, as the failure progresses, estrin production declines and gradually reaches the menopausal level. There are thus three degrees of ovarian failure—progesterone deficiency with mild estrogen deficiency, progesterone failure and estrin failure. These are respectively known as first, second and third degrees of ovarian failure.

In general, the symptoms of ovarian failure are progressive in the older groups. In the younger age groups, compensation or remission may occur. Both primary and secondary ovarian failure exhibit a diversified group of symptoms which are identical

colic, it is significant. Vaginal bleeding is present and the discharge is a brownish red without clots. Intra-abdominal bleeding occurs, recurring or increasing with each paroxysm. Fever and leukocytosis are present. Shocklike symptoms occur frequently. The examination often reveals an exquisitely tender mass to one side or behind the uterus.

Following rupture, there is usually an attack of agonizing, lancinating pain on one side, accompanied by an internal hemorrhage and followed by nausea, vomiting, fainting, collapse and shock. The pulse is rapid and feeble, the skin pallid and the breathing shallow. Air hunger and anxiety may be present. The veins are collapsed. The abdomen is distended and very tender. In the cul-de-sac, there is extreme tenderness and a mass of clotted blood. Sometimes the latter is difficult to recognize on account of the tenderness and the rather soft nature of the cul-de-sac. Rectal examination helps a great deal and should never be omitted. In patients with massive hemoperitoneum, shoulder pain due to irritation of the diaphragm may be present. Later, painful defecation may be noticed and once in his lifetime the examiner may see a bluish black discoloration around the navel (Cullen's sign).

The demonstration of an intra-abdominal hemorrhage establishes the diagnosis with reasonable certainty. The blood findings, cul-de-sac puncture, colpotomy and culdoscopy are all important and helpful.

After a large intra-abdominal hemorrhage there may be little immediate change in the blood picture. But, in time, dilution of the circulating blood occurs, with a fall in the hemoglobin value, packed cell volume and red blood cell count. In diagnosis, the degree of anemia does not parallel the clinical signs of hemorrhage. The important fact is that the blood findings are slowly progressive. A progressive lowering of the hemoglobin value on repeated determinations is, therefore, very significant. Another differential point is that the degree of anemia is generally greater than can reasonably be explained on the basis of the vaginal bleeding.

Examination with the patient under ether is a great aid to diagnosis. Often the tenderness is so extreme that a satisfactory examination is impossible in the unanesthetized patient.

A cul-de-sac puncture, using an aspirating needle, has been most helpful and safe in our experience. It not only serves to estab-

lish the fact that blood is present, but sometimes reveals pus and thereby excludes the possibility of the presence of ectopic pregnancy. Now and then a small amount of blood is obtained which might have come from the extraperitoneal tissues. Such blood is red and clots readily in the syringe. Blood from an intra-abdominal hemorrhage is dark and, when squirted onto a piece of gauze, there are numerous little clots. Under the microscope, the cells are seen to be crenated and rouleaux formation does not occur.

Posterior colpotomy also determines the presence of blood in the cul-de-sac and allows the entrance of an examining finger. Some continental surgeons consider this a most valuable aid in diagnosis.

Culdoscopy, a visual method, has found favor with some and certainly has merit in the doubtful cases. When blood is present, inspection is difficult or impossible and, therefore, in patients having an intra-abdominal hemorrhage, culdoscopy offers little advantage over simple puncture. Perhaps its greatest value is in revealing the true nature of the disease process when ectopic pregnancy is not present.

Dilation and curettage can give valuable information in doubtful cases. The finding of a well-marked decidua without chorionic elements is presumptive evidence of ectopic pregnancy. Before employing dilation and curettage, it is wise always to consider the possibility of intrauterine pregnancy, since it coexists with ectopic pregnancy in a small percentage of cases.

Ovarian pregnancy is a rare form of extrauterine pregnancy. The symptoms, signs and treatment of ruptured ovarian pregnancy are essentially the same as those of ruptured tubal pregnancy. Hemorrhages from other causes can occur from the ovary, but a severe intra-abdominal hemorrhage of ovarian origin always raises the possibility of an ovarian pregnancy. Microscopic examination of the ovary reveals chorionic villi and thus confirms the diagnosis.

Primary abdominal pregnancy with implantation on a peritoneal surface does occur. A secondary form occurs when a live embryo escapes by rupture or abortion from its primary location in the tube or ovary and implants itself on the peritoneum. Such embryos usually are abnormal and die long before term. They undergo degeneration or lithopedion formation. As a result of the latter, many bizarre circumstances arise. In those rare instances in which the fetus sur-

useful clinical asset to all who perform abdominal surgery.

In third degree ovarian failure, the hot flash is the most important and characteristic of the neurogenic symptoms. At first, it occurs only a few times daily and is limited to the head and neck. Later, it becomes more frequent and may involve the whole body. Often during sleep, the flash produces so great a sensation of heat that the bed clothes are removed to be followed in a short time by chilling and awakening. The incidence of hot flashes is fairly well paralleled by the amount of follicle-stimulating hormones in the urine. Following estrin administration, the follicle-stimulating hormones decline and the flashes are not so frequent. Thus, the level of excretion of the follicle-stimulating hormone is influenced by the level of estrin. An excess excretion of follicle-stimulating hormone is perhaps the most valuable test in the diagnosis of primary ovarian failure.

Sweating is frequently associated with hot flashes and often causes the patient much discomfort. Smothering is another frequent symptom and always arouses a suspicion of ovarian failure. Many other neurogenic symptoms occur from time to time. Among these are headache, fatigue, cold sensations, tingling and tinnitus.

Ovarian failure causes all types of menstrual disturbances. As a general rule, the minor disturbances of menstrual interval and flow occur in first degree failure. The severe types of bleeding are seen in the second degree failure. Infrequent menstruation and amenorrhea are characteristic of third degree failure. It is well established that there is no absolute correlation between the degree of failure and the type of symptoms.

In second degree ovarian failure, the endometrium is generally hyperplastic and often the glands are irregularly dilated, giving a Swiss-cheese-like appearance to the microscopic section. This glandular cystic hyperplasia, or Swiss cheese hyperplasia, is a very important characteristic of second degree ovarian failure and usually is associated with marked irregularities of the interval and of the flow. Not infrequently, bleeding is preceded by a short period of amenorrhea and this often gives rise to the suspicion of an abortion. Confirming this belief is a marked softening and slight dilatation of the cervix. Lacking is the pain which is so characteristic of abortion. The fact that painless bleeding is the rule with ovarian failure is important in diagnosis.

The general appearance of the patient is normal when primary ovarian failure occurs after adolescence. In those in whom the failure occurred before or during adolescence, there is a rather definite tendency toward an increase in the length of the arms and legs, and a span—the distance from finger tip to finger tip of outstretched arms—which is greater than the height. The abnormal length of the extremities results from the gonad's inability to exercise its effect on epiphyseal closure. This disproportion of the extremities to the trunk can also occur in women with anterior pituitary dysfunction and in normal women who reach sexual maturity somewhat late. If it is associated with a menstrual disturbance, it is a sign of great value, especially so if the disturbance dates from adolescence. In the adolescent with primary ovarian failure, the muscular system is frequently deficient and there is a tendency toward leanness which is difficult to overcome by treatment. The blood pressure is often low, the systolic pressure ranging from 90 to 100, while the pulse frequently is rapid. The breasts may be underdeveloped and the uterus has a small body and a long cervix. This gives a ratio of the cervix to the body of the uterus which is greater than the normal cervix-body ratio of 1:2.

In third degree failure, there is atrophy of the vulva and vaginal mucous membrane and the trophic state of these parts gives a good idea of the amount of estrogen available to the genitalia. A more accurate estimate of the hormones available to the genital tract is obtained by studying the endometrium. In primary ovarian failure, a low estrin level causes an increase in the level of follicle-stimulating hormones and this is considered to be a specific diagnostic test.

The diagnosis of primary ovarian failure is made in two steps. First, the presence of an ovarian failure is determined and, secondly, this is demonstrated to be primarily ovarian. The first step is comparatively easy. Either a functional menstrual disturbance, significant trophic changes in the vagina or changes in the histologic structure of the endometrium are all certain indications of a lowering of ovarian function. The second step consists in determining if the failure is primary or secondary. This is somewhat more difficult and often involves problems in general medicine and endocrinology. From a practical standpoint, the single most important differential test is the determination of the follicle-stimulating hormone.

in respect to those symptoms arising from a lack of ovarian activity. The secondary form, however, also exhibits in addition the symptoms of the primary pituitary disease, or of other diseases which result in a decreased pituitary function. Secondary ovarian failure, therefore, has all of the features of the primary form but, in addition, has grafted thereon the symptoms of another endocrinopathy.

The symptoms of ovarian failure fall into five groups—sexual, reproductive, vaginal, nervous and menstrual.

Ovarian failure is a consideration in all problems relating to sexual behavior in the female. However, it rarely is the chief factor. Ovarian hormones are an indispensable factor in the development of the normal female. However, in spite of normal ovaries, the psyche and sex impulse may be and often are distorted by psychologic and environmental factors. Hormones also sensitize the parts and the psychic centers, but a normal sex experience can occur in previously normal women who have been deprived of their sex hormones by bilateral oophorectomy. In spite of this, it is obvious that the hormones do play a role, because sexual activity and response are not the same in the older woman as in the young. The evidence seems to indicate that a lack of sex hormones, in previously normal women, produces changes in libido and response somewhat similar to that occurring from aging.

Other necessary factors which must be considered in relating ovarian failure to a sexual symptom are the normalcy of the parts, the absence of pain, the proper functioning of the nervous system and the proper psychic and sexual conduct of the male.

Normal ovarian function is necessary for normal ovulation and for the proper development of the endometrium. If the development of the endometrium is faulty as in first degree failure, there is an increased likelihood of abortion, low implantation of the placenta and placenta previa. In second and third degree ovarian failure, there is no ovulation and consequently sterility results. The development of a well-marked progestational endometrium is the most practical and accurate method of determining ovulation in the human being. The endometrium is best obtained by the biopsy method just before the onset of menstruation. This, in addition to a test of tubal patency and a determination of the sperm count, is indispensable in any study of sterility.

At puberty, the vaginal mucous membrane acquires an increased resistance to infection as the result of estrogenic stimulation. The application of this fact is useful in the treatment of certain discharges. As the patient reaches the menopause, the vagina gradually undergoes a process of involution, during which the epithelium loses its rugae, becomes thinner and is more prone to infection. Obliteration of the fornices and narrowing of the introitus gradually occur. As the process continues, symptoms of stinging and burning occur with the development of discharge (senile vaginitis). Not infrequently, there are adhesions between the anterior and posterior walls and, sometimes, the process goes on to almost complete vaginal obliteration. Bleeding is a common accompaniment of senile vaginitis and this is perhaps the most common form of postmenopausal bleeding. It should never be forgotten, however, that the presence of senile vaginitis does not exclude the possibility of cancer of the body of the uterus. Many endometrial cancers are overlooked because of the simultaneous occurrence of the two diseases.

The nervous symptoms of ovarian failure are both psychogenic and neurogenic. They vary in their intensity according to the personality of the patient and the severity of the failure. Most women with a well-balanced personality have relatively few symptoms even from complete failure. Others suffering with various personality defects have a variety of unpleasant and often severe symptoms from only mild failure. In such women, many of the symptoms have a quality which suggests the diagnosis of a primary psychoneurosis and the evaluation of such symptoms can be extremely difficult. Often it is best to reserve judgment until the results of specific therapy can be observed or the psychopathologic state can be demonstrated. Symptoms remaining in the face of adequate therapy and unexplained by a careful general examination can reasonably be considered as psychogenic in origin.

Psychosomatic symptoms pointing to an abdominal viscus are frequent and confusing. Pain is present and frequently leads to an ill-advised operation. In one series of cases of ovarian failure, 42 per cent of the patients had had one or more abdominal operations. Most of these patients were unrelieved and they again sought and found further surgical intervention. At long last, their troubles were attributed to adhesions. The recognition of such cases is a highly

conjugated estrogens (Premarin) is given intravenously and the dose is repeated every eight hours until the bleeding is checked. The first two or three doses should be supplemented by the intramuscular injection of 20 to 50 mg. of progesterone in order to insure a more complete desquamation of the abnormal endometrium when withdrawal bleeding occurs; then cyclic therapy follows as in the previous plan.

Dilation and curettage is often used to establish the diagnosis and to produce temporary hemostasis in bleeding which is refractory to treatment. In a fair proportion of women, the operation produces a remission of symptoms and no further treatment is necessary. However, this is not the rule and in a period of several months the symptoms recur. For this reason, we usually follow the curettage with endocrine treatment.

Hysterectomy is frequently used in the treatment of endocrine bleeding, but in many cases the surgeon does not know the bleeding is of endocrine origin until he finds what he thinks is a "bleeding fibroid," far removed from an endometrium exhibiting glandular cystic hyperplasia. For the deliberate use of hysterectomy, the bleeding should be severe, endocrine treatment unavailing or impractical and the reproductive function of little or no value. The advantages of hysterectomy are the definitive nature of the cure with a low mortality and morbidity, the preservation of the patient's remaining ovarian function, which is often adequate for a normal sense of well-being, and the preservation of normal sexual function.

Its disadvantages are those incident to any operation, as well as destruction of the reproductive and menstrual functions. The psychologic effect of hysterectomy has been much discussed and it is clear that when the patient does not willingly accept her postoperative state, a bad result is inevitable. Fortunately, most patients with severe bleeding gladly accept their postoperative state and are extremely pleased with the operation.

Radiation by externally applied x-ray, or by internally applied radium, is useful for those bad-risk patients in whom the reproductive and ovarian functions can be sacrificed. There are still some gynecologists who prefer radiation to hysterectomy for endocrine bleeding. It is certainly much less an ordeal and does have its advantages. Its disadvantages are its destructive effect on the ovarian and sex functions. For example,

following radiation, a patient of forty-two years of age rapidly reaches a sexual age of perhaps sixty-two years. This does not necessarily mean that intercourse is unpleasant or that orgasm is impossible, but it is not like it was. Radiation owes its curative effect on endocrine bleeding to the abrupt transformation of partial ovarian failure to complete ovarian failure. Following this, there may be severe nervous symptoms. In overcoming these by hormonal means, there is always the possibility of inducing worrisome bleeding from the uterus. Further, the cancer risk of the retained uterus seems to be greater.

THE MENOPAUSE

This is a primary type of ovarian failure normally occurring at the end of the reproductive period. It occurs as a normal physiologic change but has all of the signs and symptoms of primary ovarian failure. Some women have severe symptoms, but in most the symptoms are mild and require no treatment. The nervousness incident to the menopause comes at a time when a woman's responsibilities are often greatest. In addition, it focuses the mind on the aging process and its consequences. To many it appears that life can never be the same. Actually, the years after the menopause can be and frequently are the best of a woman's life. Reassurance and perhaps mild sedation are usually all that are necessary. In some patients, estrogenic therapy may be indicated. Symptoms which persist after adequate estrogenic therapy cannot rightfully be attributed to the menopause and must be explained and treated on some other basis.

RELAXATIONS

Defects in the pelvic supporting structures present as anterior vaginal relaxation or cystocele, posterior vaginal relaxation or rectocele and uterine descent or prolapse. These lesions may occur separately or in any combination or degree. Each of these lesions may be classified according to the degree of relaxation present. For instance, in uterine prolapse, if the cervix lies within the vagina it is called first degree; if the cervix protrudes from the vagina it is second degree; if the uterus lies outside the pelvis, it is third degree prolapse.

Certainly the trauma incident to repeated childbirth is the most important etiologic factor. However, certain individuals appear to have relaxation after only mild trauma

To be sure, many problems in differential diagnosis arise. For example, in a patient with a sexual disturbance, ovarian failure is only one of several causes and the possibilities of these must be excluded. Likewise, in patients with bleeding, one must first make a differential diagnosis of the cause of bleeding.

The successful treatment of ovarian failure depends upon individualization of the patient and the determination of her functional needs, an accurate diagnosis, elimination of constitutional disease and the intelligent choice of endocrine, surgical or radiologic treatment.

In extrinsic, or secondary, ovarian failure, the treatment consists of measures directed at the primary cause as well as at the ovarian failure. In hypothyroidism with secondary ovarian failure, for example, the treatment would be that of hypothyroidism plus that of ovarian failure.

The treatment of ovarian failure at the present time is largely a substitutional form of therapy. A total or partial deficiency of either or both of the ovarian hormones is corrected by prescribing the deficient hormone in an amount approximately equal to the deficiency at the correct time in the cycle. Under normal conditions, a drop in the amount of estrin and progesterone or of progesterone initiates menstruation, while a rise in the level of estrogen terminates menstruation. This is known as the withdrawal theory of menstruation and, while it does not completely explain the phenomena, it is a most valuable therapeutic tool as it enables us to start and stop the flow under most circumstances.

Generally, endocrine amenorrhea is a symptom of second or third degree ovarian failure. In second degree failure, there is an adequate acyclical estrin production with a total lack of progesterone. According to the withdrawal theory, it is only necessary to produce a rise and fall in progesterone to induce menstruation. This is easily accomplished by the administration of 20 mg. of progesterone for three to five days, or of Norlutin, 10 to 20 mg., for five days. Cessation of the medication causes a fall in progesterone and initiates menstruation. In third degree failure, there is a total lack of progesterone and an inadequate estrin secretion. Menstruation can be induced by first raising the hormonal level by the intramuscular injection of 20,000 I.U. (2 mg.) of a microcrystalline suspension of estrogenic substances and 20 mg. of progesterone for a

period of five or more days. By the oral route, 5 mg. of Premarin and 10 mg. of Norlutin are often effective. When the medications are discontinued, the hormonal level falls and menstruation follows. Should the period fail to appear, larger doses of hormones and longer periods of treatment should be used in subsequent cycles.

For abnormally long menstrual cycles, treatment is started on the seventeenth day after the onset of bleeding and consists of raising the hormonal level by the daily oral addition of 1.25 or 2.5 mg. of conjugated estrogens and 40 mg. of anhydrohydroxyprogesterone (Pranone)—orally active progesterone derivative—for a period of seven days. The fall in the hormonal level following cessation of treatment will usually induce menstruation at or near the normal time.

Abnormally short menstrual cycles may be offset by additive therapy. For example, in patients with twenty-one-day cycles, 1.25 or 2.5 mg. of conjugated estrogens plus 40 mg. of anhydrohydroxyprogesterone are given orally daily from the fourteenth to the twenty-fourth day after the onset of the period. The usual fall in the hormonal level at the seventeenth, or eighteenth, day will be delayed by the addition of these hormones, thus prolonging the interval.

In severe menorrhagia or metrorrhagia, the flow can usually be controlled by the daily injection of 25 mg. of testosterone propionate and 20 mg. of progesterone for five days. The addition of 20,000 I.U. (2 mg.) of a microcrystalline solution of estrogenic substances adds to the efficacy of the therapy. At the completion of therapy, the bleeding will either be greatly diminished or will have ceased. After a latent period of two to four days, the hormonal withdrawal following the cessation of the injections induces a normal menstrual period with a desquamation of the previously abnormal endometrium. This sometimes is spoken of as a medical curettage. Following this, Hamblen's cyclic therapy is in order: 1.25 to 2.5 mg. of conjugated estrogens is given from the fifth to fourteenth day after onset of the withdrawal bleeding, or the onset of the normal period, and this is increased to 2.5 or 5 mg. from the fifteenth to twenty-fourth day. This is supplemented by the addition of 40 mg. of anhydrohydroxyprogesterone or 10 mg. of Norlutin given orally from the seventeenth to twenty-fourth day.

In patients with very severe bleeding requiring immediate hem 20 mg. of

HYSTERECTOMY

Certainly no discussion of diseases of the female genitalia would be complete without mention of the operation which unfortunately is so often necessary in combating these diseases. This operation is, of course, hysterectomy.

Thus far, the main purpose has been to present the various symptom complexes which arise in the field of gynecology and to proceed from there to a probable diagnosis. The functional approach and individualization have been emphasized. In many of the diseases the most logical treatment is hysterectomy. But one should remember that there are no absolute indications for hysterectomy. While it is true that, in any series of hysterectomies, one may list the conditions for which the operation was performed, the reverse—that is, that these conditions are indications for hysterectomy in every case—is not true.

This discussion will be limited to two types of hysterectomy—total abdominal and vaginal. In situations which require the abdominal approach, the total operation is the one of choice. Situations do arise in which the subtotal operation is necessary, but anyone familiar with the total operation will rarely find a situation in which the subtotal is necessary. Radical hysterectomy is regaining considerable popularity in the treatment of cancer of the cervix and endometrium.

Total abdominal hysterectomy will be the operation of choice in a large percentage of women in whom removal of the uterus is indicated. It is axiomatic that to perform this operation properly the surgeon must have a thorough knowledge of the anatomy involved. Too often, however, this knowledge is lacking, as the all-too-frequent ureteral, vesical and rectal complications testify. Perhaps the most useful knowledge is that of the supporting structures of the uterus. Visualize the uterus and vagina as relatively flexible structures immobilized within the pelvis by ramifications of the endopelvic fascia arising from the lateral ground bundles. Remember also that these layers of fascia decussate to envelop the bladder and rectum. The operation should be performed in such a fashion that each step makes the succeeding one easier. The supporting structures of the uterus are, therefore, attacked from above downward, allowing the uterus to be mobilized upward.

The ability to perform a vaginal hysterectomy well is essential to the armamentarium of every pelvic surgeon. Frequently the

presence of associated vaginal relaxation, or uterine descensus, makes this the method of choice. Here, again, the operation proceeds by a successive attack on the supporting structures, but in the reverse order.

A knowledge of the effects of hysterectomy on the general and pelvic functions is of paramount importance in the selection of subjects for the procedure. What is the effect of hysterectomy on life? We know that it can be carried out with minimal mortality. Collected reports indicate that under good conditions the mortality is from two to five per 1000. Even this small figure is improved by the cancer prevention in those who have the operation. The general health of the patient improves in proportion to the degree of disability existing prior to the operation. Only in poorly selected patients, and those suffering from severe complications, is the general health impaired. The pelvic functions of menstruation and reproduction are lost. In most patients, this is a welcome relief, but the loss will be a severe liability in certain women if they are not properly conditioned. Ovarian function is probably not affected if the ovarian circulation is not embarrassed. The sexual function is generally unimpaired and, occasionally is improved. Vaginal support is not greatly affected by hysterectomy, as the intrinsic support of the vagina is not disturbed. Certainly any coexisting vaginal relaxations should be repaired at the time of hysterectomy.

PELVIC MASSES

In the diagnosis of pelvic masses, the usual methods apply. After taking the history and making the examination, the physician integrates the data and considers the most logical possibilities. In the differential diagnosis, he considers all reasonable possibilities and excludes as many as possible by further examinations and special studies. By this process, he is able to arrive at a working diagnosis in most cases. In some patients, the diagnosis may still be uncertain and an exploratory operation may be necessary.

Arriving at a working diagnosis of masses presumably arising from the female internal genitalia can often be easy and straightforward, if the following approach is used. The first question to be answered is: Is the mass genital or extragenital? In answering this question, it is well to remember that a diffuse abdominal swelling has five possible causes. They are sometimes spoken of as the five F's. They are: fat, fluid, feces, flatus

and this must be attributed to some defect in the tissues themselves. Occasionally these lesions occur as congenital defects and complete prolapse in a maiden lady is sometimes seen.

The symptoms of vaginal relaxation will vary, depending on the degree and character of the relaxation. One of the commonest complaints is a sensation of pressure, or bearing down, in the pelvic region. Patients frequently volunteer the information that they feel as though their insides are coming out. This symptom is usually worse on standing. Patients with rectocele complain of protrusion of the posterior wall of the vagina and inability to defecate unless the rectocele is manually reduced. Those with cystocele and urethrocele also complain of protrusion from the vagina. Varying degrees of frequency, dysuria, urgency and incontinence may be present.

Incontinence must be carefully evaluated, as it may require special attention. We have to know exactly what the situation is. Does the patient leak urine only occasionally on severe straining? Does she require protection because of frequent leakage on moderate straining? Does urine leak continuously when she is in the erect position? Often there is associated posterior urethritis and the symptoms of this condition should be identified before proceeding with repair. Otherwise the patient may be dissatisfied because of persistence of symptoms which were attributed to relaxation, but which were in reality due to urethritis.

Patients with prolapse may complain of a low backache or bilateral low abdominal pain due to tension on the intra-abdominal supporting structures. Commonly the presenting complaint is of a gradually enlarging protrusion from the vaginal outlet. In long-standing cases, bleeding and ulceration occur from pressure. At times, these lesions may simulate malignant disease and require biopsy, although carcinoma and prolapse seldom coexist. At times, the prolapse may be so severe as to produce urethral obstruction and hydronephrosis. The hydronephrosis usually regresses when adequate drainage is established, which should, of course, be accomplished before operative repair is attempted.

The pathologic state of these conditions is difficult to discuss because of the complex anatomy of the pelvic fascia. However, this anatomy must be understood before the defects can be properly repaired. Perhaps the best discussion of this matter is given by

Pelham and Amreich who describe the connective tissue ground bundle. This lateral structure splits to envelop the bladder, vagina, uterine canal and rectum with supporting fascia. It is defects in these fasciae which produce the relaxations described above.

In order to simplify the discussion, the anatomic similarity of a prolapse and a post-operative ventral hernia should be visualized. In the ventral hernia, a peritoneal sac protrudes through a defect in the transversalis fascia, rectus muscle and rectus fascia. In prolapse, the structures involved are remarkably similar to those in the ventral hernia. The triangular ligament corresponds to the anterior rectus fascia, the levator and muscles to the rectus muscles and the pelvic fascia to the transversalis fascia. Therefore, in prolapse there is a peritoneal sac containing the uterus protruding through a defect in the pelvic fascia, levator muscles and the triangular ligament.

The final result of both prolapse and ventral hernia is a protruding mass containing a hernial sac and covered by squamous epithelium. Surgical cure of these lesions follows identical lines. In hernia, the structures are dissected out, the sac is removed and closed, the transversalis fascia sutured, the muscle is brought together and the rectus fascia closed. In prolapse, the same principles are used. The dissection of the structures exposes the defect in the pubocervical fascia under the cystocele, and in the rectal fascia, over the rectocele. The removal of the sac often requires vaginal hysterectomy, as the apex of the sac corresponds with the circumferential attachment of the peritoneum to the uterus. The peritoneal portion of the uterus is part of the contents of the sac, while the extraperitoneal portion acts as a hard wedge to push aside the structures in front of the advancing hernia. After the peritoneum is closed, the cardinal and uterosacral ligaments are approximated, then the defect in the pubocervical and rectal fasciae is closed—this corresponds to closure of the fascial layer in the repair of a ventral hernia. Suturing the levators together restores the muscular component of the perineum. The triangular ligament is the fascial part of the perineum comparable to the anterior rectus fascia and suturing of this layer completes the operation except for skin closure. When preservation of sexual function is important, the procedure is complicated by the necessity of maintaining an adequate vaginal outlet.

fingers are brought together and placed just in front and above the os. The right hand is fully pronated and presses the uterus against the fingers of the left hand, the uterus is thus caught between the palmar surfaces of the fingers of both hands and can be palpated easily and accurately. When the impact of the uterus against the anterior abdominal wall is not visible, and the anterior surface of the lower uterus cannot be felt by the vaginal fingers, palpation is started at the promontory of the sacrum and, by a series of dipping motions, it is continued downward until the abdominal fingers transmit an impulse to the fingers beneath the cervix, then the fingers of the vaginal hand are rearranged and the uterus is palpated as has just been described. If the uterus cannot be felt posteriorly in the cul-de-sac or found anteriorly, a partially filled bladder is suspected and the patient is catheterized before it is assumed that the uterus cannot be outlined.

Is the mass adnexal? Palpation of the uterus separate from the mass and the exclusion of an extragenital mass definitely identify a lateral mass as adnexal. The corollary that palpation of an ovary and the exclusion of an extragenital origin identify a mass as uterine is also true, except in certain rare instances of ectopic gestation, hydatic cysts and discrete tubal masses.

It is impossible to palpate the normal tube. To palpate the ovary, the vaginal fingers are placed in the lateral vault of the vagina and pressure with the vaginal hand is applied firmly inward toward the sacrum and outward toward the side wall of the pelvis, while the abdominal hand is pressed down, so that the tips of the abdominal fingers come close to the tips of the vaginal fingers. In this position, the tips of the fingers partially encircle the ovary if it is in the normal position and, if the ovary is not felt, the same relative position of the fingers is maintained while the hands move slowly downward toward the pubis. By so doing, the fingers pass over the ovary and can feel it if the fingers are fairly closely approximated.

With uterine masses, one must differentiate between those conditions designated by the first four letters of our mnemonic, PREMIEO. These are pregnancy, retroversion, enlargement and myoma. If the mass is adnexal, the differentiation is between the conditions designated by the last three letters of the mnemonic. These are inflammation, ectopic pregnancy and ovarian

mass. Many times, it is impossible to state definitely if the mass is uterine or adnexal. In such a situation, one must make a differentiation between the various uterine and adnexal masses. In making this differentiation, the history, the constitutional reaction, the findings in the blood and urine and the characteristics of the mass are considered. This information, together with the condition of the cervix and the position of the mass, its size, shape, consistency, mobility and tenderness, usually gives the data necessary for establishing the diagnosis.

In pregnancy, the cervix is soft and as the pregnancy advances toward term it gradually becomes effaced. In abortion, the cervix is soft, open and may contain blood clots or pieces of placenta. In ectopic pregnancy, there may be slight softening of the cervix, but this is generally not well marked. Endocrine bleeding causes a softening and dilatation of the cervix similar to that occurring in abortion.

A central position of a mass suggests a uterine origin, a lateral position indicates an ovarian origin. However, it is not unusual for an ovarian cyst to present in the midline and for a uterine tumor to be felt in a lateral position. Every now and then an experienced examiner may feel a lateral mass which has the characteristics of an ovarian cyst. At operation, no cyst is found and the uterus is the site of a normal pregnancy. The palpatory illusion of a cyst resulted from the fact that the relaxed uterine isthmus allowed the fundus to fall into a lateral version. When the uterus contracted, it returned to the former midline position. Any of the genital masses can present in the cul-de-sac. The most common is the retroverted fundus.

The size of a mass is of some diagnostic importance, especially if considered in relation to the history. Perhaps, in a suspected pregnancy, there is a two months' period of amenorrhea with a uterine mass the size of a four and one-half months' gestation. This would indicate that the suspicion of pregnancy was incorrect or that there was some additional cause of uterine enlargement such as a myoma. In ovarian cysts, size has considerable diagnostic significance. The extremely large cysts, for example, are almost always of the pseudomucinous variety. In young women with menstrual disturbances, cysts less than 4 cm. in diameter are usually follicle cysts. Ectopic gestation and pelvic inflammation form masses which are sometimes large enough to present supra-

and fetus. The usual physical examination of the abdomen elicits the data obtained by inspection, palpation, auscultation and percussion. The pelvic examination extends the scope of the examination and adds much useful information. When abdominal fluid is encapsulated, and the lower pole of the mass can be felt in the pelvis, the tumor is almost certainly ovarian in origin. Overdistention of the urinary bladder simulates a pelvic tumor. If one recognizes the possibility and catheterizes the bladder, mistakes will not occur. When free fluid is present, it can often be related to a pelvic mass such as an ovarian carcinoma or to secondary carcinomatous nodules. An adnexal mass with free fluid suggests the possibility of tuberculous peritonitis or Meigs' syndrome. Feces in the bowel cause abdominal distention and fecal masses in the pelvis sometimes resemble tumors. A fecal bolus can be differentiated from a tumor by its putty-like consistency and its tendency to pit or dent on pressure. In doubtful cases, a good cathartic eliminates the mass and allows a more satisfactory subsequent examination. Gaseous distention of the abdomen may be from a functional cause such as air swallowing, or from an organic cause such as intestinal obstruction, tumor or inflammation. Often times the inflammation is of adnexal origin and involves the small bowel.

The large bowel is rarely, if ever, obstructed as the result of extrinsic pressure by tumors. A left-sided mass associated with a large bowel obstruction is almost certainly, therefore, the result of either carcinoma or diverticulitis. If there is no large bowel obstruction, masses due to diverticulitis, or carcinoma of the sigmoid or cecum, can mimic adnexal masses. If an operation is elected, a mistake of this kind can be embarrassing to the surgeon and dangerous to the patient. This is especially so if the surgeon is not too well grounded in gastrointestinal surgery. For this reason, some surgeons make it a rule to examine the colon radiologically in patients with left-sided masses. Certainly, this, in conjunction with a good gastrointestinal history, will eliminate most mistakes of this kind. While ectopic kidney is a rare lesion, it will occur from time to time, and for the sake of completeness it is well to keep the possibility in mind.

In practice, the elimination of an extragenital mass is largely dependent upon recognizing the possibility of an extragenital mass in diagnosis. Is it appendix, cecum, bladder, kidney or sigmoid? These are

routine questions which should never be overlooked. When these questions are answered in the negative, one may safely assume the mass to be of genital origin.

Is the mass uterine? This is the next question and the answer depends in great part upon the vaginoabdominal examination. As soon as he inserts the finger, the experienced examiner immediately begins to form impressions which gradually crystallize into definite opinions. Light palpation with one finger reveals a tremendous amount of information. From it, one can determine the characteristics and consistency of the cervix, its degree of dilatation and effacement and the presence of masses in the cervical canal. The finger, gently sliding from the os up over the anterior surface of the cervix, may establish the presence of a continuity with the anteverted fundus or, laterally, the finger reaching the fornix, comes upon an area richly rewarding to the gentle touch. In this area, the lower pole of many masses presents. Comparing the height of the vault yields much information. Detecting a relative diminution in the height of a vault frequently means trouble above. Posterior to the cervix is the area where light palpation is most valuable. As the finger passes along the posterior cervix to the cul-de-sac, it may encounter the buckshot nodularity of endometriosis, the induration of carcinoma or the lower pole of any of the pelvic masses. The most common of these is the retroverted uterus.

For testing the mobility of the uterus, two fingers are best. Most examiners use the first two fingers of the left hand in the vagina and the right hand on the abdomen for vaginoabdominal palpation. The initial position of the vaginal hand is midway between pronation and supination, the index finger points slightly to the patient's right, while the second finger points a little to the patient's left, thus forming a little V in which the cervix rests. From this position, the vaginal hand can elevate the uterus by exerting upward pressure on the cervix. Often one can see the impact of the uterus against the anterior abdominal wall. This is a great help in determining the placement of the abdominal hand, the most advantageous position being just at the upper margin of the point of impact. When the right hand is properly placed and presses down upon the uterus, the impulse is transmitted to the fingers of the vaginal hand. To bring the hands into the proper position for palpation of the uterus, the left hand is supinated, the

tient having a perforated appendix with pelvic peritonitis. In this condition the fever may be high, the pulse rapid and the tenderness bilateral. The history is of the greatest value, especially so if at the onset the original localization was in the right lower quadrant or if there had been a previous attack of either salpingitis or appendicitis. In some cases, a differential diagnosis is impossible and it is better to open the abdomen than to allow possible appendicitis to progress. Before doing so, it is always helpful to re-examine the pelvis with the patient under anesthesia. With the patient asleep and tenderness and rigidity abolished, it is possible to feel adnexal masses that heretofore were not palpable.

Other common diseases which must be considered in the differential diagnosis are urinary tract infection, twisted ovarian cysts and ectopic gestation. Of these, the most difficult to differentiate is ectopic gestation. In this differentiation, cul-de-sac aspiration and examination with the patient under anesthesia are often decisive.

There are two principles in the treatment of the patient having acute gonorrheal pelvic infection: first, treatment of the infectious process and, second, prevention of subsequent infections. Treatment of the primary infection is almost always successful with appropriate medication and adequate dosage. Penicillin, 300,000 units given intramuscularly daily for three to five days, produces a dramatic effect. The oral administration of 200,000 units, three times a day for seven days, is also satisfactory. In resistant or difficult cases, the new broad-spectrum antibiotics are useful. The sulfonamides are also effective, but less so than the antibiotics. Bed rest, hot douches and supportive treatment are helpful measures in severe cases.

It is now well established that a recurrence of symptoms following adequate treatment is caused by reinfection and not by an exacerbation of the original disease. Therefore, the prevention of subsequent attacks depends upon eliminating the source of the reinfection by either curing the infected consort or having the patient avoid him. In the case of the innocently infected wife, the physician may have to exercise considerable tact and discretion in order to eliminate the erring husband's infection. The physician's obligation to the patient has not been fulfilled until this has been done.

In patients with neglected or untreated cases, a pelvic abscess may develop. This requires drainage, which is best accom-

plished through the cul-de-sac. Continuous drainage and obliteration of the abscess cavity depend upon the insertion of a rubber tube into the cavity. Generally the tube selected is of the type used for drainage of the common bile duct. This is far too small. A proper tube is as large as a finger. It is readily constructed from a chest tube. The tube remains in place until activity subsides and the cavity is obliterated. Generally this requires six or more weeks. Of course, antibiotic therapy is continued throughout the febrile phase. The addition of cortisone hastens the absorption of the inflammatory exudate.

Chronic Gonorrheal Salpingitis. Repeated infections cause blunting and adhesions about the ends of the tubes with subsequent tubal obstruction. Infection persisting in the obstructed tube produces the well-known "pus tube" or pyosalpinx. Not infrequently the fimbriated end of the tube becomes plastered against the ovary and the infection produces an abscess involving the ovarian stroma and the lumen of the tube. Unfortunately, many patients return time after time with more severe and disabling infections until at last they become "pelvic cripples." Outstanding in these unfortunate women are one or more of the following complaints: sterility, dyspareunia, pelvic pain, menstrual disorders, pelvic mass, pelvic abscess.

In the course of subsequent attacks, other organisms join the gonococcus in its destructive work. Owing to the factor of a mixed infection, the response to antibiotics is often not so immediate as in the initial attack. Further, the infection is well walled off and for this reason not so amenable to treatment. In these difficult cases, the addition of cortisone has seemed to hasten the absorption of the inflammatory exudate in a manner which heretofore has not been seen. The dosage of cortisone should not exceed 1 gm. and the duration of treatment is almost four weeks. When cortisone is given under this plan, the patient receives 50 mg. a day for two weeks and 25 mg. a day for the next twelve days.

Sterility is primarily a mechanical problem secondary to tubal occlusion. Surgical procedures for the reconstruction of the occluded fallopian tube are still in the developmental phase and are not recommended except in unusual circumstances. Ovarian failure may further complicate the sterility problem if the function of the ovary has been impaired by the inflammation.

Dyspareunia is always difficult to evaluate.

pubically. A mass the size of a four and one-half months' pregnancy, however, would be very unusual in these conditions.

Shape can be helpful, but it also can lead one astray. Generally, the fibroid uterus is asymmetrical and nodular. But fibroids can produce a symmetrical enlargement. Cysts are usually symmetrical, but when multilocular they can be asymmetrical and even nodular. Shape, therefore, is of only relative, not specific, diagnostic significance.

Consistency is another characteristic of relative diagnostic significance. Fibroids usually are hard but, if edematous or undergoing cystic degeneration, they can feel semifluctuant. Cysts may be semifluctuant or hard and solid appearing. A pelvic abscess is not fluctuant until late. Usually the lower pole of an abscess is hard. Clotted blood in the cul-de-sac has a rather characteristic feeling. It is soft, cystic and may be semifluctuant. The margins are not well defined. Later, as the clot organizes, it becomes harder.

When a mass is fixed, it is the result of inflammation, cancer or endometriosis (I-C-E). If a mass is freely movable, it suggests pedunculation. Mobility and fixation are valuable in diagnosis when they can be clearly demonstrated. Pedunculated fibroids and many ovarian cysts are freely movable. Inflammatory masses are usually fixed. In retroversion, the uterus may be fixed or movable. If there is any doubt as to the nature of the condition, an attempt should be made to replace the uterus. The upward mobility of the normal anteverted uterus can be impaired by a previous inflammatory process. This is detected when the vaginal fingers attempt to elevate it in vaginoabdominal palpation.

Tenderness is of great diagnostic importance. However, extreme care must be exercised in attributing the tenderness to a mass. Many masses which appear to be tender may be so on account of tenderness in the abdominal wall or as a result of a functional nervous condition. Real tenderness means inflammation resulting from an irritation due to bacterial causes, endometriosis or as the result of a degenerative process.

INFECTIONS

The surgical significance of pelvic infection is much less since the advent of chemotherapy and antibiotics. At present, these agents prevent or control most gonorrheal or puerperal infections, while in the past at

least one-fourth of all gynecologic operations were for pelvic infections.

Acute Gonorrheal Infection. Oftentimes the lower genital tract phase of gonorrheal infection is relatively asymptomatic. Extension to the tubes occurs by way of the endometrium. The endometritis is usually transient and of no clinical significance. This is not so of salpingitis. At first there is purulent endosalpingitis, but it progresses rapidly to pansalpingitis and to pelvic peritonitis. The constitutional reaction is well marked with fever tending to be higher than in most intra-abdominal diseases. The temperature generally is above 101° F. and frequently much higher. Leukocytosis is also well marked, often there are more than 15,000 white blood cells per cu. mm. of blood. Elevation of the sedimentation rate occurs early in the disease. The lower abdominal pain is severe and there is marked tenderness over the internal genitalia. Distention occurs early. Nausea and vomiting occur but are overshadowed by the violence of the other symptoms.

Pelvic examination reveals exquisite tenderness on the slightest manipulation of the cervix. Tenderness in the region of the adnexa is often unbearable. Early in the disease there may be a "fullness" in the adnexal regions, but it is difficult to feel circumscribed masses until somewhat later.

It is necessary to differentiate salpingitis from the other common conditions responsible for lower abdominal pain. Acute appendicitis, by its very nature, requires immediate operation; salpingitis does not. Appendicitis is a gastrointestinal disease with nausea and vomiting as early symptoms. At first the pain is generalized. Later it localizes in the right lower quadrant. With salpingitis, the nausea and vomiting are not so prominent and the distribution of the tenderness is lower and generally bilateral. In salpingitis, the patients look sick and have a well-marked febrile reaction. In appendicitis, the fever is not so high and neither is the leukocyte count. But the leukocytosis in appendicitis is greater in proportion to the fever than it is in salpingitis. In typical appendicitis, the pelvic examination usually reveals little or no pelvic tenderness. Movement of the uterus is free and painless. In salpingitis, digital examination reveals acute bilateral adnexal tenderness. Upward pressure on the cervix reveals extreme tenderness.

Differentiation is not so easy in the pa-

Perhaps the most characteristic feature of these cases is their slow resolution. There is no dramatic abatement of fever and infection as occurs in gonorrheal infections. The improvement is apparent from week to week rather than from day to day. Treatment must be aggressive and persistent until all signs of activity have disappeared.

Tuberculosis. At present, genital tuberculosis has decreased in frequency to the extent that it has become one of the lesser problems in gynecology in this country.

The most common type of genital tuberculosis is the type encountered as an integral part of generalized tuberculous peritonitis. Tubercles are scattered over the surface of the genitalia, as well as the intestines, and may be associated with ascites and/or adhesions. This type of infection is not usually complicated by deep-seated genital foci and, consequently, is of little concern to the surgeon except in differential diagnosis.

Pelvic tuberculosis, exclusive of generalized peritonitis, is felt to be a local manifestation of a systemic disease. The primary focus in the lungs, bones, intestines or lymph nodes is thought to be the source of hematogenous spread to the pelvic organs. The fallopian tubes are involved in nearly every subject, while the endometrium is infected in about 70 per cent of the patients and the ovaries in from 30 to 40 per cent. The process usually starts in the tube where edema and tubercles develop and the tube may coalesce. The involvement of the endometrium and ovaries in a large percentage of subjects is due to extension from the tubal nidus. As the acute stage subsides, healed tubercles develop with subsequent adhesions and, frequently, masses. The lesions may break down and caseate, producing marked systemic reactions, and it is this stage which is most easily recognized.

The diagnosis of genital tuberculosis is particularly difficult because of the variability and indefiniteness of the symptoms. The onset of symptoms is usually vague and generally the symptoms are those of a chronic pelvic infection. Frequently constitutional symptoms, such as malaise, anorexia, fever and weight loss, are present. The local symptoms may suggest gonorrhea, ovarian tumor or appendicitis, the resemblance varies with the stage of the disease. In the absence of a history of an acute pelvic infection, menstrual disturbances and sterility associated with pelvic pain and masses are strong argu-

ments in favor of the diagnosis of tuberculosis. The diagnosis of pelvic tuberculosis is frequently made by endometrial biopsy carried out during a routine sterility work-up. If the diagnosis is suspected, it may be confirmed by the use of Halbrecht's method of culturing menstrual blood.

It is obvious that frequently genital tuberculosis is not diagnosed correctly preoperatively. Often it is not diagnosed until the tubes are examined microscopically. Diagnostic observations which may help correct this deficiency are a history of chronic illness; palpation of masses in the pelvis; a low degree of fever, a low white blood cell count, no benefit from antibiotics other than streptomycin; improvement with streptomycin, especially when combined with PAS; positive endometrial biopsy; positive smears; positive cultures of menstrual blood; peritoneoscopy; hysterosalpinography.

There remains considerable difference of opinion in regard to the accepted treatment of pelvic tuberculosis. The advent of the new antituberculous drugs, streptomycin, para-aminosalicylic acid and isonicotinic acid hydrazine, has, of course, modified the treatment of the disease and has made more cases amenable to surgery. It also has permitted the use of conservative surgery in selected patients and has led some observers to believe that medical treatment alone frequently is satisfactory. The variability of the type and extent of the lesions makes it difficult to prescribe a standard operative procedure. It is felt, however, by a majority of gynecologists that the only successful definitive therapy in patients with serious cases is bilateral salpingo-oophorectomy and hysterectomy. When this procedure is not contraindicated, there is a better chance for cure. Optimal conditions for surgery are usually obtained by giving a course of streptomycin and PAS preoperatively and this medical treatment must be continued in the postoperative period for successful termination of the case. It is well to emphasize that drainage is contraindicated in these patients, as this predisposes to fistula formation.

The final evaluation of various forms of surgery and medical treatment, or combinations of these forms of therapy, must await the test of time.

OVARIAN TUMORS

The code word for pelvic masses is PREMIEO; the O designates ovarian masses.

No other organ in the body develops such

Tender, adherent adnexal masses or an adherent retroversion may produce this disturbing symptom. Surgical intervention may be necessary—the type and extent of the procedure vary with the needs of the patient. In general, the patients having the older or more severe cases will usually require hysterectomy.

Pelvic pain is a natural consequence of the lesions producing dyspareunia. Its evaluation proceeds along the lines discussed under pelvic pain. Surgery may be necessary in some subjects.

Menstrual disorders are frequent in these patients. Disturbed circulation or parenchymal ovarian damage produces the all-too-familiar picture of ovarian failure. In many of the subjects, chemical control may be attained by cyclic replacement of the deficient hormones. Eventually, some of these patients will require surgery.

Pelvic masses, in addition to causing pain and dyspareunia, present a problem in differential diagnosis. If the differential diagnosis is uncertain, exploration may be necessary.

Nowhere can the principles of the functional approach be better employed than in the treatment of the complications of chronic pelvic inflammation. Experience has demonstrated the danger of conserving a functionless uterus when surgery is necessary. Yet in some cases this danger must be accepted as a calculated risk. While most generally advisable, the removal of the functionless uterus is not an invariable rule.

Puerperal and Postabortal Infections. By definition, puerperal and postabortal infections mean infection following delivery or abortion. Women who have gonorrhea can have a flare-up of this infection after labor or abortion. The pathologic state and the treatment are the same as for gonorrheal infection in the nonpuerperal state.

However, infection, when it occurs, is usually with one or more organisms. Aerobic streptococci are present in 40 per cent of the subjects, *Staphylococcus pyogenes* var. *albus* in 25 per cent and hemolytic streptococci in 5 per cent.

Following labor or abortion, there is an open wound of the uterus at the placental site. In addition, there may be lacerations of the cervix, vaginal tract or perineum. The lochia provides a good culture medium and bacterial contamination almost invariably takes place. However, the usual organisms are not very pathogenic and the body de-

fenses are adequate in all but the exceptional patients. In these, the defense mechanism is overcome. The bacteria then gain access to the uterine wall, rich in lymphatics and blood vessels. As a result, the infection spreads rapidly to the extraperitoneal tissue between the leaves of the broad ligament. This extraperitoneal cellulitis is the characteristic lesion of puerperal pelvic infections.

The diagnosis is usually not difficult. The patient always gives a history of recent delivery or abortion. The systemic reaction is usually marked with temperature elevation. There is generalized lower abdominal tenderness. Examination reveals a typical brawny induration of the pelvis.

Treatment consists of antibiotics, usually penicillin or one of the broad-spectrum antibiotics, oxytocics to insure contraction of the uterus and minimize bleeding, bed rest, fluid replacement and active search for complications.

Complications are frequent and consist of abscess formation, thrombophlebitis and peritonitis. The presence of one or more of these complications produces changes in the disease picture with the typical findings of these syndromes superimposed on the previously described symptoms and signs.

Abscess formation in the extraperitoneal spaces is not unusual but is often difficult to detect. Frequently these abscesses present in the inguinal region. The persistence of a septic course after adequate treatment and the appearance of fluctuant masses in the pelvis or abdomen calls for further treatment. When present, these abscesses must be drained. This is usually accomplished best through the cul-de-sac or through a lower abdominal extraperitoneal approach.

Septic thrombophlebitis is a common sequelae of pelvic cellulitis and must be regarded with alarm. Most cases resolve following antibiotic therapy, but when septic emboli occur they may be fatal. Collins and others advocate ligation of the vena cava in these subjects and, in an occasional patient, this procedure may be lifesaving.

Peritonitis may occur from perforation of the uterus, reflux through the tubes or by direct extension of the infection. When it occurs, it produces paralytic ileus with abdominal distention and nausea and vomiting. The usual measures of intestinal intubation and decompression with fluid replacement and antibiotics will usually suffice. Here again, abscesses may form and must be drained when present.

both physical and mental, is implicated. It is our belief that the function of one ovary is never as good as the function of two ovaries. The remaining ovary may not permanently compensate for the loss of the other ovary, as, for instance, one kidney may do after surgical removal of the other kidney. As previously mentioned, the basis of the functional approach to pelvic surgery is the conservation of useful function in terms of life, health and the pelvic functions. This concept applies most aptly to ovarian surgery.

When an exploratory laparotomy is performed for a pelvic mass, even if one is certain that an ovarian tumor exists, the exact nature of the tumor cannot be determined until the mass is visualized. Frozen sections, as a rule, are of little benefit. Because of this, microscopic diagnosis usually must be delayed until permanent sections are available. It is by a knowledge of the clinical and gross characteristics of ovarian tumors that the pelvic surgeon must make a tentative diagnosis. This diagnosis is applied to the patient in terms of function and the best solution possible for the patient is then offered. An example of two different individuals with the same type of tumor may best demonstrate this approach.

A twenty-three-year-old female, gravida 0, had been married six months. This woman had been having menstrual irregularities since her marriage. The flow was excessive in amount and occurred at eight- to thirty-one-day intervals. She was examined because of this irregularity and a 9 cm. mass was found. At operation, the mass was found to be a papillary serous cystadenoma of the left ovary. The right ovary, tubes and uterus appeared normal. Although a clinical characteristic of these tumors is bilateral occurrence with certain malignant potentialities, it was felt that the functional needs of the patient outweighed the risks, and only a left oophorectomy was performed.

A forty-three-year-old female, gravida III, saw her physician for the same complaint of irregular menstruation of the same type as that of the previous patient. A 9 cm. mass was felt in the left adnexa and at laparotomy a papillary serous cystadenoma with only internal papillary growths was found. Taking into consideration the age of the patient, the tendency to a bilateral occurrence, the malignant potential inherent in the tumor and the functional needs of the patient,

total hysterectomy and bilateral salpingo-oophorectomy were performed.

In the first patient, a young woman, the pelvic duties of childbearing, ovarian function, menstruation and sexual function were at stake. With close observation and cyclic therapy, it was not felt that the risk of recurrence, malignant potential and the present menstrual irregularities outweighed the positive value of preserving the childbearing, menstrual, sex and ovarian functions.

In the second patient, the childbearing function had been fulfilled, menstruation was becoming a nuisance and the irregularities were apparently due to diminishing ovarian function. In this woman, it was felt that the risks involved were not counterbalanced by the value of retaining the reproductive and menstrual function.

Our classification of ovarian tumors is very simple and is one which fits into the functional approach to pelvic surgery. It is a clinical classification based on the malignant characteristics of the various ovarian tumors. This malignant potential often is the determining factor in the functional approach.

The tumors are divided into three groups:

- I. Ovarian tumors without malignant potential.
 - A Nonproliferative tumors—follicular cyst, corpus luteum cyst, germinal inclusion cyst
 - B Endometrial cyst
 - C Brenner tumor
- II Ovarian tumors with malignant potential
 - A. Cystadenoma, serous, pseudomucinous
 - B. Dysgerminoma
 - C. Arrhenoblastoma
 - D. Granulosa cell tumor
 - E. Theca cell tumor
 - F. Fibroma
 - G. Dermoid cyst
- III Malignant ovarian tumors
 - A Carcinoma—primary solid carcinoma and cystic carcinoma
 - B Teratoma
 - C Sarcoma
 - D Metastatic carcinoma

In order that these tumor masses can be classified at the operating table, a working knowledge of the pathologic characteristics of the ovarian tumors is essential.

The symptoms of ovarian neoplasms are variable and depend on several factors, such as the type of tumor, its size and location. Frequently, slow growing, benign tumors can become rather large neoplasms without producing any symptoms and occasionally are found on routine physical examination. Symptoms may occur earlier in intraliga-

a variety of neoplastic growths as does the ovary. To understand the nature and significance of these new growths, one must look to the embryonal development of the ovary.

Beginning with an accumulation of cells on the anterior aspect of the wolffian body, the ovary passes through several stages of development before assuming the characteristics of the female sex gland. It is important to understand that it is impossible at one stage of development to determine by histologic examination what the sex of the cell mass is going to be. This phase is spoken of by embryologists as the undifferentiated period of development. Of equal importance are the changes which occur during the stages of differentiation. At one particular stage, the primitive ovary shows many of the characteristics of the male testicle. These changes are only transient and are followed by changes showing the characteristics of the ovary. Several investigators have spoken of the development of the female gonad as bisexual in nature and consider the female ovary as an organ more advanced in development than the male gonad. These multiple developmental changes are the basis for the wide range of tumors that may occur in the ovary. In addition, it is of importance that the mature ovary contains a variety of different types of cells which add to the complexity of tumor formation.

The classification of ovarian tumors has been a subject of much controversy since Waldeyer, in 1870, presented a classification based upon the histogenesis of the tumors. Many additional classifications of ovarian tumors have been presented in the literature by many authors. It is now realized that very little is known concerning the histogenesis of many of the ovarian neoplasms. The fallacy of the classifications is that the basis of knowledge is unstable.

Undoubtedly, a universally acceptable classification is most important for clinical comparison and statistical reporting. One of the more applicable classifications of ovarian tumors is that presented by Kottmeier of the Radiumhemmet in Stockholm, Sweden. This classification is presented as an excellent histologic classification of ovarian tumors with clinical significance.

- A Non-neoplastic tumors, follicle cyst, corpus luteum and regression cyst
- B Endometriosis and endometriotic cyst
- C Primary neoplastic tumors
 1. Neoplasms with endocrine significance

- a Feminizing ovarian tumors, granulosa cell tumor, theca cell tumor
- b Virilizing ovarian tumors, arrhenoblastoma, adrenal rest tumor, Leydig cell tumor
- c Ovarian tumor with inverse endocrine symptoms, folliculoma, lipiodique
- d Gynandrioblastoma

II Neoplasms with no endocrine significance

- a Germ cell tumor, dysgerminoma-embryoma ovarian tumors (sometimes producing gonadotropic hormone), dysgerminoma, mesonephroma (Schiller), chorionepithelioma

b Ovarian tumors.

1. Benign tumors, dermoid cyst, struma ovarii
2. Malignant tumors, teratoblastoma, malignant degeneration of a dermoid cyst

c Stromatogenous tumors

- 1 Benign tumors, fibroma, myoma, angioma
- 2 Malignant tumors, sarcoma

d Epithelial tumors

- 1 Benign tumors, papillary tumors with no signs of marked proliferation, serous and pseudomucinous cystadenoma with no histologic sign of marked irregular proliferation of the epithelium, Brenner tumor
- 2 Tumors with questionable malignancy, also called semimalignant epithelial tumors, papillary tumors and cystadenoma with epithelial changes identical to those seen in invasive carcinoma, no proved invasion in the stroma, pseudomyxoma peritonei
- 3 Malignant tumors, carcinoma proved invasion in the stroma. The carcinoma can be divided into
 - (a) Primary ovarian carcinoma
 - (b) Ovarian carcinoma developing from serous or pseudomucinous cystadenoma
 - (c) Cancer uteri et ovarii

D Metastatic neoplastic tumors

Although a good universal laboratory classification of ovarian neoplasm is desirable, a good clinical classification usable in relation to the functional approach is essential.

Because of the close interrelationship of all the female genital organs, no one organ can be removed without having a definite effect upon the other organs and their functions. The ovary is the main site of estrogen and progesterone production, as well as the only site for the production of ova. Thus, in terms of pelvic function, reproduction and ovarian, menstrual and sexual functions are involved when ovarian surgery is undertaken. In addition to this, the general health,

the cyst, the more frequently the lining cells are flattened.

Many of these cysts are found accidentally on routine pelvic examination. Abnormal uterine bleeding resulting from ovarian dysfunction may be present in association with these cysts. Pain or lower abdominal discomfort may at times become a prominent feature.

A corpus luteum cyst is another non-neoplastic cyst of the ovary which is a physiologic exaggeration of a normal structure. Instead of the corpus luteum undergoing its normal course of regression, the cavity becomes distended with an amber fluid. Frequently the cystic enlargement is a result of excessive hemorrhage during the normal course of development. Occasionally the fluid is chocolate in appearance which points up the fact that all cysts with a thick chocolate material are not due to endometriosis.

The corpus luteum cyst is singular and rarely gets larger than 4 to 5 cm. in size. It is characteristically lined by a thinned-out layer of lutein cells. This type of cyst may produce hormones similar to the corpus luteum and therefore may be associated with amenorrhea or oligomenorrhea or it may disrupt the hormonal balance and produce irregular uterine bleeding.

ENDOMETRIAL CAST (ENDOMETRIOSIS)

Endometriosis is the growth of endometrial glands and stroma in an abnormal location. This condition divides itself into two categories: internal endometriosis, or adenomyosis of the uterus, and external endometriosis, in which the ectopic endometrium is outside the limits of the uterus. The frequency and presence of endometriosis have seemingly increased in the past ten to fifteen years. The majority believe that increased incidence represents an increased knowledge of the disease as well as an increased ability and effort to recognize endometrial implants at the time of operation. For these reasons it is assumed that the increase in frequency of endometriosis is not real. Some surgeons have reported that 32 per cent of all abdominal gynecologic operations revealed endometriosis. The most common location of the implants of endometriosis are the ovaries (this may be bilateral), uterosacral ligaments, the cul-de-sac, broad ligament and the pelvic peritoneum.

It is generally accepted that internal endometriosis is due to a downgrowth of the

endometrium in the uterine musculature. The etiologic basis of external endometriosis was brought to medical attention in 1921 by Sampson's theory of tubal reflux. Sampson suggested that endometrium cast off in menstruation may regurgitate through the tube, adhere and grow on the ovaries, in the pelvis or in adjacent tissues. Meyer believes that endometriosis is due to a growth stimulus acting on cells derived from the coelomic epithelium. The endometrium and endosalpinx both represent a modified and differentiated coelomic epithelium. On the other hand, the genital epithelium of the ovary represents the original coelomic epithelium. It is Meyer's theory that in ovarian endometriosis the genital epithelium of the ovary can differentiate cells which are capable of forming endometrial-like tissue. The same possibility exists wherever coelomic epithelium or its vestiges occur, including the pelvic peritoneal surfaces, the umbilicus and hernial sacs. Lastly, there is Halban's theory which states that the aberrant endometrium has its source in endometrial particles transported by the lymphatics to various locations of the pelvis. This theory can account for many of the lesions found in the lymph nodes of the pelvis, but it is doubtful if it can explain all of the various sites of endometriosis in the body. The presence of endometrial-like tissue in lymph nodes has received much attention recently in connection with the study of the spread of adenocarcinoma of the corpus uteri. The tendency in the last few years has been toward acceptance of a combination of the Sampson and Meyer theory. The consensus, however, still favors Sampson's theory for the explanation of pelvic endometriosis. On the other hand, many use the coelomic metaplasia theory to account for lesions not explainable by the regurgitation theory.

Endometriosis is a disease originating only during menstrual life. Usually it appears in women between the ages of thirty and fifty years. Sterility is one of the common symptoms associated with endometriosis, 30 to 40 per cent of the patients with endometriosis never become pregnant. Associated pathologic lesions are very frequent; these include myoma, endometrial hyperplasia and ovarian failure. Internal endometriosis, or adenomyosis, is found most frequently in women in their early forties and is not as commonly associated with sterility as is external endometriosis. Pain is the most common symptom of endometriosis, but there are some

mentary tumors, some malignant tumors or as a result of hemorrhage or torsion

Pain or discomfort is one of the earlier symptoms of ovarian neoplasm. Usually the pain is dull or "nagging" in nature, involving the lower abdomen and perhaps one side in particular. The pain may radiate down the thighs. Backache over the sacrum may be present, particularly if the cul-de-sac is involved. Unilateral backache just lateral to the sacrum, if present, is a good indication of the side of origin.

The effect of ovarian neoplasm on adjacent organs is again dependent on the characteristics of the neoplasms. Frequency, urgency and even urinary retention may be the result of pressure by the tumor growth on the bladder.

Often noted are the presence of vague gastrointestinal symptoms in relation to the ovarian tumors. Constipation, abdominal discomfort due to pressure and nausea and vomiting may all be present.

The more acute symptoms of ovarian tumors are due to the complications of the tumors. Torsion, rupture, necrosis, hemorrhage, infection and gangrene are the more frequent complications. The symptoms due to these complications may be short or long in duration. Fever is usually present. Pain is a dominant feature. In gangrene, the patient is extremely toxic and the picture may resemble that of a severe intraperitoneal accident. In spontaneous rupture or hemorrhage, a shocklike picture may be seen. The treatment of patients in whom complications occur is surgical.

There are several features which may aid in the clinical and macroscopic diagnosis of ovarian neoplasms.

Clinical signs and symptoms of the patient must be considered. These findings may include uterine bleeding, pain, ascites, abdominal enlargement, evidence of hormonal changes and changes in sexual characteristics.

The gross appearance of the tumor, such as color, size, degree of firmness and the presence or absence of a capsule, is of much importance.

The location of the tumor or tumors is of significance. Whether the tumor is unilateral or bilateral is of importance when one considers either the clinical diagnosis or proper operative therapy. Other conditions in relation to the location of the tumor, such as the involvement of adjacent structures, presence or absence of peritoneal implants, or in-

volvement of the mesenteric nodes, are of extreme importance.

The next aid in diagnosis is the gross section of the tumor. This involves such characteristics as whether the tumor is cystic or solid. If cystic, the characteristics of the fluid may be helpful. If solid, the color and consistency are of value in the diagnosis. Occasionally, the presence of necrosis, hemorrhage or cystic degeneration may add to the above findings.

The age of the patient is of great significance, as certain tumors have a definite age preference which may be useful in diagnosis.

NONPROLIFERATIVE TUMORS

This group of tumors includes the persistent follicle cyst, corpus luteum cyst and the theca-lutein cyst. They are classified as nonproliferative because there is no actual growth or proliferation of the cellular elements. The cysts may be said to represent nothing more than an abnormal physiologic accumulation of fluid within the ovary.

It is a normal phenomenon that only a few of the many primordial follicles develop to the stage of producing a mature ovum. The remaining follicles degenerate, their fluid is absorbed and is replaced by scar and, in time, by the normal ovarian stroma. Atresia of a larger follicle is usually attended by the formation of a small cyst. This persistent follicle cyst is rarely solitary and seldom of more than 1 to 2 cm. in diameter. Generally the persistent follicles are asymptomatic unless the accumulation of fluid is excessive or the production of these small cysts is markedly increased. The enlargement of the cyst is not due to a cellular growth, but to an increased accumulation of fluid. These cysts are usually classified as multiple follicle cysts and the ovaries which contain them are known as polycystic ovaries. Not infrequently one of these multiple small follicle cysts accumulates more fluid than the other follicles. In size, it may reach a diameter of 8 cm. The main cavity of the cyst is unilocular, but there are other small follicle cysts in the walls or adjacent to the main cyst. These cysts are thin walled and usually translucent in appearance. The surface is smooth, both internally and externally. The fluid within the cyst is usually light amber in color.

The microscopic appearance depends somewhat on the size of the cyst. The smaller the cyst, the greater is the resemblance to the ovarian follicle. The larger

been associated clinically with postmenopausal
dence
it for

signs of
the Brenner tumor.

Grossly, the appearance of the Brenner tumor is similar to that of fibromas; the mass is firm, smooth and varies in size from one which can be seen only through the microscope to a relatively large growth. Most of the tumors are small, averaging about 3 to 5 cm. in diameter. It is of interest that approximately 20 to 30 per cent are found in association with a pseudomucinous cystadenoma.

The cut surface of the Brenner tumor shows a characteristic uniform yellow tint. Necrosis, hemorrhage and cystic degeneration are rarely seen. The tumor does not have a definite capsule but has a pseudo capsule of compressed ovarian stroma.

The microscopic picture is characteristic, there are epithelial cell nests or columns in fibrous tissue matrix. The cell nests often show an area of central cystic degeneration which looks a little like an ovum in a follicle.

The Brenner tumor is generally regarded as a benign neoplasm, but an occasional malignant one has been reported.

CYSTADENOMAS

The cystadenomas are the largest group of proliferative tumors of the ovary. Approximately 75 to 80 per cent of all ovarian neoplasms are cystadenomas. The ratio of incidence of the cystic to the solid ovarian tumor is approximately 3:1.

There are two types of cystadenomas—the pseudomucinous and the serous. These tumors get their names from the character of the fluid in the cysts.

The pseudomucinous cystadenoma is so named because of the mucin-like contents of the cyst. Although the fluid appears and feels like mucin, it is not a proteid and does not give the characteristic reaction with acetic acid. These tumors may vary in size from the microscopic lesion to the most enormous of all tumors. Medical literature reports tumors of this type weighing as much as 300 to 350 pounds. Even today, fifty- and sixty-pound tumors are seen in patients from rural areas.

The pseudomucinous cystadenomas are more common in the forty- to fifty-year age group. The majority of the cysts are uni-

lateral in nature; less than 10 per cent are bilateral.

Grossly, the capsule is thickened and whitish blue in color. Areas of firmness can be felt scattered about the tumor surface. Brenner tumors and dermoid cysts may be found occasionally within the wall of the cyst.

On cutting of the tumor, the mucoid content is characteristic. The material is a thick, jelly-like substance with clear or greenish color. If internal hemorrhage has occurred, a brownish color is seen. The cysts are always multilocular. Generally, several locules have become one large cavity because of interlocular pressure. Papillary growths within the cyst cavity occur in only 5 to 10 per cent of these lesions. External papillary growths are relatively rare. These tumors rarely become malignant.

Microscopically, the lining of the cyst is seen to be composed of a single layer of tall, columnar epithelium—the picket-fence epithelium—resembling that of the endocervix.

The treatment, of course, is surgical. The extent and nature of the operation depend on the associated pathologic conditions and the functional needs of the individual. Since the malignant tendency of the tumor is low, conservatism is possible if it is necessary to preserve the reproductive function. In older patients, hysterectomy and salpingo-oophorectomy may be the operation of choice.

The tumor that Ephraim McDowell removed from Mrs. Jane Todd Crawford was of the pseudomucinous type. This operation marked the beginning of surgery of the abdomen. Fortunately for Mrs. Crawford, McDowell and surgical history, pseudomucinous tumors are usually not adherent and are well pedunculated.

The serous cystadenoma occurs as frequently as does the pseudomucinous cystadenoma. Serous cysts differ from pseudomucinous cysts in these ways: they rarely grow to a size larger than a man's head, more often than not, they are bilateral; if a pedicle is present it is short, adhesions to surrounding structures are common, papillary growths, either internal or external, are frequent and the tendency to malignancy is great.

On incising the cyst, the serous, amber fluid is noted. When hemorrhage has occurred within the cyst, a more chocolate-colored fluid is seen. Internal papillary growths vary; some occur in scattered areas,

subjects who have not had the slightest discomfort. The lesions vary in location, therefore, the pain arising from them varies in location and nature. The pain is either unilateral or bilateral, usually it is bilateral but more marked on one side than on the other. Characteristically, it is exaggerated premenstrually or menstrually and a residual soreness follows the period. In some instances, acute attacks of pain are entirely unrelated to menstruation. The pelvic distress may vary from a moderate bearing-down discomfort to a severe, sharp, knife-like attack. The invasion of the uterine musculature by endometrial tissue may be manifested by a visceral type of pain resembling dysmenorrhea or some change in the character of dysmenorrhea. Dysmenorrhea is a common symptom of both internal and external endometriosis. Frequently the dysmenorrhea is an acquired or secondary type. However, there is nothing specifically characteristic about the dysmenorrhea associated with endometriosis. The duration of pain, particularly in the more extensive cases, is usually longer than the one-day cramps of primary dysmenorrhea. Menstrual irregularities are found in approximately one-third of the subjects. These may be either a decrease in the interval or an increase in the amount. The usual explanation for the menstrual disturbance is that it is secondary to ovarian failure resulting from the endometriosis. Other symptoms such as dyspareunia, backache and pain in the rectum or bladder may present. While all of the symptoms should suggest endometriosis, any or most may be present in association with other pelvic conditions. The physical findings may also vary in accordance to the extent and the nature of the disease. One or both adnexa may be fixed and adherent to the uterus. Frequently the uterus is in an adherent, retroflexed position and may contain one or more myomas. Myomas occur in more than half, and nonproliferating cysts in more than a third, of the women who have endometriosis.

The most characteristic physical finding is a "shotty" induration in the cul-de-sac and along the uterosacral ligaments. Usually there is, in addition, a lack of mobility of the uterus, enlarged and fixed adnexa and retroversion. Induration in the cul-de-sac and uterosacral ligaments is best detected by palpating the posterior vaginal fornix with the second finger while elevating the uterus with the first finger. Rectal palpation adds valuable information, especially concerning the uterosacral ligaments. The induration

feels like several buckshots imbedded in the area. At times, the lesion is so extensive that it invades the mucosa of the posterior fornix, producing scarring and small blue-black cysts.

Fortunately for the patient, endometriosis progresses slowly and rarely becomes malignant. Hence, in women in whom the diagnosis is clear, surgical treatment should be postponed until the severity of the symptoms forces operation. For reasons which are not clear, pregnancy seems to be the best treatment.

Large doses of testosterone produce pituitary depression with a decrease in estrin production and improvement of the symptoms. Even small doses of androgens given for seven days before the onset of the menstrual period may produce a worthwhile diminution in symptoms. Large doses of stilbestrol are also advocated. The drug is given over a period of several months in a gradually increasing fashion. More recently progesterone and progesterone-like substances have been used. Amenorrhea is produced over a period of three to four months with clinical improvement noted in many of the cases. Its mechanism of action is probably the same as that of pregnancy. Irradiation will suppress estrogenic secretion and the lesions will regress. This form of treatment has the same disadvantages as does castration radiation for ovarian failure. We rarely use it.

In patients with disabling symptoms resistant to treatment, operation is necessary. No other pelvic condition tests our faith in the functional approach as does endometriosis. The problems are difficult. In the patients in whom childbearing is not a factor, hysterectomy may be the operation of choice. When childbearing is a factor, conservative operations are in order. These combined with presacral neurectomy will often produce a satisfactory result. It is interesting that most of the pain in endometriosis is relieved by removing the uterus. This can allow the conservative treatment of involved ovaries if the preservation of ovarian function is considered necessary.

BRENNER TUMOR

Brenner tumors usually occur in the postmenopausal period. They produce no symptoms except for those arising from pressure. The majority of the neoplasms are discovered accidentally at routine physical examination or at operation for other causes. A few of the reported Brenner tumors have

gland can reproduce all of the signs and symptoms characteristic of a masculinizing tumor of the ovary. The Stein-Leventhal syndrome must be considered in patients in whom hirsutism and amenorrhea are the dominant features. Special laboratory procedures which include a glucose tolerance test, x-ray study of the bones and determination of 17-ketosteroids and 11-oysteroids are helpful in arriving at the diagnosis. The response of the steroid to intravenous administration of ACTH is helpful in differentiating adrenal conditions. These procedures must be combined with a good physical examination. Examination with the patient under anesthesia and the use of the cullescope aid in clarifying the diagnosis.

Grossly, the tumor may vary from a very small size to a growth of 10 to 20 cm. in diameter. The small tumors are usually solid. As the tumor grows, cystic degeneration is common. The color varies from a grayish to a bluish or purplish hue. On cut section, the tumor shows a definite lobulation not commonly observed in other ovarian tumors.

The histologic diagnosis frequently is made with ease because of the tumor's close resemblance to the male gonad. On the other hand, the diagnosis may be difficult because of the marked anaplastic nature of the cells. A cordlike arrangement of cells is helpful. The differentiation between arrhenoblastoma and sarcoma of the ovary may be extremely difficult.

Arrhenoblastomas should be considered as malignant. The true evaluation of the degree of malignancy has been confused because of the small number of reported cases and the early reporting of cases. Some of the tumors are highly malignant. In some patients, recurrence and death have occurred as late as ten to twelve years after surgical removal of the tumor.

The prognosis and therapy depend on the findings at the time of operation. If the tumor is well encapsulated and can be removed without rupture, the prognosis is good. If rupture of the capsule has occurred and metastatic spread is present, the prognosis is grave. The details of the treatment are similar in all respects to those of carcinoma of the ovary.

GRANULOSA CELL TUMOR

This is a functioning ovarian neoplasm, the origin of which is controversial. Robert Meyer suggested that the tumor arises from persistent granulosa cell rests remaining

from the early development of the primordial follicles. His concept was widely accepted until recently. There is now suggestive evidence that the tumor develops from cells of the early undifferentiated mesenchyme.

The tumor is most frequently reported in the prepuberty female child or the postmenopausal woman. Actually, the majority of the neoplasms occur during the period of reproductivity. Only 5 to 10 per cent occur in children before puberty, 30 to 35 per cent of the tumors are seen in postmenopausal women.

The symptoms are due to increased secretion of estrogen. In the young child, the signs of precocious puberty are present. Menstruation may occur. The development of secondary sexual characteristics is seen. These are enlargement of the breast, the growth of pubic and axillary hair and puberal changes of the vulva. In the postmenopausal woman, the signs are again due to the stimulating effect of estrogen. Uterine bleeding is the one important sign. The return of secondary sexual characteristics does not occur. When the tumor develops in the mature menstruating female, menstrual irregularity is noticeable. Periods of amenorrhea lasting two months to two years are seen. This is usually followed by a menometrorrhagic type of uterine bleeding. Enlargement and softening of the uterus are felt. There is a sense of fullness in the breasts.

Grossly, the tumor may vary in size from a few millimeters to an extremely large growth. A tumor of moderate size is the usual finding. The neoplasm is firm and encapsulated. The outer surface is smooth and lobulated. On section, a yellow color is characteristic. Cystic degeneration is a common finding.

Microscopically, the tumor is divided in three types—follicular, cylindrical and sarcomatous. The tumor type is dependent on the distribution of the granulosa cells. The follicular type is the most common variety. The cells are arranged in small clusters, or rosettes, about clear spaces which often contain vacuoles similar to the Call-Exner bodies. Connective tissue gives the tumor a trabeculated appearance. Cellular areas are divided into lobules of varying sizes.

In the cylindrical type, the cells are arranged in columns. The connective tissue is more predominant and often vascular. The rosette-like arrangement of cells is lost.

others will fill the entire cyst cavity. Malignant changes are most often seen in large, friable, necrotic, cauliflower-like papillary growths.

Microscopically, the epithelium is variable in appearance. The lining cells may resemble tubal epithelium, both ciliated and non-ciliated, or simply consist of one or two layers of small, round, vesicular cells.

The treatment is always surgical. These are dangerous tumors and should be treated by hysterectomy and bilateral salpingo-oophorectomy in women of the older age group. In the younger woman, some consideration must be accorded to the functional needs. This must be balanced against the risk of retaining the opposite ovary. This is not too great if the tumor is not of the papillary variety. It is greater when there are internal papillae and very great when there are external papillae. The surgeon must examine the ovary to be retained with the greatest care.

DYSGERMINOMA

In most large gynecologic clinics, one to two dysgerminomas will be seen each year. Approximately 450 of these tumors have been reported in the literature. The age distribution of the tumor varies, the ages of the patients may be from two to seventy-six years. More than 76 per cent of the lesions occur in patients between eleven and thirty years of age. The average age for the appearance of dysgerminoma is around twenty to twenty-one years.

There are no endocrine symptoms. This has led to the belief that the tumor originates from embryonal cells presenting from the undifferentiated stage of gonadal development. This tumor resembles the seminoma in the male. Underdeveloped genitalia and breasts are frequently associated. The lesion has been reported to occur frequently in the pseudohermaphrodite. This, again, is suggestive as to the etiologic basis of the tumor.

Dysgerminomas grow rapidly. They are bilateral in approximately 15 per cent of the subjects. In size, the tumor may vary from microscopic to one that is large enough to fill the entire abdomen. Under the microscope, the tumor varies in appearance, depending on the degree of cellularity. The cells are large and clear with centrally placed deep-staining nuclei. This tumor is spoken of as a large cell carcinoma. There is always a varying degree of fibrinous tissue with lymphocytic infiltration. The fibrinous

areas surround clusters of large, clear cells which give the growth a characteristic appearance. In the more cellular tumors, characteristic fibrinous appearance is seen only in the edges of the lesion.

The prognosis of the dysgerminoma depends entirely on the findings at operation. All dysgerminomas are potentially malignant. In freely movable encapsulated tumors with no perforation of the capsule, the prognosis is favorable in approximately 90 per cent of the subjects. In bilateral tumors or tumors in which there is evidence of perforation or rupture the prognosis is poor.

Treatment depends upon the operative findings and the functional needs of the patient. Since most of these tumors are seen in younger individuals, the functional needs are most important in selecting the type of therapy. If the tumor is encapsulated and movable, unilateral oophorectomy is the treatment of choice in the young individual in whom the childbearing function is of significance. Postoperative radiation in small doses is advisable. This is directed at a 10-degree angle laterally to minimize the amount of radiation to the opposite ovary. The upper abdominal quadrants also receive small doses of x-ray therapy as they are a frequent area of metastasis. On the other hand, if the tumor shows evidence of capsular perforation or metastasis spread, the therapy should be the same as for ovarian carcinoma. Great benefit can be obtained with carefully directed deep x-ray therapy. The tumors are exceedingly sensitive to x-ray

ARRHENOBLASTOMA

The arrhenoblastoma is a relatively rare ovarian tumor. This neoplastic growth has received much attention because of the dramatic changes which it produces in the secondary sexual characteristics—defeminization and masculinization—of the patients.

The tumor is most frequently seen in the young, very rarely in postmenopausal individuals. The majority occur in women in the twenty- to thirty-year age group.

Amenorrhea and a loss of fat are the first noticeable signs, the breasts become flattened, the stature slowly acquires the male characteristics; the hair distribution becomes that of the male, a beard becomes prominent and shaving is frequently required; enlargement of the clitoris takes place and voice changes occur.

The differential diagnosis is difficult. These patients usually require very careful investigation. Disturbance of the adrenal

Calcification may be noted on cutting, imparting a gritty feeling to the knife.

Two per cent of these lesions become malignant. Soft areas are uncommon in fibromas; when they are found, sarcomatous changes must be suspected.

The therapy is always surgical. Fibromas and metastatic ovarian carcinomas sometimes appear quite similar grossly, therefore, in all patients having fibromas, especially if these are bilateral, the abdomen should be explored with care.

DERMOID CYST

Dermoid cysts account for 10 to 15 per cent of all ovarian neoplasms. Much controversy exists concerning the origin of these cysts. There are two theories: (1) they arise from the imperfect development of blastomeres, (2) their source is an abnormal development of an unfertilized ovum. Of late the misplaced-blastomere theory has gained much support.

At the operating table, dermoid cysts are readily recognizable. They rarely grow larger than 12 to 15 cm. in diameter, the capsule is thick and whitish blue in color, on palpation, firm, hardened areas can be felt in the capsule. Frequently the tumors are pedunculated and nonadherent to the surrounding structures. It is important to remember that in approximately one-quarter of the patients the tumor will be bilateral. The bilateral cysts are not necessarily of the same size. It is a good rule never to fail to examine the opposite ovary for a second dermoid cyst. In doing this, all cystic structures should be punctured. When found, the small dermoid cysts are easily shelled out with preservation of normal ovarian tissue.

On incision of the capsule, a yellow, thick, sebaceous material is found, coiled throughout the cavity are large masses of hair, teeth and bony structures may be present.

Microscopically, ectodermal elements are the predominant tissues. Stratified squamous epithelium, hair follicles, and sebaceous glands may all be present; other structures such as cartilage and stratified ciliated columnar epithelium can be found by a careful search.

The tendency of dermoids to become malignant is low. Less than 2 per cent of the tumors reveal malignant characteristics. While the dermoid is a teratoma, it differs from the malignant solid teratoma in that it is cystic, usually benign and shows microscopic predominance of ectodermal elements.

The treatment of dermoid cysts of the ovary depends on the age and the functional needs of the patient. In the younger patients, every effort should be made to preserve normal ovarian tissue. Cystic masses 5 to 7 cm. in diameter can frequently be shelled out, leaving functioning ovarian tissue. This is most important in the young. A tumor in the opposite ovary must not be overlooked. In the older individuals who have satisfied their reproductive needs, hysterectomy with unilateral or bilateral salpingo-oophorectomy is probably the treatment of choice.

CARCINOMA OF THE OVARY

Carcinoma of the ovary comprises one of the larger groups of ovarian tumors and the ovary ranks second only to the uterus as a site of cancer in the female genital tract.

Within this group of tumors there are a number of special malignant types in which there is no agreement regarding classification. Clinically, the group is subdivided into the primary solid adenocarcinomas and the cystic adenocarcinomas or the cystadenocarcinomas. The latter tumors are the more common in an approximate ratio of 2:1.

Clinically, ovarian carcinoma is difficult to diagnose because in the early stages of the disease it produces no symptoms. Pain is one of the first symptoms to appear, but, when this occurs, metastatic spread is likely. Abdominal enlargement, due either to ascites or the tumor, is noted in more than 50 per cent of the subjects. In Meigs' series, 30 per cent demonstrated vaginal spotting, postmenopausal spotting was a feature in 10 per cent of the patients. It is of interest that sterility has been noted in as many as 40 per cent of the women who develop carcinoma of the ovary.

Age is an important consideration in this group of tumors. Shands and Clarke found that the percentage of ovarian tumors which were malignant among patients less than forty years of age was only 2.7, in patients between forty and fifty years of age, it was 14.3, in those over fifty years of age, it was 69. The condition can be summed up in the following manner. a primary ovarian carcinoma is a common tumor growth; it is practically never observed in children and is rare among women younger than forty years of age, once the menopause has been reached, the likelihood of an ovarian neoplasm being malignant is greater than 50 per cent.

Primary Solid Adenocarcinoma. Occasionally the determination of whether a solid tumor is benign or malignant must be made

The sarcomatous variety is very cellular. Large diffuse areas of closely packed cells are characteristic. The diagnosis is frequently difficult.

The therapy is surgical removal. Unilateral oophorectomy is the procedure of choice in the younger individual with a clinically benign tumor. In the postmenopausal woman, bilateral salpingo-oophorectomy and hysterectomy is a better approach. In the older patient, the presence of an associated adenocarcinoma of the uterus should not be overlooked. Histologic examination of the endometrium is essential in the preoperative work-up. Tumors which are clinically malignant should be treated as carcinoma of the ovary.

The prognosis of the clinically benign tumor is good. Unfortunately, 20 to 25 per cent of the patients will be found to have a clinically malignant lesion at operation. Recently the development of late recurrence has been noted fifteen to twenty years after the removal of the primary tumor. The material from the Radiumhemmet shows a poorer prognosis in the sarcomatous variety of the granulosa cell tumor.

THECAL CELL TUMOR

The reported incidence of thecal cell tumor has increased in the past few years. More than 150 of such tumors have now been reported in the literature. This growth occurs most frequently in women over fifty years of age. However, 30 to 40 per cent are in women between thirty-five and fifty years of age. It is very rare that a thecal cell tumor is reported in an individual under thirty-five years of age.

The symptoms of thecal cell tumor are due to the fact that the tumor secretes estrogen. As a result, postmenopausal bleeding and menstrual irregularity are common symptoms. Disturbances of menstruation, however, are not invariable, as thecal cell tumors have been found in postmenopausal women who showed no symptoms.

Grossly, the tumor may vary from a microscopic size to 15 to 20 cm. in diameter. The small tumors have no capsule but are sharply demarcated by color and consistency from the surrounding ovarian stroma. The large tumors have a pseudocapsule formed by compression from the adjacent stroma. In shape, the tumors are usually ovoid or spherical, in consistency, firm and somewhat elastic, depending on the degree of cellularity. Cystic degeneration is occasionally present and focal areas of calcification occur.

In cut sections, the tumor is seen to have an irregular, yellowish appearance with some grayish white mottled areas. In some areas, it may resemble a fibroma.

Microscopically, the appearance varies from that of a highly cellular structure containing small clumps of spindle cells with well-vacuolated cytoplasm and clusters of ovarian lutein-like cells to a more fibrous form in which the predominant cell is an elongated spindle cell. The use of special stains to demonstrate a reticulum and the presence of fatty materials may be helpful. Collagenous strands of tissue are prominent in the fibrous type tumor. This can be shown with Masson's trichrome stain. The tendency to malignant degeneration is slight, only three or four malignant theca cell tumors have been reported. It is the general opinion that the tumors are almost always benign, but Greenhill calls attention to the possibility of late recurrences which are not reported in the literature. He states that malignant change occurs in about 25 per cent of these growths.

The therapy consists of removal of the tumor. As a general rule, these tumors occur in the older individual and bilateral salpingo-oophorectomy and hysterectomy is probably the therapy of choice.

FIBROMA

Fibromas of the ovary are usually benign and may develop any time after the onset of puberty. The majority are found clinically in women in the later years of reproductive life. Only 1 to 2 per cent of ovarian neoplasms are fibromas.

The growth rarely produces symptoms until it becomes large enough to fill the true pelvis. Then the complaints are usually vague and result from pressure on the other pelvic organs. Other than presence of a mass and a sense of heaviness, urinary and gastrointestinal symptoms are the most common. Ascites is present in almost 40 per cent of the patients whose tumor measures more than 6 cm. in diameter. In 2 to 3 per cent of the patients with ascites, hydrothorax is also present. This is the so-called Meigs' syndrome.

At operation, the ovarian fibroma is found to be solid, encapsulated, hard and gray-white. In more than 90 per cent of the cases, the tumor is unilateral.

The cut surface is white with small areas showing a yellow tinge. Occasionally a small hemorrhagic area is noted. The surface is trabeculated with a whorled arrangement.

the process of seed metastasis. Cells from an external papillary growth form implants throughout the peritoneal cavity. This group of tumors, therefore, should be classified separately from those tumors which are both clinically and histologically malignant.

Grossly, the cyst is thin walled and multiloculated. Its contents are serous, varying from yellow to brown in color. A chocolate color results from an intracystic hemorrhage.

The presence and location of the papillary growths vary. The internal proliferative areas may involve only a small area of the cyst wall, but the usual appearance is that of closely matted-together papillary growths that almost fill the cyst cavity. The papillae are cauliflower-like and friable and the same type may appear on the external surface.

These tumors are usually fixed to surrounding structures and this makes a clean surgical removal difficult. Metastatic implants are most frequently seen in the cul-de-sac. However, the process may be so extensive that all the abdominal viscera are involved.

Microscopically, the epithelial cells appear in multiple layers. The cells are anaplastic with large, dark, irregular nuclei, characteristic of carcinoma cells. In some tumors, areas with benign epithelium are seen in contrast to other areas with malignant changes. Glandular structures are common. When stromal invasion has occurred, cell masses resembling solid adenoma may be present.

The prognosis of patients with serous cystadenocarcinoma which is malignant clinically but benign histologically is not too bad. The tumor should be treated, however, as any malignant lesion of the ovary. Patients with tumors which are histologically malignant have a five-year survival rate of 16 to 20 per cent. In patients in whom widespread metastatic implants are present, the prognosis is graver. It is very heartening, however, to find an occasional patient having serous cystadenocarcinoma with widespread metastasis that responds dramatically to therapy.

Pseudomucinous cystadenocarcinoma. The frequency of this tumor is much less than that of the serous variety, the incidence of malignancy is also much less.

Malignant pseudomucinous cysts are usually unilateral and relatively large. They may fill the entire abdominal cavity. External papillae are rare. On section, the tumor is seen to be composed of numerous irregular-shaped cysts with solid areas of varying size.

These areas contain the malignant portion of the tumor.

Microscopically, histologic sections of benign, tall, cylindrical cells of the picket-fence type are usually present, but the solid areas have a more adenomatous appearance. The glands are lined by multiple layers of anaplastic cells. Nuclear changes and mitoses are present and solid cellular masses invade the fibrous stroma.

The prognosis of the patient having pseudomucinous cystadenocarcinoma is dependent on the clinical findings at the time of operation. Many of these tumors with early malignant changes can be removed surgically with good results. In patients in whom stromal invasion has occurred or in whom obvious metastasis is present the prognosis is poor.

SOLID TERATOMA

Solid teratoma of the ovary is a very rare tumor. It may occur at any age but is more common in the young person, the majority of patients being under twenty years of age. The tumor is rare in the postmenopausal woman.

Teratomas are almost always unilateral. They grow rapidly and wide metastasis is common.

Grossly, they are firm, solid tumors with a tendency for early capsular perforation with involvement of adjacent organs. On section, their appearance is variable. Portions of any tissue or organ in the body may be reproduced, though usually in the rudimentary form. Even a partially developed fetus may be seen.

The therapy is surgical removal followed by postoperative x-ray therapy.

The prognosis is poor. More than 90 per cent of the subjects will die within one year after the onset of therapy.

SARCOMA OF THE OVARY

Sarcoma of the ovary is very rare. No age groups are exempt. However, there appears to be an increased incidence in the younger individual. In some series, 30 to 40 per cent of the ovarian tumors in children are sarcomatous.

Grossly, the tumor is solid with a nodular surface. The color varies from gray to yellow. Cystic degeneration is common and on section gives the tumor a Swiss-cheese appearance. The consistency varies with the degree of cellularity. The more cellular tumors are soft and brainlike.

Microscopically, the picture is variable.

from the specimen obtained at operation. If the tumor growth has broken through the capsule and formed peritoneal or visceral implants, the diagnosis is easy. The diagnosis is more difficult when the tumor is encapsulated. The majority of the encapsulated ovarian malignant growths are less than 5 cm. in diameter. In some series, the tumors are bilateral in 80 to 90 per cent of the subjects.

In general, the tumor surface is irregular with areas of nodularity. On palpation, areas of softness are felt throughout the tumor. The mass may vary from round to kidney shaped. On cross section, the color is usually grayish yellow or grayish pink. The consistency is variable, but the majority have soft, friable and brainlike tissue.

In the advanced cases, the tumor growth invades the adjacent structures, and its normal anatomic relationship is completely lost. The growth may fill the entire pelvis and incorporate the small and large bowel. One sees tumor implants on the peritoneum and all of the abdominal organs. The omentum is frequently adherent to the pelvic mass and large neoplastic growths are found throughout the omentum.

The treatment of carcinoma of the ovary is a combination of radiation and surgery. Preoperative x-ray offers much to younger patients with a sound diagnosis, and to older patients in whom the ovarian function need not be conserved. Cell blocks and Papanicolaou smears of ascitic fluids and fluid aspirated from the cul-de-sac are helpful in the suspicious case. Preoperative therapy is given through two pelvic portals— anterior and posterior. A dosage of 800 r to 1200 r is given through each portal. Surgery follows eight to fourteen days after the completion of the radiation therapy. The structures are edematous, the cleavage planes are better and a more complete removal of the tumor is possible.

When at operation a malignant tumor of the ovary is found with evidence of pelvic metastasis, bilateral salpingo-oophorectomy and complete removal of the omentum is the procedure of choice. The uterus is not removed. It is preserved for the use of intra-uterine radium two to three weeks postoperatively. With this procedure the amount of radiation to the cul-de-sac can be greatly increased. The dosage varies with the length of the uterine cavity.

Deep x-ray therapy is begun immediately after the operation. The therapy is given to

the lower abdomen and pelvis in small fractionated doses for three to six months. Therapy is also given to the upper abdominal quadrants in patients in whom definite implants are found in this area. Hormonal therapy with 20 to 30 mg. of testosterone given daily seems to help.

In patients with ascites, preoperative x-ray therapy is given to large anterior and posterior fields. This is followed by fractionated doses of deep therapy directed at the tumor growth. Only after adequate shrinkage and mobility of the tumor have occurred should surgery be performed. It should not be rushed.

In
lative
given

ated doses of deep x-ray therapy. In subjects with ascites, injection of radioactive gold intraperitoneally may control the ascitic fluid formation for as long as four to six months. The dose is 125 to 150 mc, and this can be repeated at intervals. Generally the use of palliative therapy can add one to two years to a patient's life.

In those patients in whom the malignant growth is discovered at operation and who show no evidence of peritoneal spread, the operation should be bilateral salpingo-oophorectomy and total hysterectomy. Deep x-ray therapy follows in the postoperative period.

Primary Cystic Carcinoma. Much controversy exists concerning the origin of the

cystic carcinomas arise are the cystadenomas, either pseudomucinous or serous, and the dermoids. The treatment of the cystadenocarcinoma is similar in all respects to the treatment of the primary solid carcinoma.

Serous cystadenocarcinoma. In addition to being cystic, these tumors are bilateral. Most are characterized by papillary proliferations. These are both internal and external papillary types.

The pathologic diagnosis does not at all times agree with the clinical behavior of the tumor. For example, one may find bilateral cystic tumors with external papillary proliferations and the abdominal tumor is a benign tumor. Such a situation results from

these lesions to subside and recur in a fashion which may seem never ending. It is difficult to eradicate the staphylococci; they like the warmth and moisture of the vulva. But their presence is not the sole factor. Here, as in all infections, there is a general as well as a local factor. As long as the body defenses are in good working order, the bacteria give no trouble, but, when resistance becomes low, infection occurs. Generally one looks for chronic infection, malnutrition, anemia and diabetes, as well as debilitating conditions. Locally, trauma from scratching, pruritus, intertrigo or discharge may be found.

Furunculosis. Pain and itching attract the attention of the patient to the parts where she finds a red, tender and slightly elevated nodule. This can either regress or proceed onward to suppuration. In the latter case, it will become more brawny, larger and very tender. In time, central necrosis occurs and the apex becomes yellow, indicating that the boil is "ripe." Following rupture or incision, the boil drains until the core or central necrotic mass separates. The condition is usually minor but can be very painful, troublesome and annoying.

Folliculitis. In follicular vulvitis, the infection occurs within a hair follicle and forms a lesion which may be similar to a boil. At other times, the lesions are superficial and usually multiple. They have a tendency to occur in groups. The lesion is a pustule with a hair projecting from its center. Around the pustule, there is a zone of redness.

Hidradenitis of the vulva. Vulvar hidradenitis is similar to axillary hidradenitis but is rarer. The infection occurs in the large coiled apocrine glands. The lesion is somewhat similar to a boil but is situated in a deeper structure, it is slower in coming to a head and has a greater tendency to burrow. As a rule, the infection seems to be of a lower grade, taking longer to suppurate and reach the surface. The chronicity of the condition is disturbing to the patient.

Treatment of staphylococcal infections of the vulva. The principles of treatment of staphylococcal infections of the vulva are definite. First, the condition of the individual lesion is attended to, incision is made when suppuration is present. Next, the vulva is decontaminated by the daily use of a detergent with a skin antiseptic. This is followed with an appropriate antibiotic ointment. Lastly, the general resistance is built up and

generally antibiotics are used only in severe cases.

Herpes Vulvae. In many respects herpes vulvae resembles the common fever blisters occurring on the lips. A sensation of heat and tension precedes the development of bleblike lesions. These form on a red, indurated base. The lesions are painful and spread easily. In patients with simple cases, the application of antibiotic ointments with cortisone is effective. In patients with recurrent or intractable cases, weekly inoculation with smallpox vaccine builds up resistance and helps to overcome the infection.

X-ray Burns of the Vulva. Unfortunately, one of the more frequent types of acute inflammation of the vulva is the result of x-ray therapy given to patients with pruritus vulvae. The skin of the vulva is very sensitive and can tolerate only a small amount of deep x-ray therapy and in these particular subjects the results have been quite unsatisfactory. The pruritus usually persists and the end result is a reddened, swollen, acutely infected vulva.

Bartholinitis. This is an infection of the Bartholin's glands which are located at 4 and 8 o'clock in relation to the vaginal outlet. A frequent cause of the infection is the gonococcus. Streptococcus or Staphylococcus may also be the etiologic agent. Even Trichomonas has been found in many chronically infected Bartholin's glands.

In the acute stage, the gland is swollen, tender, hot and painful. On careful examination, the duct of the gland may be seen to exude a small amount of pus with pressure on the swollen gland. Occasionally the infection will subside gradually if the duct remains open and acts as a drain for the gland. The resolution is seldom complete and the usual result is a chronic infection of the Bartholin's gland. The other alternative of the acute stage is abscess formation. The abscess will either drain spontaneously or it must be incised. In spontaneous drainage the usual result is inadequate drainage and a prolonged course of infection and chronic inflammation. If the abscess is incised adequately, the course is much shorter and much more gratifying.

In patients with chronic bartholinitis, induration may be present with a slight enlargement of the gland. The areas may be asymptomatic for years. On the other hand, acute exacerbations may occur with abscess formation or cyst formation due to an occlusion of one of the ducts. The size of the

The cells may be spindle-like or of the round cell variety.

The treatment is surgical. The tumor is very malignant and the prognosis is poor.

METASTATIC OVARIAN CARCINOMA

The ovaries are well-known sites for involvement by metastatic implants. Two abdominal areas furnish the majority of the secondary ovarian malignant processes.

First, carcinoma arising from the pelvic viscera may involve the ovary. The primary lesion may be the corpus uteri, fallopian tubes or the pelvic portion of the large bowel. Lymphatic metastasis or tubal regurgitation is the method of spread, particularly in uterine carcinomas.

The other source is the viscera of the upper abdomen. Carcinomas of the gastrointestinal tract, gallbladder and pancreas are the usual primary lesions. The secondary metastatic tumors in the ovary are known as Krukenberg tumors.

Grossly, these tumor growths are solid and usually about the size of a man's fist. They are rarely larger than 6 or 7 cm in diameter. The tumors are almost always bilateral. They have a tendency to retain the general shape of the ovary and not infrequently are lobulated. The external surface is relatively smooth and adhesions to surrounding structures are rare. There is usually a well-developed capsule.

On section, the appearance is variable. Some areas are firm, others are spongy. Hemorrhage or cystic degeneration may be seen.

On microscopic examination, the stroma is seen to be fibrinous with a myomatous appearance in areas due to edema and degeneration. Scattered throughout the stroma are nests or strands of round swollen cells. The cells are vacuolated. The nuclei appear as long, crescent-shaped bodies situated against the cell membrane. These epithelial cells have undergone mucoid change and give the cells the characteristic signet-ring appearance.

Clinically, the symptoms referable to the primary neoplasm of the upper abdomen are overshadowed by those of the ovarian neoplasm in 30 to 40 per cent of the patients. Ascites may be present in approximately one-third of the subjects. The important point for the surgeon to keep in mind is that bilateral solid, lobulated ovarian tumors may be metastatic and a thorough investigation of the upper abdomen is most essential.

THE VULVA

Skin covers the specialized tissues which make up the vulva. Of course, this skin is somewhat different from that on other portions of the body, but it is skin nevertheless and general skin diseases do affect it. The vulva has an environment all its own and thus modifies the diseases and makes it difficult to diagnose them. To complicate the situation a little more, one must recognize another group of diseases which largely limit themselves to the vulva and have little or no general manifestations.

Women are very conscious of their vulva and attach an unusual significance to its diseases. Sometimes even the actual disease stimulus is cerebral in nature and the vulval symptoms are but distant manifestations of deep mental unrest. The vulva, then, is an area in which dermatology, gynecology and psychiatry overlap.

Intertrigo, *Intertrigo*, by definition, is a chafe or a chafed patch of skin. It is caused by the rubbing together of two skin surfaces. In fat women the inner side of the thigh rubs the outer side of the labia majora. When the skin is thin, as in the young and the old, less rubbing produces more of a chafe. Moisture from excessive sweating, discharge or urinary incontinence macerates the skin. To make matters worse, itching occurs and results in scratching; infections with the ordinary bacteria or with fungi follow. In diagnosis, the first consideration is to determine the presence or absence of a fungus infection. When fungi are not present, treatment depends on simple measures to prevent chafing, dry the moisture and overcome infection.

Staphylococcic Infections on the Vulva. Staphylococcic infections of the vulva cause furunculosis, folliculitis and hidradenitis. These three conditions are often described as separate, clear-cut diseases, which they really are not. While one type of infection overshadows the others, all of the lesions may not be of the same type. With furunculosis, the infection takes place in a sweat gland, with folliculitis, in a hair follicle, and with hidradenitis, in an apocrine gland. Each of these lesions has a different appearance because it occurs in a different skin structure. One can readily see when a lesion suppurates and ruptures that it will contaminate the skin of the area. This can cause lesions of the original type, or of the other types, depending on the skin structure infected. This accounts for the tendency of

structive in nature. The therapy of syphilitic lesions of the vulva has been revolutionized since the advent of penicillin and its various forms of administration.

Tuberculous Vulvitis. This is a rare condition. As a general rule, tuberculosis in the female genital system is usually secondary to tuberculosis of the fallopian tubes. Tuberculosis of the vulva can be primary, particularly in patients whose husbands have tuberculous epididymitis. The lesions are usually irregular, small, punched-out ulcers that are hard to heal by the usual methods of therapy. Making the diagnosis is frequently difficult. Many times it is impossible to differentiate the lesions even by biopsy from those of syphilitic chancre. The use of smears and tumor biopsy tissue stained for the acid-fast bacillus is often diagnostic. Guinea pig inoculations are an old but important means of diagnosis and can be helpful when other means fail.

Cancer of the Vulva. An ulcerative lesion of the vulva, particularly in the elderly woman, must be considered as cancer until proved otherwise. The average age of patients with carcinoma of the vulva is fifty-five to sixty years. The carcinoma is squamous cell in type. Under the microscope, it has a very characteristic appearance, the cells are very highly differentiated with frequent pearl formation. Usually the lesion develops as a small nodule which later ulcerates or becomes papillomatous. Unfortunately, the physician rarely sees the patient when the lesion is small. In one recent study, the average diameter of the lesion was 5 cm. when the patient first consulted a physician. The lesion can become extensive and involve the urethra and the opposite labia, forming a kissing type of ulceration. The disease spreads by direct extension and by way of the lymphatics. Lymphatic extension is thought to be by the process of embolism. The superficial femoral and inguinal nodes are frequently involved early in the course of the disease. Lymphatic extension can occur to the nodes on the same side as the lesion or to the opposite side; this results from the rich anastomosis which exists between the lymphatic channels of each side of the vulva. The deep femoral and deep inguinal nodes and the nodes upward along the iliac vessels are involved at a later stage of the disease. It is important to remember that the presence of palpable nodes is not a certain indication of carcinomatous involvement, in many pa-

tients the nodes are palpable because of inflammatory changes. On the other hand, the lack of palpable nodes does not exclude node involvement.

It is the consensus that surgery is the preferred form of therapy in carcinoma of the vulva; the operation has progressed from simple vulvectomy to a far more radical excision of the vulva and the adjacent lymph nodes. In this country, Taussig was the pioneer in advocating an extensive en bloc dissection of the vulva and lymph nodes. The operation calls for radical removal of the vulva and large wedges of skin extending from the vulvar incisions toward each inguinal area, plus a bilateral node dissection including all of the superficial and deep nodes, and an extraperitoneal dissection of the nodes up to the bifurcation of the aorta. In many patients the skin cannot be primarily completely approximated. However, this is of less significance than in other areas as rapid granulation and epithelization of the open wounds result in an acceptable scar. Infection of the wound postoperatively is present in most patients. This is combated by the use of antibiotics and drainage. The accumulation of serous fluid and lymph beneath the skin flap is treated by aspiration or by the insertion of catheters or polyethylene tubes in the dependent areas and the use of constant suction. Thrombophlebitis and phlebothrombosis must be constantly guarded against in the patients. The use of leg exercise, of elastic support and ambulation is good prophylaxis.

The employment of radiation is extremely limited except in patients in whom urethral involvement is present. Radon seeds are used by some physicians in subjects having local recurrences. In the experience of many, the use of electrocoagulation has been more successful in the treatment of local recurrences than has any other form of therapy. The Radiumhemmet in Sweden uses electrocoagulation of the vulva instead of surgical vulvectomy as a primary form of therapy.

Kraurosis and Leukoplakia. Kraurosis is a shrinkage of the tissues of the vulva. It is seen in elderly women, in patients following radiation menopause and in patients who have had radiation therapy for carcinoma of the cervix. The condition consists of a loss of subcutaneous fat, the labia become flattened, the skin is thin and is usually reddened. There is a narrowing of the introitus and, as a result, dyspareunia is a common

cyst depends on the site of the duct blockage. The cysts may vary from 1 to 5 cm. in diameter. The treatment consists of excision or marsupialization of the cyst. In recent years, because of the extreme vascularity of the tissue and the painfulness of the condition, these cysts have been marsupialized by making a longitudinal incision across their entire diameter and suturing the linings to the skin surface. They are packed open for forty-eight to seventy-two hours and thereafter the patient is instructed to keep the opening patent by inserting her finger into the incision each day. The end result is a small dimple at the site of the previous cyst. Hospitalization of these patients is usually for a two- to three-day period. The tenderness is markedly less and the end results are as good as the complete removal of the cystic structure.

Gonorrhea. Gonorrheal urethritis and gonorrheal infections of the Skene's ducts still occur; however, the frequency in both private practice and clinic practice has decreased markedly with the appearance of chemotherapy. The urethritis does not play a prominent role in the over-all picture of infection in the female. The female urethra is short and in most patients there is a tendency for spontaneous resolution of the infection of the urethra. Trigonitis, however, may be persistent. On the other hand, the drainage of the Skene's ducts is inadequate and persistent infections are common. At one time it was necessary to destroy these ducts by the use of the cautery. However, with the advent of bactericidal drugs the results are quite different.

Chancroid. Ducrey's bacillus causes this ulcerative lesion, it is sometimes called a dirty chancre or a soft chancre. The lesions, usually multiple and very ragged in appearance, have a purulent ulcerative surface. They are soft and not indurated as in syphilis, edema frequently is present if they are on the labia majora. A characteristic feature of the disease is secondary inguinal lymphadenitis. Frequently the lymph glands suppurate and form inguinal abscesses. These are known as buboes.

The diagnosis can be made by smears of the lesion with the demonstration of a gram-negative, short, coccus-like rod. The microorganisms frequently appear in pairs or chains. Cultures are used and are most reliable. The intradermal skin test, developed by Greenblatt, is useful to confirm the diagnosis. It is diagnostic three to six weeks after the initial infection.

In the treatment of Ducrey infection, sulfadiazine gives very satisfactory results. The dosage is 1 gm. every four hours. Several of the wider range antibiotics also can be helpful. It is better to aspirate the buboes than to incise them.

Granuloma Inguinale. This is a chronic skin infection that is usually very distressing to the patient. Developing as a small papule and followed by ulceration, it spreads over the entire genital area. This condition is limited almost exclusively to members of the Negro race. The etiologic agent is the Donovan body. Diagnosis depends on demonstration of these bodies. The smear is best stained by either Wright's or Giemsa's method. Tissue biopsy is important in the diagnosis of this lesion. Good surface smears are difficult to obtain because of the large amount of cellular debris that is present. For this reason the bodies are more easily seen in smears from tissue or in stained sections. In treatment, good results follow the use of Chloromycetin and Terramycin.

Lymphogranuloma Inguinale. This condition is caused by a virus. The lesion usually develops as a superficial ulcer followed by multiple ulceration and inguinal adenitis. The spread of the infection is by the lymphatics. Diagnostically the Frei test is important. In the treatment of lymphogranuloma inguinale, sulfadiazine has been an old stand-by. Terramycin, Chloromycetin and other wide-range antibiotics are more frequently used at the present time.

Syphilis. As in the male, the primary lesion of syphilis is the chancre. In the female, it is most often seen on the labia. It is firm, hard and nodular in character. It is usually single, however, sometimes there may be a kissing type of lesion. The chancre is not as commonly seen in the female as in the male, because of its relative painlessness and the inaccessibility of the female vulva to personal inspection. The diagnosis is made by the darkfield examination. Reactions to serologic tests are usually positive within two to three weeks after a primary lesion occurs.

The condyloma latum, the flat, moist papule of secondary syphilis, is important. It appears slightly elevated, but with a flat surface that looks grayish and necrotic. The lesions are multiple and may involve only a small area of the vulva or, on the other hand, they may involve the entire vulva and perineal region. The tertiary lesions of the vulva have been seen very rarely in the past ten years. When present, they consist of extensive gummatous ulcerations. They are de-

symptom The pasty, thin skin frequently develops infection. The result is a secondary condition known as chronic atrophic vulvitis. At times this condition may become acute, with redness, tenderness and edema of the vulva. Leukoplakia-like changes may develop.

There are two types of leukoplakia—atrophy and hypertrophy. Hypertrophic leukoplakia is characterized clinically by elevated, whitish, parchment-like areas, with a tendency to fissure formation and infection. Pruritus, dysuria and vulvar irritations are prominent symptoms of this condition. Microscopically, there is an increased keratinization of the surface of the squamous epithelium with an increase of cellularity of the basal layers and with pronounced invagination of the rete pegs into the underlying tissue. Mitotic figures are common and hyperactivity of the cells is of frequent occurrence. In the atrophic form, there is a thinning of mucous membrane and a loss of collagen in the underlying stroma.

Of great importance is the relationship of leukoplakia to carcinoma of the vulva. It has been stated by some that one-half of all cases of carcinoma of the vulva are preceded by a leukoplakic vulvitis. The therapy of leukoplakia varies widely. The usual patient will relate a large number of different types of therapy which have been tried in her particular case. They include use of various salves, ointments, dyes and x-ray. In general, these therapies have not been too satisfactory. In some of the patients with an atrophic type of the disease, the use of estrogen creams has been of benefit. Recently the advent of cortisone ointments has improved the results in some of these patients. On the other hand, the usual course consists of multiple forms of therapy, followed in time by vulvectomy. In most subjects, vulvectomy is unnecessarily delayed and frequently carcinomatous changes are present before it is performed. The patient's fear of mutilation has much to do with this delay. Fortunately, mutilation is not nearly as great as expected and the cosmetic result is generally well accepted. The relief of the itching and irritation is so great that the patients readily accept their postoperative states and are well pleased with their operations.

An *incomplete fracture* is one in which the continuity of the bone is only partially divided. There are several varieties. A *fissure fracture* is one in which there is a crack partially through the bone. This may be either transverse or longitudinal. A *depressed fracture* may involve only the outer table of the skull, not passing completely through the bone. A bullet wound may create a *puncture fracture* without a break across the bone. A *greenstick fracture* is one which has occurred from marked bending, so that the bone is splintered on the convex side, but remains intact on the concave side, like a splintered branch of a green tree.

A *complete fracture* is one in which the entire continuity of the bone is divided. The fracture line, if single, may be transverse, oblique, spiral or even longitudinal, and often there is more than one line of fracture. A *comminuted fracture* is one in which there are two or more lines of fracture which divide the bone into more than two fragments. At a joint, this may be a combination of a transverse and a longitudinal fracture producing a T fracture, or a combination of two oblique fractures producing a V fracture. An *impacted fracture* is one in which, with or without lateral displacement, the firmer cortical bone is telescoped into the softer cancellous bone. This occurs particularly at the neck of the humerus and of the femur. A *compression fracture* is one in which two opposite surfaces of the bone are driven closer together than normal. This usually is noted in cancellous bone with considerable fine comminution, often resulting in a definite diminution in the area of bone shown in the x-ray picture, as in fractures of the vertebrae. A *sprain fracture* is a sprain in which a small fragment of one of the bones has been pulled off, usually at the site of a ligamentous attachment. A *spontaneous fracture* is one which occurs without apparent competent exciting cause. Strictly speaking, it is not spontaneous, as the break is necessarily caused by trauma, even though this is slight. It is usually found in patients with bone atrophy, osteogenesis imperfecta or general conditions affecting bone. A *pathologic fracture* is one which occurs without apparent competent exciting cause at the site of local disease of the bone.

Displacements of the fragments may be lateral, angular, longitudinal and rotary, or a combination of these types. The displacements interfere with the proper axis of an extremity. Posterior angulation produces : is known as dishing. Longitudinal dis-

placement may produce shortening of an extremity, called overriding, or it may result in separation of the fragments, as seen in fractures of the patella or olecranon, or in overpull in the use of traction.

A fracture is described as being located either in the shaft or in the extremities. At the ends of the bones there is a further designation according to the anatomic part broken, e.g., surgical neck, tuberosity, condyle, head or articular fracture or epiphysal separation. An articular fracture is one in which the fracture line runs across the attachment of the joint capsule. An intra-articular fracture lies entirely within the joint. An epiphysal separation is a fracture which passes wholly or in part through the epiphysal line. It is often unrecognized but is of great importance because bony union of the epiphysis may result with arrest of growth. A subperiosteal fracture is a complete fracture without displacement in which it is believed that the periosteum has not been torn. Multiple fractures may be at different levels in the same bone or in different bones. The term *complicated fracture* is sometimes used when recovery will be complicated because of damage to artery, nerve or joint.

Etiology. Fractures, particularly of the clavicle, elbow and forearm, are common in children between the ages of two and four years on account of unsteady gait and frequent falls. Between the ages of four and six years, many greenstick fractures occur because the bones are soft. Between six and twelve years, if a fracture occurs near a joint, there is likely to be epiphysal separation. The incidence of fractures increases from six years on, reaching its maximum between the ages of thirty and forty years, that is, it coincides with the age of greatest activity. On account of bone atrophy, fractures of the neck of the humerus and of the neck of the femur are particularly common in old age.

The incidence is about the same in boys and girls up to four or five years of age, after which fractures occur more commonly in males up to forty-five years old. This is undoubtedly a result of the more active life and more hazardous trades of males. Some authors state that fractures are from seven to ten times more frequent among males than among females during this period. After forty-five years, the number is nearly equal in the sexes, with a slight preponderance among females in advanced age.

Bone atrophy is a predisposing cause of

THE BONES AND JOINTS

Considerations in the Treatment of Closed and Open Fractures

By ROBERT H. KENNEDY, M.D.

ROBERT HAYWARD KENNEDY has been active for many years in educating the medical profession and the laity to the many facets in the surgery of trauma in which they have a common responsibility. He is well qualified because of his wide experience. Educated at Amherst College and Columbia University, he has spent his professional life in New York City. Dr. Kennedy was formerly Professor of Clinical Surgery at New York University Post-Graduate Medical School.

A fracture is the breaking of a bone or cartilage usually resulting from external violence. Injury to the soft parts overlying a fracture is an almost invariable part of the injury and always requires consideration.

Varieties. A *closed fracture* is one in which there is no communication between the bone at the site of fracture and the outside air. Usually this means that there is no overlying wound of the skin or mucous membrane. An *open fracture* is one in which there is a communication between the site of the fracture and the outside air through

an opening in the skin or mucous membrane. This may have been caused either from within or from without. It is possible for an overlying wound not to communicate with the fracture, thus then being a closed fracture, although it is preferable for purposes of treatment to consider it as open. If an open operation is performed on a closed fracture, an open fracture is produced. If the unbroken skin and soft parts slough away in a closed fracture, an open fracture may be produced.

Fractures may be incomplete or complete.

ment, but if it is lived up to, it is obvious that the splinting will rarely be done by a physician. Splinting must be considered as only a means of aiding transportation, not a part of the definite treatment of the fracture. The physician must be prepared to instruct the public on the most effective manner of transporting a patient with a fracture to the physician's office or to a hospital. In general, those trained by the Red Cross and Boy Scouts know more about first aid than most physicians, because little responsibility has been accepted by the physician until the injured person arrives at the office or hospital.

To quote from *An Outline of the Treatment of Fractures*, issued by the American College of Surgeons.

The injuries resulting from fractures are not limited to those occurring at the time of the accident. Unwise attempts to use the injured extremity may cause or increase displacement of fragments, increase the lacerations of soft parts, and perhaps lead to penetration of the skin by the ends of the bone. Similar additional trauma is often due to the awkward efforts of the bystander. A man is struck by an automobile, thus breaking his leg. Except for the broken bone, without displacement, the original injury may be merely a slight periosteal tear and a mild contusion of the soft parts, but he is helped to his feet and the leg gives way and the fragments slide by each other, thus stripping off the periosteum and tearing the muscles. He falls to the ground only to be picked up and carried to the sidewalk with the leg dangling. Larger blood vessels are torn and the end of the bone comes through the

end of the bone re-enters the wound with a bit of trouser and the dirt of the street. He is lifted up and carried to a car or ambulance. This time someone carries the injured leg with better intentions than

out the area. During his ride and in the transfer to the accident ward or the doctor's office, unless he has been carefully splinted, there is more jolting and more damage. Would that his troubles were over, but two

Compare this exaggerated picture with a similarly injured man who is allowed to remain where he is until a proper splint can be applied, or at least until he can have someone pull hard on his foot as he is being lifted and carried, whose examination is thoroughly but gently carried out, and whose treatment is instituted with but little additional injury. The difference in these two cases as regards period of disability and amount of permanent functional disturbance is great.

Principles of first aid: (1) If suspicious

that a fracture is present, render care as for a fracture, (2) combat any existing shock, (3) avoid every unnecessary manipulation, (4) protect any existing wound by the best means available, (5) splint effectively before transporting the patient, wherever found, and (6) transport carefully.

The injured person should first be examined rapidly in order to attempt to determine whether he is seriously hurt. The clothing usually does not need to be removed. In examining a patient, try to keep all parts thoroughly covered except the part which is actually being examined at the moment. One should depend on pain, loss of function or deformity for the emergency diagnosis of fracture and should rarely, if ever, try to obtain crepitus or false point of motion. If the patient thinks that he felt a bone snap, for emergency purposes one should be satisfied with his history and not attempt to prove the diagnosis on the street. If suspicious that a fracture is present, always treat the patient as if the diagnosis of fracture had been confirmed.

The saving of life comes first and the saving of limb second. If the patient is in shock, this demands treatment before anything is done for the fracture. There is no use in splinting a limb carefully, while neglecting to treat shock from which the patient may be dying. On the other hand, traction on an extremity may be the most effective means of combating shock. If morphine is available and the injured person is in pain, its administration is frequently the first and best treatment for shock. It allays pain and thereby quiets the patient's restlessness. The body heat must be maintained by sufficient extra covering.

If a wound is present which possibly connects with a fracture, it should not be washed. A sterile compress should be placed over the wound, preferably without the previous application of any antiseptic. Bleeding should be stopped. It is rare that this cannot be done with a firm compression bandage. Tourniquets should not be used until compression has proved of no avail. Death has been caused by an improperly applied tourniquet which allowed some arterial blood to enter the part and only shut off the venous return. It is common to see all bleeding stop as soon as a tourniquet is removed. When a tourniquet has to be applied it should not be removed until definitive shock therapy has been instituted.

Do not attempt to replace the fragments in an open fracture which has projecting

fracture in old age, from prolonged lack of use, as in patients with paralysis or ankylosed joints and in those with general paresis, tabes and syringomyelia. Osteogenesis imperfecta, or idiopathic fragilitas ossium, is an inherited tendency to spontaneous fracture. Generalized bone conditions, such as rickets and osteomalacia, and localized bone disease, such as sarcoma, metastatic carcinoma, destruction of bone in acute osteomyelitis and bone cysts, are favorable to the occurrence of fracture.

There are three exciting causes of fractures—direct violence, indirect violence and muscular action.

A fracture by *direct violence* is one in which the bone is broken immediately beneath the point of impact. Injury to the soft parts always accompanies the fracture, which is quite frequently open. The line of fracture usually is transverse or slightly oblique and is often comminuted. The common example at present is found in a patient whose leg has been run over by the wheel of an automobile.

A fracture by *indirect violence* is one in which compression or bending is exerted at a distance so that a bone gives way at its weakest point. A typical example of the compression action of indirect violence is seen in a fall from a height in which the person lands on his heels. According to the position of the person landing, he may sustain comminuted fracture of the os calcis, fracture of the lower extremity of the tibia often with fissures running longitudinally, fracture of the shaft of both bones of the leg, compression fracture of one or more vertebrae or fracture of the base of the skull. Similarly, a fall on the extended palm may result in a fracture of the lower extremity of the radius, the head of the radius, the lower extremity of the humerus, the surgical neck of the humerus or the clavicle. The site of the fracture varies both with the exact position of the skeleton at the moment of impact and with the age of the patient. The bending action of indirect violence is well seen in fractures sustained in turning the ankle, in which the weak point of the fibula immediately proximal to the external malleolus is the frequent site of fracture. If at the same time that the bending action occurs there is a certain amount of rotation of the body on the foot, the fracture is often spiral rather than simply oblique. Fractures caused by indirect violence are less likely to be comminuted. If a fracture is open, it is usually opened from the inside by a fragment

of bone which pierces the skin. The injuries of the soft parts are those caused by the sharp ends of the fragmented bone. Fractures by indirect violence occur much more commonly than those by direct violence.

Fractures by *muscular action* are less common, the most frequent examples being fractures of the olecranon and patella. A sudden contraction of the triceps or the quadriceps, usually because of an unexpected movement, fractures these bones transversely. More rarely, a long bone is fractured by muscular action, e.g., the shaft of the humerus when the person is throwing a baseball or the shaft of the femur when a patient with tabes merely rolls over in bed. The mechanism of fracture may be due in an individual patient to a combination of any two or all three of the direct causes.

The comparative frequency of fractures in various bones is difficult to determine. Many series of such statistics have been published including thousands of cases, but they are usually in entire disagreement as to the order of frequency. This is easy to understand. The usual site of the fractures seen in hospital wards is different from that seen in the dispensaries. A hospital in a residential district admits patients with fractures who are usually in other locations than those patients from an industrial or congested district. A hospital with an ambulance service may have more lower extremity and skull fractures, while a hospital without ambulance may have more upper extremity fractures because the patients are ambulatory. All of these factors obviously account for the statistical variations.

There are probably more fractures of the upper than of the lower extremity. Fractures of the phalanges and ribs are probably most numerous. Following these, without attempting to place them in order of frequency, the common fractures are of the lower extremity of the radius, the region of the ankle, the metacarpals, the shafts of the bones of the leg, the skull, the clavicle and the humerus.

First Aid and Transportation. Except on hospital ambulances, first aid after fractures is more likely to be rendered by laymen than physicians. In many instances this is the critical part of the whole treatment. It is necessary to know the principles of first aid for use while serving as ambulance surgeon, but it is of even greater importance to be able to guide and instruct the general public. "Splint 'em where they lie" is properly the first principle of fracture treatment.

the spine, sometimes unrecognized, than from any other injury. If the injured person complains of pain in his back, it may be that his back is broken. If he complains of pain in his neck, he may have a broken neck. Do not lift an injured person or his head until he has told you whether he can move his legs or fingers. If he cannot move his legs, he has a broken back. If he cannot move his fingers, his neck may be broken. In either instance the spinal cord is injured. If the patient's body is bent while he is being carried in the former instance, or if his head is lifted so as to give him a drink in the latter instance, the injured spinal cord is inevitably ground between parts of the broken spine, thereby destroying any useful remnant of the cord which may have escaped injury. Do not allow the injured person to sit up. If a fracture of the spine may be present and the victim is unconscious, handle him as though his neck were broken.

For the patient with possible fracture of the dorsal or of the lumbar region, the underlying principle of hyperextension should be observed in moving and transferring him from the site of accident. He should be carried face downward on a rigid support. Wherever found, the patient should be slowly and evenly rolled over so that he rests on his abdomen on this rigid support. One of his forearms should be placed under his head, which is turned to the side as in the Schafer resuscitation method. Whenever the patient must be moved at all before the rigid support is obtained, he may be rolled onto his abdomen on a sheet or blanket. This sheet may then be lifted by two persons, one at each end, and the patient carried prone in this improvised hammock.

In case of possible fracture of the cervical vertebrae, gently slide the patient sidewise onto a rigid support so that he rests face upward with the arms at the side. Never tilt the head forward. No pillow should be placed under the head or neck. Pillows or sandbags may be placed each side of the head to prevent rotation.

as the legs should be tied together. The position of the thighs and legs should be that naturally assumed. If enough assistance and the necessary material are at hand, a body swathe may be placed about the pelvic girdle. This should be applied snugly but not tightly.

Lower extremities. The only effective and

advisable method for transporting a patient with a fracture of the long bones of the lower extremity is by some form of traction fixation. This requires the use of a splint of the Thomas type so that pull is exerted from fixed points above and below, the traction remaining the same, whatever the position of the limb or splint. Overriding is characteristic of these fractures and there can be no generally effective immobilization without traction. In addition, traction relieves pain and shock and prevents further damage during transportation. The traction fixation splint should be applied if there is any possibility of fracture between the hip joint and the foot, no matter whether the injuries are closed or open.

The full-ring Thomas splint can be used. More generally applicable and advisable splints of the Thomas type are the Keller-Blake hinged half-ring splints. These should be applied wherever the patient is found without changing his position.

There are certain standards that are necessary in the application of this general method. It does not make any difference what particular procedure is used so long as one appreciates what must be accomplished. In the use of traction there are six requirements. There must be some adequate form of hitch and it is necessary to protect the part beneath the hitch so that it will not be injured. The traction hitch should be applied above the ankle or wrist. There must be some means of increasing traction by twisting so that the desired pull is obtained. The extremity, being in traction, must be supported. One must not depend merely on traction for the entire support of the limb. Not only must the extremity be supported from below, but lateral movement must be prevented. The whole splint must be suspended so that the heel will not, even for a moment, rest on the ground, the floor of the ambulance or elsewhere.

Take, for example, a patient with a possible fracture of the shaft of the femur. The patient is covered with blankets. Morphine is administered, if available, under medical supervision. The foot, with or without the shoe on, is grasped firmly by an assistant with both hands placed laterally. Gentle, steady, firm traction is made in the axis of the extremity. Manual traction is maintained until splint traction is established. While traction is being made, the whole limb is slowly lifted several inches from the ground. The half-ring splint is slipped from the outer side beneath the extremity. The side bars of

bone. If the bone disappears beneath the skin in the course of the application of traction, this should not cause anxiety. The patient must be operated on in any case to clean up the wound. It is important that word shall accompany the patient that the bone has been exposed, in order to guide the treatment by the next physician.

If materials are not available to splint the fracture properly, the patient should not be lifted into the first automobile and rushed to a doctor's office or hospital. It is far better to cover the patient adequately and let him lie on the ground where he was found until he can be splinted and moved in an ambulance. If it is necessary to change his position at all before splinting, in the instance of an extremity fracture, pull should be exerted on the injured part while he is being moved.

Special Indications in Individual Fractures. *Lower jaw.* Try to bring the pa-

tient's lower teeth against the upper teeth gently. Apply the center of a narrow bandage under the chin. Pass one end over the top of the head and cross the two ends above one ear, tying them tightly at the base of the skull, the crossing being on the side injured. Do not use a four-tailed bandage.

Clavicle, scapula, humerus and elbow.

Forearm, wrist and hand. Padded splints of wood or heavy cardboard will suffice for transportation.

Spine. If the mechanism of injury is such that a fracture of the spine may have been produced, transport the patient as though a fracture had occurred, even though no objective signs are discovered in a cursory examination. Death or permanent disability results more commonly from improper transportation of the patient than from a fracture of

bones. From 10 to 30 cc. of a 2 per cent solution is sufficient. The skin at the site of the needle puncture must be prepared in the same way as for any operating room procedure. The needle is inserted at a point close to the fracture site, the plunger is withdrawn slightly until blood appears in the syringe, the Novocain is then injected. Relaxation is usually obtained within from two to five minutes. Unless the injection is into the hematoma, as proved by blood in the syringe, it is rarely successful. It is a simple procedure. No extra anesthetist is required. There is no struggle and consequently no danger of further displacement of the fragments either while the anesthesia is being induced or during recovery. Furthermore, the patient can cooperate in the application of splints, for example, by sitting up for the application of a shoulder spica. Twenty-four hours after a fracture is sustained, the blood is frequently coagulated, diffusion of the anesthetic does not occur and no relaxation results. During the first twenty-four hours, the anesthetic is quite uniformly successful. The only other contraindication is the occasional damage to a large vessel or nerve by the needle. Its use

is indicated in all simple fractures of an extremity. If more than one bone is broken, injection will be required at each fracture site. The relaxation usually lasts from one-half to three-quarters of an hour and gives sufficient time for the physician to reduce the fracture, apply splints, take a roentgenogram and, if the position is not satisfactory, attempt reduction again without further injection of the anesthetic. Meantime the patient is awake and cooperative. Local anesthesia can rarely be used in children. It should not be used in patients with open fractures.

Two other forms of regional anesthesia are used, nerve block and field block. Nerve block, or plexus block, requires considerable skill and practice. Brachial plexus block is excellent in cases of fracture of the humerus. Field block does not demand special skill, but does require a considerable amount of anesthetic. Both of these forms may be employed for open fractures.

General anesthesia has been used in patients with fractures for a great many years. Ether is preferred for a long procedure. Nitrous oxide, cyclopropane or ethylene, with oxygen, is suitable for short procedures. Ether gives more complete relaxation. All require the presence of a skilled anesthetist. When the fluoroscope is used in

connection with reduction, there is too much danger of ignition of the ether vapor, or of cyclopropane, or ethylene to permit employment of such anesthetic agents. Gas-oxygen is less dangerous from this point of view, but its administration is difficult in a dark room.

Spinal anesthesia is excellent in cases of fractures of the lower extremities. From 50 to 100 mg of Novocain injected beneath the dura in the fourth lumbar interspace will usually give complete relaxation for an hour.

Intravenous anesthetics are used considerably, particularly Pentothal sodium. It is best given in small doses, repeated if necessary, with skilled observation of the patient. Complete relaxation is liable to be accompanied by dangerous respiratory depression.

In the late treatment of fractures, an anesthetic is sometimes advised when it is thought necessary to manipulate joints and break up adhesions. This is a dangerous procedure and should never be resorted to until every other method of stretching has failed.

Open (Compound) Fractures. The basic principles in the management of a patient with an open fracture are as follows: treatment of shock and hemorrhage, prophylaxis and treatment of wound infection; accurate reduction and complete immobilization. In actual practice, these three are associated at the same time and disaster may be the result of neglect of any one of them. If a tourniquet must be used, it should be applied as close to the wound proximally as possible since gangrene may result. Intermitent release of the tourniquet may result in profound shock.

Treatment of shock and hemorrhage. Shock and hemorrhage are frequently grave and attention must be devoted to them first.

Morphine is always indicated for pain, except in head injuries, but only in the amount necessary to control pain. In the instance of multiple injuries, including the brain, it may still be given if accompanied by caffeine.

Body temperature must be maintained in some way, but this must be done with judgment and the patient not kept bathed in perspiration, with loss of body fluids.

In most instances a pressure dressing is all that is necessary to control bleeding. The tourniquet has been grossly misused. An ineffective tourniquet has often caused serious loss of venous blood, which ceases as soon as the tourniquet is removed.

The major function of traction fixation as

Figure 2 Lower extremity in a Keller-Blake hinged half-ring splint with traction fixation applied in transportation

the splint are placed in the median horizontal plane of the thigh so that the ring rests against the tuber ischi. The strap is buckled over the anterior surface of the thigh. The lower end of the splint rests against the body of the assistant who is still applying traction. The ankle region is protected by cotton wadding or the shoe. A traction hitch is applied—an army traction strap or muslin bandage about the ankle or adhesive plaster to the leg. The traction hitch is fastened to the end of the splint and traction is increased by a Spanish windlass action with a tongue depressor and adhesive plaster, or a long nail. The manual traction is then released. The extremity is supported in the splint by means of muslin hammocks and clips applied before the splint is put on or by a wide cotton bandage wrapped from below upward about the extremity and traction bars after traction is applied. Lateral movement is prevented by turns of muslin bandage tied above and below the knee in the former instance (Fig 2). The end of the splint is suspended to the stretcher bar or to the roof of the ambulance. A foot piece is advisable if transportation is to be prolonged.

In hospital practice a traction splint should be applied immediately in the emergency room, if it has not been done before. The patient is transported to the x-ray room and to the ward with traction on. The removal of the patient's clothes is supervised so that if traction must be loosened, it is maintained manually until it can be reapplied. The traction splint is kept on until the patient is in the operating room and under the anesthetic.

If a Thomas splint is not available for a fracture of the lower extremity, it must be appreciated that unless manual traction is exerted during transportation there is always danger of increasing the extent of the injury. Formerly, long, side wooden splints were applied from the axilla to beyond the

foot for fractures of the hip and thigh, but these are difficult to apply and probably do more harm than good. It is preferable simply to bind the thighs and legs together using the uninjured leg as a splint.

For a fracture of the patella, leg or ankle a pillow which is drawn firmly around the part in its proper relation is fairly satisfactory. A padded posterior wooden splint will suffice for patellar fractures and two lateral wooden splints extending from midthigh to foot may be used for leg and ankle fractures. For all fractures of the foot, any splint of firm material which keeps the heel and toe from touching any object will suffice.

It is important to remember that the type of first aid and transportation is a large factor in the ultimate recovery. It has been stated that in World War I the mortality of gunshot wounds of the femur was reduced from 80 to 20 per cent by the routine use of the Thomas splint. Physicians need to be cooperative in urging the public to carry out these methods of transportation and not insisting, as do some, that a fracture should not be touched until the patient reaches the doctor's office or the hospital.

Anesthesia. Whenever any change in position or manipulation of fragments is indicated, an anesthetic should be used, this insures relaxation of muscles and allows the surgeon to be free to do whatever he finds necessary. Because one believes that reduction will be easy, this does not justify failure to use an anesthetic. Even if it is possible to obtain a perfect reduction without its aid, more damage to soft parts is liable to occur as a result of the resistance of unrelaxed muscles. The patient's statement that he can stand the pain is not of importance, as the anesthetic is not given for this reason, but to relax the muscles and allow as perfect replacement of fragments as possible.

Local anesthesia is the best, induced by an injection of Novocain directly into the hematoma around the ends of the fractured

bones. From 10 to 30 cc. of a 2 per cent solution is sufficient. The skin at the site of the needle puncture must be prepared in the same way as for any operating room procedure. The needle is inserted at a point close to the fracture site; the plunger is withdrawn slightly until blood appears in the syringe; the Novocain is then injected. Relaxation is usually obtained within from two to five minutes. Unless the injection is into the hematoma, as proved by blood in the syringe, it is rarely successful. It is a simple procedure. No extra anesthetist is required. There is no struggle and consequently no danger of further displacement of the fragments either while the anesthesia is being induced or during recovery. Furthermore, the patient can cooperate in the application of splints, for example, by sitting up for the application of a shoulder spica. Twenty-four hours after a fracture is sustained, the blood is frequently coagulated, diffusion of the anesthetic does not occur and no relaxation results. During the first twenty-four hours, the anesthetic is quite uniformly successful. The only other contraindication is the occasional damage to a large vessel or nerve by the needle. Its use is indicated in all simple fractures of an extremity. If more than one bone is broken, injection will be required at each fracture site. The relaxation usually lasts from one-half to three-quarters of an hour and gives sufficient time for the physician to reduce the fracture, apply splints, take a roentgenogram and, if the position is not satisfactory, attempt reduction again without further injection of the anesthetic. Meantime the patient is awake and cooperative. Local anesthesia can rarely be used in children. It should not be used in patients with open fractures.

Two other forms of regional anesthesia are used, nerve block and field block. Nerve block, or plexus block, requires considerable skill and practice. Brachial plexus block is excellent in cases of fracture of the humerus. Field block does not demand special skill, but does require a considerable amount of anesthetic. Both of these forms may be employed for open fractures.

General anesthesia has been used in patients with fractures for a great many years. Ether is preferred for a long procedure. Nitrous oxide, cyclopropane or ethylene, with oxygen, is suitable for short procedures. Ether gives more complete relaxation. All require the presence of a skilled anesthetist. When the fluoroscope is used in

connection with reduction, there is too much danger of ignition of the ether vapor, or of cyclopropane, or ethylene to permit employment of such anesthetic agents. Gas-oxygen is less dangerous from this point of view, but its administration is difficult in a dark room.

Open (Compound) Fractures. The basic principles in the management of a patient with an open fracture are as follows: treatment of shock and hemorrhage, prophylaxis and treatment of wound infection, accurate reduction and complete immobilization. In actual practice, these three are associated at the same time and disaster may be the result of neglect of any one of them. If a tourniquet must be used, it should be applied as close to the wound proximally as possible since gangrene may result. Intermittent release of the tourniquet may result in profound shock.

Treatment of shock and hemorrhage. Shock and hemorrhage are frequently grave and attention must be devoted to them first.

Morphine is always indicated for pain, except in head injuries, but only in the amount necessary to control pain. In the instance of multiple injuries, including the brain, it may still be given if accompanied by caffeine.

Body temperature must be maintained in some way, but this must be done with judgment and the patient not kept bathed in perspiration, with loss of body fluids.

In most instances a pressure dressing is all that is necessary to control bleeding. The tourniquet has been grossly misused. An ineffective tourniquet has often caused serious loss of venous blood, which ceases as soon as the tourniquet is removed.

The major function of traction fixation as

a first-aid measure before the patient is transported is to prevent or relieve shock and hemorrhage. Traction on a broken extremity relieves pain by putting muscles at rest and it diminishes extravasation by causing relaxed fascia again to exert pressure on tissues within it. Traction also limits further injury due to the churning about of fragments, thereby preventing increased shock and increased hemorrhage.

Fluid replacement is necessary at the earliest possible moment. Loss of plasma from the blood, not lowered systolic pressure, is the early sign of shock. Whether whole blood or plasma expanders are required has now been fairly well standardized by accurate laboratory tests.

Multiple injuries are frequent in patients with open fractures. One must endeavor to determine immediately, and without added trauma or exposure, whether injuries to the brain, spine, chest, abdominal viscera and kidneys are present, are a probable source of shock and hemorrhage, require postponement of any further treatment of the open fracture or require first consideration when the patient's condition will allow any further procedure.

Prophylaxis and treatment of wound infection. This should commence at the scene of accident and should be continued concurrently with the treatment of shock and hemorrhage.

The wound should be covered, if possible, with a sterile dressing. The use of antiseptics and irrigations is contraindicated.

Traction fixation before moving the injured person from the site of accident is important in the prevention of infection. Whether the fracture is opened from within or from without, the tissues are contaminated. Not to put the muscles at rest, and therefore to allow the fragments to move about, increases the area of contamination.

The wounds of open fractures are of three types and with each of them traction fixation is to be employed.

In a type 1 wound, if the open fracture is one in which there is merely a slight wound and if there is no known soiled bone inside the wound, the traction splint will not only protect the underlying tissues but will keep the bone from coming out through the opening and getting dirty or spreading dirt around inside.

In a type 2 wound, if the open fracture is one which has been produced by a blow from some sharp object which penetrated the extremity and if the sharp object was

dirty, causing contamination of the wound the application of traction will keep the contaminating organisms from being spread around underneath the skin.

In a type 3 wound, if the fracture is such that the end of the bone comes out through the skin and becomes dirty, a more difficult decision must be made. One fears the result of carrying soiled bone back into the soft parts, as may happen under traction. This type of fracture is not common and is an injury extremely serious as regards both life and limb under any circumstances. The patient must be operated upon at the first possible moment. In order to transport the patient without danger of added trauma from the fragment of bone which remains inside the wound or without added contamination of the soft parts, the use of traction is proper.

At first, wounds are contaminated, not infected, and this contamination is in large part removable. With laboratory control of the requirements of the circulatory system, shock does not necessitate waiting beyond the optimum time before excision; shock or hemorrhage can be treated and the wound debrided all at the same time. Without chemotherapy, we set an arbitrary limit of six hours from the time of accident within which excision may be done with expectation of success. But the danger of infection is greatly lessened if it can be done in one or two hours instead of six hours. In some instances, when the injured person does not reach the doctor until between six and twelve hours have passed, excision may still be tried, although with much less hope of success, for contamination will usually no longer be limited to the surface. After twelve hours, excision is contraindicated. Operative intervention then must be limited to enlarging the wound, laying open deep pockets and removing gross foreign bodies. With the use of antibiotics from the time of injury to the time of operation, the period during which only contamination may exist and infection may not have set in has been found prolonged in many instances to seventy-two hours or more.

Unless the injured person is known to be immunized by toxoid, tetanus antitoxin should be given immediately to all in whom there is possible clothing or soil contamination. Repeating it is to be considered if there is any further operative intervention after the first week. If the injured person is known to have been immunized by toxoid to

0.5 cc. of tetanus toxoid should be injected, if available. Otherwise, tetanus antitoxin should be administered.

Gas gangrene serum is useless as a prophylactic. It should be used in therapeutic doses on the least suspicion of the presence of gas bacillus infection in the wound.

If it is believed that the excision has been well made, that circulatory disturbance or contamination has not been too severe and that the general condition of the patient is good, primary closure of the wound without a drain is the procedure of choice. This was not true until the antibiotic era. The antibiotics must never be substituted for adequate surgery. Closure may require relaxing incisions or primary split-skin grafts. Partial closure with a drain is not good surgery in these patients. When conditions make it advisable that the wound be left open, it is often proper to do a delayed closure after seven to ten days if the wound is then dressed for the first time and appears clean. This delayed closure does not include undercutting of the edges of the wound.

All pockets should be kept open. If their sides are allowed to fall together, secretions may pocket off, making ideal media for growth of bacteria. Two to four layers of dry gauze act as an effective drain. It must reach every part of the depth of the wound, preventing dead spaces. The wound must never be packed tightly and it should not be dressed frequently.

Without complete immobilization, muscular action may change the site of contamination or infection at any moment. An unpadded plaster encasement, with or without internal fixation or two-pin traction, comes nearest to furnishing complete immobilization of the soft parts in order to prevent or allay infection. This does not include a window in the plaster at the site of the wound, which destroys even pressure and allows edema and stasis of fluid, with increased danger of infection.

If emergency traction, excision, serums and drugs, drainage of the wound and immobilization have not been adequate or successful and infection is established, the principles are the same as in the care of any soft part infection early and of osteomyelitis later, with this difference—in spite of treatment of the infection, one must bend every effort to preserve reduction and immobilization of the fracture. The two problems cannot be separated.

In the prophylaxis and treatment of wound infection, whether early or late, the

virulence and extent of the contamination and the severity of the soft part damage must be considered, as well as the elapse of time. More contamination will usually place in a fracture which is opened from outside than in one that is opened from the inside, but both unquestionably demand excision. Major blood vessel damage is such that the part distal to it cannot survive. The muscle damage may be such that the limb is evident immediately or at the time of excision that a useful limb cannot possibly be obtained. With these factors in mind, amputation should sometimes be performed to save life or prevent prolonged morbidity with a useless extremity as a final result.

Accurate reduction and complete immobilization. It is necessary to save the patient from death due to shock and hemorrhage and from death or loss of limb from infection. It is necessary also to aim for primary union of the fracture at the same time.

Application of traction fixation at the time of accident makes reduction simpler in the operating room. Traction should be continued under all circumstances until the patient is on the operating table and in the form even there.

Unless hemorrhage or the time involved makes it impossible, x-ray examination should be carried out before excision.

In many instances, adequate excision and visualization of the line of fracture and perfect reduction can be obtained by sight rather than by palpation. Its accuracy is important as regards both infection and union. Reduction should not be delayed until infection is controlled.

Complete immobilization is necessary. Excision is to be effective in preventing infection. If the fragments in an oblique fracture are slipping slightly each day, the likelihood that infection will become established is increased. Unquestionably, immediate rigid internal fixation of the fracture is the best answer. A dry gauze drain, without closure of the wound, can be used in the presence of metal. Internal fixation should be rigid. This can be accomplished with screws, plate and screws, or in highly selected cases the intramedullary nail.

There is always the possibility that infection may be spread through the marrow from one end of the bone to the other, but the results of an intramedullary nail are tragic. Possibly an experienced hand might lightly contaminated, well-excised wound, particularly where multiple injuries are present, the general management of the patient

a first-aid measure before the patient is transported is to prevent or relieve shock and hemorrhage. Traction on a broken extremity relieves pain by putting muscles at rest and it diminishes extravasation by causing relaxed fascia again to exert pressure on tissues within it. Traction also limits further injury due to the churning about of fragments, thereby preventing increased shock and increased hemorrhage.

Fluid replacement is necessary at the earliest possible moment. Loss of plasma from the blood, not lowered systolic pressure, is the early sign of shock. Whether whole blood or plasma expanders are required has now been fairly well standardized by accurate laboratory tests.

Multiple injuries are frequent in patients with open fractures. Repeating it is to be considered if there is any further operative intervention after the first week. If the injured person is known to have been immunized by toxoid more than three months previous to injury,

Everyone knows that ecchymosis is one of the cardinal signs of fracture. But not everyone realizes that its location, the time of its appearance and its extent may be valuable indications pointing to important pathologic occurrences and vital therapeutic needs for the best results.

LOCAL CHANGES FOLLOWING FRACTURE

The consensus today, based on both clinical and experimental evidence, supports the view that the repair process following fracture is a local phenomenon. The general state of the patient's health, his age, with the exception of infancy and childhood, the existence of acute or chronic general disease (syphilis, arteriosclerosis, nephritis, tuberculosis, arthritides, cardiac disease) and the existence of generalized metabolic disturbances (osteomalacia, rachitis, scurvy, diabetes) have no proved effect on the rate or degree of healing of a fracture. Of the various endocrine functions, not one has been shown to have any appreciable effect on the actual primary healing process, in the presence either of excessive or of diminished activity. It is true that individual researches may indicate to the worker some effect, but for each contribution of this type one may find, from apparently just as reliable a source, a contradictory conclusion. Despite suggestive reports from certain reliable authors of a correlation between the serum calcium and phosphate values and their interrelationship with fracture healing, extensive checks have failed to support this point of view. Moreover, a patient with a negative calcium balance and with marked generalized bone decalcification has, after sustaining a fracture, shown a normal or increased rate of fracture healing, later decalcifying the callus to the same degree as the rest of the skeleton. On the basis of clinical and experimental findings, major attention should be devoted to the local problems involved in the pathology and healing of fractures.

Consider what actually happens. At the time of injury the bone is broken and, coincidentally, there is a variable degree of damage to the surrounding soft parts by laceration or contusion.

The blood free in the tissues and the dead tissue resulting from the injury constitute irritants. In fact, even with a moderate pathologic condition, the patient may show within a few hours a rise in temperature, an increase in the leukocyte count and a raised sedimentation rate. There is, in effect, an

aseptic inflammation; the parts surrounding the fracture are rapidly infiltrated by hemorrhage, edema and inflammatory exudate. Here, then, is the first clinically applicable knowledge of the pathologic picture. At the time of injury, and for a variable period of from ten to thirty or forty minutes after injury, the part may be said to be in a state of local shock. It is analgesic, after the initial momentary sharp pain of the fracture, and its neuromuscular apparatus is practically paralyzed. A patient seen in this period will state that the arm or leg is "numb." It will be markedly flaccid and relaxed. It is in this stage that a bystander, by merely pulling on the part, can readily and accurately reduce a dislocation or even a badly displaced fracture with practically no pain to the patient. It happens practically every day on some field of sport or athletic activity and is accepted as a matter of course, even by the layman. But only within the last few years has there been an appreciation of its application to the emergency use of traction through the application of Thomas type of arm and leg splints with windlass traction, which is now the approved standard of the American College of Surgeons, as represented by its Fracture Committee. The use of immediate emergency traction on simple fractures, if universally adopted, would constitute the biggest single advance in the treatment of fractures in the present generation.

Following the passing of the short period of local shock, sensation returns to the part and muscle spasm and pain follow. With muscle spasm there is the risk of increased deformity and additional interference with the vascular and lymphatic circulation. Within a few hours, hemorrhagic and inflammatory infiltration has pooled about the site of the fracture, forming a fusiform swelling and exerting lateral pressure on the surrounding soft tissues. The shortened and spastic muscles change from elastic, extensible structures to lardaceous, semisolid masses which can be stretched only with great difficulty, even with damage. These muscles now constitute a mechanical bar to reduction. Had the fracture been reduced and held before this happened, the hardened and less distended tissues would act instead as splinting for the reduced fracture. This is the basis for the general principle that a fracture should be reduced and reduction retained as soon after injury as possible. Since this process is rapidly progressive and is complete within from six to eight hours,

pler by its use, a real gamble may be taken by inserting an intramedullary nail. However, its use in open fractures should be rare. It should never be used in children.

Any metal may be removed if infection sets in or when bony healing has progressed sufficiently. Although ideal, it is questionable whether this method should be used in patients with open fractures by surgeons inexperienced in the rigid internal fixation of closed fractures. Of course, external immobilization is required in addition at the completion of the operation.

Next in order of effectiveness of immobilization is the unpadded plaster encasement. It presents grave dangers and offers less security but is probably safest for the surgeon who treats only an occasional fracture patient.

Skeletal traction, with a distal pin only, Russell traction in patients with fracture of

the femur, adhesive plaster traction, padded plaster of paris encasement and splints of any material do not measure up completely to the requirements for immobilization. Conditions arise in which any one of them may have to be the method of choice in the individual patient. If there is a question of adequate circulation of the part, of the thoroughness of the excision or of the virulence of the contaminant, a closed plaster encasement should not be used for several days at least, but some form of traction and suspension should be used instead which allows observation of the wound and the surrounding tissues.

Pathology and Repair of Fractures

By PAUL C COLONNA, M.D.

PAUL GRENSHAW COLONNA, born in Norfolk, Virginia, educated in Virginia and Maryland, came north for his training in orthopedic surgery. He spent five years as Professor of Orthopedic Surgery at the University of Oklahoma and then went to Philadelphia where he was the Professor of Orthopedic Surgery at the University of Pennsylvania School of Medicine for sixteen years. An interest in anthropology has correlated well with his chosen surgical specialty.

The intelligent care of fractures demands, as a prerequisite, a general knowledge of the pathologic condition accompanying the injury, the factors involved in the process of repair and the correlation of these with the disturbed physiology which one hopes to restore to normal. Without such knowledge, a fracture bids fair to remain an x-ray picture throughout its course. Such a point of view can never lead to really adequate treatment. An understanding of pathology and repair, the biochemical changes and minute cellu-

lar activities brought into play are matters of great academic interest. These processes are reflected in the signs, symptoms and disturbed physiology which indicate the basic principles of treatment. A fracture must not be regarded only as a solution of bony continuity, but equally and sometimes more important is the accompanying trauma to the surrounding soft parts with minor or serious injury to the vital structures such as the skin covering, circulation or nerve tissues.

becomes established as adult fibrous connective tissue, then no bone formation occurs. If this is so, and if our ideas on the deposition of calcium as a result of phosphatase activity within a limited pH range approaching the alkaline side are correct, it would seem that if the acid pH phase is prolonged by reason of the amount of tissue death or by reason of a circulatory status which makes impossible the carrying away of the products of tissue death, the healing tissue may differentiate before any calcium deposition can be effected, with the result that the healing remains fibrous. The deposition of calcium in the lower pH ranges may be so slow that so-called delayed union occurs.

In this understanding of the process lie possible explanations for many of the apparent vagaries connected with fracture healing. It is to be kept in mind that, when local destruction of intrinsic bone circulation has occurred as a result of fracture, then the most important factor in the maintenance of an efficient repair level is the available accessory circulation of the soft parts—blood vascular and lymphatic. On this factor hinges to a large extent how much growth of healing granulation tissue can occur and how soon deposition of calcium in this tissue can take place.

The study of these phenomena has led to an appreciation of the fact that attention to the circulatory efficiency of the part, particularly in its more minute phases rather than in the major vessels, is a big factor in promoting normal, or rather average, healing. This has a definite bearing on the present-day tendency toward pin fixation and open operations, thereby permitting early active mobilization of the part, early intensive physical therapy and elevation, since those three adjuvants, in that order, are the most effective means of improving the local circulatory status.

The pathologic condition of the fracture line is a matter of considerable importance in an evaluation of the suitability of various methods of treatment in a given case.

GUIDES FOR FRACTURE TREATMENT

Some guides for fracture treatment based on the principles of wound healing are as follows.

1. *First aid* in fracture cases should aim at as extensive and complete immobilization of the part as can be achieved and should include fixed traction, if possible, applied as soon after injury and with as little trauma as feasible.

2. *Shock and injury* should be treated coincidentally. Except when the patient is moribund, the treatment of shock should be carried out simultaneously while the fracture is being given early definite treatment.

3. *Reduction* should be accomplished before the muscles and soft parts have lost their elasticity by reason of infiltration of exudate and hemorrhage. This is just as true for traction-suspension, open reduction and fixation, pin fixation or any other method as it is for manual manipulation and plaster fixation. It means that reduction by open or closed methods should be complete within eight to twelve hours, or sooner if possible.

4. That method of treatment which allows the most *active function* of the extremity during bone healing is, if it can be adequately carried out, the best method from the dual standpoint of successful bone healing and of short convalescence time. Whether or not the theoretically best method is practically applicable in the individual case depends upon the analysis of the patient and his lesion, upon the qualifications of the doctor and upon the organization and equipment available.

5. *Physical therapy* should be regarded as an adjunct to, or an inadequate substitute for, active function and both patient and doctor should thoroughly understand this.

6. *Postreduction immobilization* should aim at as rigid fixation of the fragments as possible.

7. Fractures heal primarily by the *formation of callus* about the fracture site and circulatory restoration in the soft parts is a vital factor in the process.

8. In *compound fractures*, the treatment of the wound along with adequate reduction and fixation of the fracture should be accomplished just as soon, in terms of minutes after injury, as it can be done. Early wound treatment with delay in reduction and fixation is a mistake.

The pathologic condition of the soft tissues has a definite bearing on the methods of reduction and should constitute the basis of any intelligent effort at reduction.

Lastly, it is essential to recognize that, for each region of the body, important soft part structures are liable to damage. Examination of the patient includes elimination of the possibility of injury to them. The soft-part lesion, if present, may constitute an urgent reason for altering the method of treatment ordinarily used for the fracture in question.

For instance, in a lesion involving the middle third of the humerus, the radial nerve is

it becomes obvious that one should think of reduction in terms of minutes after injury, not in terms of hours or days. An hour spent in waiting around an accident ward may mean the difference between ease and difficulty of reduction. This is of major importance in any fracture of the shaft of a long bone but of less practical significance in fractures such as Colles' fracture at the wrist and uncomplicated malleolar fracture at the ankle, where muscular resistance is not so potent a factor. It is, however, a matter of considerable import in patients who require skin or skeletal traction. When a patient has waited overnight to have pin or wire or adhesive traction applied, what might have been an easily accomplished reduction by the stretching of elastic and extensible muscle bellies with a minimum of trauma may turn out to be an indifferent reduction accomplished with difficulty through the necessity of dealing with infiltrated, inelastic muscle masses. The blame for failure is placed on the shortcomings of traction and suspension instead of on ignorance of or lack of consideration for the pathologic change going on during the overnight wait. If emergency fixed traction had been applied in the interim, much of the difficulty would have been obviated. When a wait is necessary, this type of traction is the best means of minimizing the potential damage due to delay.

Following this pathologic stage there is clotting, i.e., laying down of a fibrin network in the hemorrhage and exudate in the tissues. This network joins the bone ends and adjacent soft parts in a web of interlacing fibrils along which tissue repair is to take place. The remaining fluid portions of blood and exudate seep to the surface slowly along the tissue planes if the soft parts about the fracture are but little lacerated, or appear rapidly beneath the surface if there has been extensive laceration of the soft parts. The ensuing discoloration of skin due to the presence of the blood pigment in the fluid portion of the blood is known as ecchymosis. It is obvious that an early, rapid appearance of ecchymosis at the fracture site indicates a large amount of tissue damage, being proportionately greater the deeper the involved bone lies from the skin. *Ipso facto*, it indicates the need for methods of treatment which will allow maximum early attention to the pathologic condition of the soft parts.

On the other hand, ecchymosis which appears late, particularly at a point distant from the fracture, indicates a minimal

amount of soft part damage with a more favorable prognosis for the early return of function. If the elbow joint is involved, for example, as in fractures of the radial head or lower humerus and in dislocations, very early ecchymosis on the front of the elbow, sometimes within an hour from the time of injury, indicates extensive laceration of the joint capsule and brachialis anticus and a threat of ossification about the front of the elbow. Special treatment is urgently needed under such circumstances.

As a result of the death of tissue, hemorrhage and progressive circulatory stagnation of lymph and blood following rapidly after fracture, the pH of the local tissue fluid becomes acid. With this acidity, there occurs over the next week or ten days a decalcification of the fracture site.

Coincident with this chemical change, the healing process proceeds, as with any other wound, by the growth of new fibroblastic cells along the fibrin network, from all available connective tissue sources—the marrow cavity, with its so-called endosteum, the periosteum and the fascial planes and muscular stroma, if they are opened into by the fracture.

This healing process is what one would expect in any wound. At some stage during the process, calcium is deposited in the healing tissue to surround the cells. The tissue then is called *callus* instead of granulation tissue. Whether or not osteoid tissue (early callus) contains calcium or merely a pre-osseous substance in which calcium is deposited, whether or not specific bone-forming cells are involved in the process, either by direct growth and migration of "osteoblasts" from adjacent bone and periosteum and endosteum or by "metaplasia" of connective tissue cells in reply to the "physiologic demand," and whether or not ferment activity (phosphatase) is an integral part of the story are at present matters of academic interest. The practical clinical application of this phase of the story lies in the fact that the calcium deposited in the newly formed connective tissue is for the major part derived from local decalcification at the fracture site and that its deposition occurs coincidentally with the alteration of the pH of the tissue fluids locally toward the alkaline side.

Moreover, there is a great deal of evidence to support the viewpoint that this deposition of calcium into the healing tissue to form bone can occur only while the tissue is still undifferentiated. Once the healing tissue

becomes established as adult fibrous connective tissue, then no bone formation occurs. If this is so, and if our ideas on the deposition of calcium as a result of phosphatase activity within a limited pH range approaching the alkaline side are correct, it would seem that if the acid pH phase is prolonged by reason of the amount of tissue death or by reason of a circulatory status which makes impossible the carrying away of the products of tissue death, the healing tissue may differentiate before any calcium deposition can be effected, with the result that the healing remains fibrous. The deposition of calcium in the lower pH ranges may be so slow that so-called delayed union occurs.

In this understanding of the process, the possible explanations for many of the apparent vagaries connected with fracture healing. It is to be kept in mind that, when local destruction of intrinsic bone circulation has occurred as a result of fracture, then the most important factor in the maintenance of an efficient repair level is the available accessory circulation of the soft parts—blood, vascular and lymphatic. On this factor hinges to a large extent how much growth of healing granulation tissue can occur and how soon deposition of calcium in this tissue can take place.

The study of these phenomena has led to an appreciation of the fact that attention to the circulatory efficiency of the part, particularly in its more minute phases rather than in the major vessels, is a big factor in promoting normal, or rather average, healing. This has a definite bearing on the present-day tendency toward pin fixation and open operations, thereby permitting early active mobilization of the part, early intensive physical therapy and elevation, since those three adjuvants, in that order, are the most effective means of improving the local circulatory status.

The pathologic condition of the fracture line is a matter of considerable importance in an evaluation of the suitability of various methods of treatment in a given case.

GUIDES FOR FRACTURE TREATMENT

Some guides for fracture treatment based on the principles of wound healing are as follows:

1. *First aid* in fracture cases should aim at as extensive and complete immobilization of the part as can be achieved and should include fixed traction, if possible, applied as soon after injury and with as little trauma as

2. *Shock and injury* should be treated coincidentally. Except when the patient is moribund, the treatment of shock should be carried out simultaneously while the fracture is being given early definite treatment.

3. *Reduction* should be accomplished before the muscles and soft parts have lost their elasticity by reason of infiltration of exudate and hemorrhage. It means that reduction by open or closed methods should be complete within eight to twelve hours, or sooner if possible.

4. That method of treatment which allows the most *active function* of the extremity during bone healing is, if it can be adequately carried out, the best method from the dual standpoint of successful bone healing and of short convalescence time. Whether or not the theoretically best method is practically applicable in the individual case depends upon the analysis of the patient and his lesion, upon the qualifications of the doctor and upon the organization and equipment available.

5. *Physical therapy* should be regarded as an adjunct to, or an inadequate substitute for, active function and both patient and doctor should thoroughly understand this.

6. *Postreduction immobilization* should aim at as rigid fixation of the fragments as possible.

7. Fractures heal primarily by the *formation of callus* about the fracture site and circulatory restoration in the soft parts is a vital factor in the process.

8. In *compound fractures*, the treatment of the wound along with adequate reduction and fixation of the fracture should be accomplished just as soon, in terms of minutes after injury, as it can be done. Early wound treatment with delay in reduction and fixation is a mistake.

The pathologic condition of the soft tissues has a definite bearing on the methods of reduction and should constitute the basis of any intelligent effort at reduction.

Lastly, it is essential to recognize that, for each region of the body, important soft part structures are liable to damage. Examination of the patient includes elimination of the possibility of injury to them. The soft-part lesion, if present, may constitute an urgent reason for altering the method of treatment ordinarily used for the fracture in question.

For instance, in a lesion involving the middle third of the humerus, the radial nerve is

frequently injured. If this is not noted at the time of the original injury, it may not be discovered until six or eight weeks later when immobilization is ended. Similarly, the median nerve at the wrist may be involved in badly displaced Colles' fractures and in lunate dislocations. The peroneal nerve is often involved in lesions about the fibular neck or by direct violence in this region, though the fracture is of the tibia. Lesions about the internal humeral condyle may involve the ulnar nerve and those about the external condyle may involve radial or superficial radial nerves. Dislocations of the shoulder or surgical neck fractures frequently involve the axillary nerve. Supracondylar fractures of the humerus with displacement are the commonest cause of Volkmann's ischemic contracture. The local tension about the front of the elbow and the state of the radial pulse before reduction, after reduction and in the immobilized position must be carefully noted. One frequently sees patients in whom prompt and adequate provision for the correction of the circulatory embarrassment has aborted a Volkmann's contracture, the very early signs of which were already present when the patient was first seen. Unfortunately, in many subjects, a check on the radial pulse is not considered as part of the examination in handling a lesion of the elbow. Knowledge of this complication of supracondylar fractures requires immediate concern for the radial pulse.

There are numerous examples of impending disaster lurking in lesions of the soft parts complicating a fracture. Each region of the body has its "soft part trap," so to speak, and it behooves the surgeon to know these so they can always be looked for, anticipated and, if possible, avoided.

If the laceration extends through the skin, allowing communication between the fracture and the outside air, the fracture assumes a specific significance as a compound fracture.

DELAYED UNION AND NONUNION OF FRACTURES

Delayed union and nonunion may be epitomized in the following brief statements.

1. All fractures heal as do wounds elsewhere unless there is a mechanical, chemical or anatomic bar to healing. This healing, in comparison with that of wounds of the soft place through the medium of

new connective tissue known as *granulation tissue*. When referring to delayed union and nonunion, one in reality refers to a delay or failure in the process of calcium deposition in the healing connective tissue, which is commonly designated as new bone formation. The anatomic bar to healing lies in the absence of a sufficient accessory circulation to compensate for that destroyed by trauma and to remove adequately and rapidly the products of tissue death. Some regions of the body, even under apparently optimum conditions, are characterized by slow average healing time and by the frequent occurrence of delayed union and nonunion in adults. The neck of the femur (subcapital or midcervical), the junction of the lower and middle thirds of the tibia, the scaphoid of the carpus (proximal half) and the base of the fifth metatarsal are characteristic regions.

In patients who have fractures in these regions and simultaneous fractures in regions not so characterized, there is no perversion of healing in the latter, all other factors except location being equal.

2. Variations in the character and amount of the healing process in bone following a fracture are dependent on factors limited to the region of the body involved, quite independent of the subject involved. Slow union and nonunion in the adult are not dependent on the age per se of the patient, on his general state of health, on the presence of a chronic general disease such as syphilitic or cardiovascular or renal disease, on general wasting due to other causes, on general metabolic disturbances affecting either the general calcium and phosphorus metabolism (osteomalacia) or other phases of metabolism (diabetes) or on acute infectious disease. Nonunion, except for mechanical reasons, is practically never seen in children.

3. The four factors involved in the mechanism of the healing of fractures and capable of being clinically influenced are, the local pathologic condition, the growth of granulation tissue, an available local source of calcium for the ossification of the healing tissue and a proper biochemical status of the local tissue fluids throughout the healing process.

Local Pathologic Condition. The items of importance under this factor are: (a) The amount of tissue necrosis. When massive, it destroys the available sources for the growth of granulation tissue and under all circumstances creates a pH to the acid side in the hematoma and tissue fluid. The

the fracture. This pit is of importance in the production of the local source of calcium and is the essential early stage of the biochemistry of the tissue fluid. An acid pit interferes with calcium deposition.

b. The growth of granulation tissue is influenced by the hematoma or blood clusion at the site of the fracture: first, by the fibrin and fluid content locally and, second, by the establishment of a local source of calcium, holding the freed calcium in situ.

c. The significance of the circulatory status in the different stages of fracture healing lies in its influence on the growth of granulation tissue and on the establishment and utilization of a local source of calcium through its effect on the pit of the tissue fluids.

d. Chemical influences which have an effect on the growth of granulation tissue are the local use of chemotherapeutic agents or disinfectants. The use of radiation diathermy and too early mobilization are physical influences.

e. The mechanical element, i.e., the interposition of living or dead material impermeable to the growth of granulation tissue between the fragments.

Growth of Granulation Tissue. The items of importance under this factor are as follows:

a. All other things being equal, the amount of callus produced is directly proportional to the amount of granulation tissue produced.

b. The destruction of available sources for the growth of granulation tissue.

c. The anatomic characteristics of the part regarding sources for the growth of granulation tissue and accessory circulation.

d. The amount of fluid persisting for a long period at the site of the fracture.

e. Chemical and physical influences and the mechanical element which limits the growth of granulation tissue between the fragments.

Available Local Source of Calcium. The items of importance are the amount of bone necrosis, the density and degree of fragmentation of the necrotic bone, the influence of fibrin and collagen in fixing the calcium locally through chemical affinity and the biochemical status of the local tissue fluids.

Proper Biochemical Status of the Local Tissue Fluids throughout the Healing Process. This factor involves the necessity in the local tissue fluid of a pit on the acid side in the early days following the fracture in connection with the establishment of a local

source of available calcium and a reversion of the pit toward the alkaline side before the calcium made available can be to any extent deposited in the new tissue to form bone. The constituents normally involved in this phase of the process are the amount of tissue necrosis and the blood and lymph circulatory status of the part.

Prevention of Delayed Union and Nonunion. What, then, can be done to prevent delayed union and nonunion? The objects of concern are:

1. Early and accurate replacement of displaced fragments, with assurance at the time of reduction that there is no interposition of tissue.

2. The restoration to normal of the lymph and vascular circulation as rapidly as possible through elevation of the part, early physiotherapy and the use of functional muscular activity whenever possible.

3. The meticulous care of wounds in cases of compound fracture. Gentleness and conservation of sound tissue are not incompatible with thorough and efficient debridement. It pays to be conservative on the score of considering a debrided wound safe to sew up tightly. Chemical disinfection of a wound is not desirable. No method of wound treatment which creates tension in the tissues can be considered sound.

Where facilities for operative work on bone are of high standard as regards equipment, technique and personnel, many feel that in an open fracture rigid fixation of the fragments by plate or screw at the time of the debridement, with the wound left open, is justified through minimizing the chances for delayed union or nonunion by eliminating the foothold for infection engendered by constant movement of the fragments. Such a procedure is never justified unless the facilities for carrying it out are as specified.

1. Where the facilities for operative work on bone are of the highest standard as regards equipment, technique and personnel, it is today the belief of many that operative reduction, with internal fixation sufficiently rigid to permit postoperative active mobilization in balanced suspension, is the ideal method for fractures of the long bones in adults. It is certainly very doubtful whether operative reduction and internal fixation are justifiable, except on the basis of absolute necessity, unless rigid fixation cannot otherwise be secured. The early active use of the musculature as an aid to the minute circulation is one of the chief recom-

mentations for the use of the method. Any necessity for postoperative immobilization nullifies this important advantage. Moreover, it is felt that if open reduction is indicated, it should be done within the first few hours after injury, in order that the blood, dead tissue and inflammatory exudate can escape through the operative wound or can be removed. This minimizes the burden placed on the local circulation in removing products of tissue death in order that the *pit* of the tissue fluids can revert toward normal as rapidly as possible, thereby facilitating the early deposition of calcium in the undifferentiated healing tissue.

When the fracture lies in a region characterized by slow or indifferent healing, the rigid internal fixation can be augmented by the use of osteoperiosteal or other forms of grafts as prophylaxis against nonunion.

It is to be strongly stressed that the use of operative reduction as a method of choice can be conscientiously adopted only when exacting conditions as to organization, equipment, personnel and technique can be met and when the mechanical principles involved in securing rigid fixation capable of standing functional strain are thoroughly understood.

TREATMENT

There are many reasons to believe that a bone graft does not grow but acts as a scaffolding and as a source of calcium for the calcification of the healing granulation tissue and is one of the sources for the enzymes concerned in the calcium deposition. The removal of fibrous tissue and sclerotic bone aids circulatory increase and granulation tissue growth and invasion. The graft rarely presents sufficient fixation to permit early active movement, especially since osteoperiosteal or cancellous grafts offer the most effective osteogenetic qualities—a fact which has been demonstrated both clinically and experimentally. If possible, there should be additional rigid fixation, obtainable from plate, screw or other rigid media when feasible, such as intramedullary nailing or massive bone graft, for this permits earlier activity. The postoperative treatment should follow the same prin-

ciples as those laid down for the prevention of delayed union and nonunion.

In addition to the prophylactic measures which may be employed against delayed union and nonunion, the following rather conservative measures are available:

1 Needling of the fracture site: This consists of passing a sharp heavy needle repeatedly about and through the fracture site, producing a certain amount of tissue stimulation and hemorrhage about and between the bone ends and setting up a variable degree of inflammatory reaction. According to one school of thought, this may stimulate osteoblasts to produce bone; according to another, it recreates the original pathologic conditions of the fracture and is followed by ossification in accordance with the conditions which obtain in fracture repair. At any rate, this procedure is followed by union in a certain number of cases. There are no positive criteria whereby one may gauge what fractures are apt to respond to this treatment.

2 The injection of whole blood between and about the bone ends: The same objection applies here as in the case of needling without injection. In addition to whole blood, various other mildly irritating substances have been employed with similar results. The use of calcium emulsions for injection has been attempted, but has not given very promising results. In instances of late nonunion, this method is not applicable. Although the successful use of this procedure has been reported, it does not seem on the whole to be any more valuable than plain needling.

3. The use of Bier's hyperemia intermittently over a considerable time: The effect here is again on a circulatory stimulation basis. This method is not in general use today for many practical reasons, yet it is physiologically sound in producing an increase in the blood supply locally.

4. Cotton's method of tapping the greater trochanter with a mallet. This technique has been employed in stimulating a delayed union in fracture of the neck of the femur.

5 Mommensen's method of subminimal stimulation. This is of particular use in stimulating and hastening delayed union of the

Figure 3. Massive onlay graft.

Figure 4. Inlay graft.

tibia. In this method, a suspended mallet is attached to a brace which is arranged to strike the heel of the foot by the patient controlling the mechanism by hand.

6. The initiation of cautious weight bearing in patients with fracture of the lower extremity, either with a so-called *Bolter* walking iron or walking plaster.

7. The drilling or boring of numerous holes in the bone cortex after an open exposure of the fracture site. This creates channels through the sclerotic bone for revascularization of the fragments and may be very helpful.

Perhaps the most successful of these methods is based on the following three principles: removal of the avascular scar tissue between the separated bone ends, the bringing of healthy bone into close contact, locally bringing to the part additional bone elements which may act as a scaffolding along which healthy granulation can invagate itself.

In addition to these more or less conservative methods of stimulating bone healing in delayed and nonunion of fractures, one must consider the great value which the different types of bone grafting offer. One may select the homogenous bone graft when there is an area or a large cavity to be filled in, as this type of graft allows using the bone bank. This method has its vigorous adherents because of its availability and because of the ease of storing large quantities of bone. But it has its great limitations, one of these being that, statistically, bone union can be more successfully obtained with the autogenous type of graft than with the homogenous. However, the use of homogenous bone provides a valuable method of bone grafting and should be available in all reconstructive work on the skeletal system.

The autogenous graft is available within limited amounts but has been used most successfully by a great number of surgeons for many years. The tibial graft introduced by Albee many years ago opens up a wide field for the application of bone grafting. Cortical bone is available from any of the long bones that are superficially placed, espe-

cially the rib and fibula. The osteogenetic power of the rib and the tibia makes them favorite sites of election, but any and all of these cortical bone-grafting methods can be improved by additional use of cancellous bone packed in and about the site of the delayed union or ununited fracture. The crest of the ilium is a favorite site for obtaining cancellous bone.

All of the grafting methods should follow the general rules of fracture treatment, that is, fresh bone surfaces apposed and rigid immobilization for a sufficient time to allow bone union.

The massive onlay graft (Fig. 3) has much to recommend it. It was primarily popularized by Phemister and Henderson.

The inlay type graft (Fig. 4) represents a common method of treatment.

The osteoperiosteal type of graft does not give the rigid immobilization from the graft but brings many of the osteogenetic elements in close contact at the site of delayed union or nonunion.

The sliding type of graft is often utilized because of the ease of application and because it does not require a separate incision. It does not, however, produce statistically as high a percentage of bone union (Fig. 5).

Another method is the dual graft popularized by Boyd (Fig. 6). This consists of two grafts placed on either side of the fracture site and held by through-and-through screw fixation giving rigidity. Frequently it is augmented by cancellous bone packed in and about the site of fracture. It has the particular advantage of bringing a great mass of bone, both cortical and cancellous, to the site and has produced a most satisfactory percentage of successes, particularly when used with many difficult types of nonunion, such as in a fractured bone of a congenital pseudoarthrosis patient.

The intramedullary type (Fig. 7) is not as popular today as formerly and should be used only as a last resort. The medullary cavity is blocked by inserting a large graft into the marrow cavity.

Fractures and Dislocations

Fractures and Dislocations of the Upper Extremity and Spine

By SAM W. BANKS, M.D.

SAM WALLACE BANKS, a North Carolinian by birth, was educated at the University of Richmond and the University of Chicago. Trained in anatomy, his early interest in investigation centered about the bacteriology and immunology of chronic staphylococcal osteomyelitis. He has made many contributions to the literature of orthopaedic surgery and is Associate Professor of Orthopaedic Surgery at Northwestern University.

THE HAND

Fractures of the Distal Phalanx. These fractures usually are the result of direct, crushing violence and are associated with contusion of the soft tissues and hemorrhage beneath the nail. They are frequently of the comminuted variety. There is ordinarily little displacement of fracture segments and, in the absence of an open wound, the fingers should be immobilized on a curved metal or plaster splint for three or four weeks. Open fractures must be promptly debrided, explored and the bone fragments reduced. Small fragments of bone may be removed if necessary, but large pieces should be aligned for maximum length and shape of the phalanx. Primary arthrodesis of the distal interphalangeal joint is justified if the articular surface is irreparably damaged. An intramedullary pin traversing the distal and middle phalanges facilitates fixation and early fusion. The wound should be closed either by suturing the skin margins or by using a skin graft. Every effort should be made to salvage as much of the finger as possible. Secondary infection is not uncommon and requires vigorous treatment.

Fractures of the Middle Phalanx. Displacements due to injuries of this phalanx depend on the action of the tendon of the flexor digitorum sublimis as related to the fracture site (Fig. 8). If the site is proximal

to the tendon attachment, it will result in flexion angulation of the distal fragment and phalanx, with the proximal fragment in extension. If the site is distal to the insertion of the tendon, it will produce flexion of the proximal fragment and dorsal displacement or angulation of the distal fragment. It is important to recognize these two types of displacement if failure in correcting the deformity is to be avoided.

Reduction is accomplished by re-aligning the distal fragment on the proximal one with the patient under local anesthesia. The digit is immobilized either by applying a skin-tight plaster splint with the interphalangeal joints in flexion or, preferably, by use of a forearm cast which includes the finger. The latter procedure is especially suitable when the fracture is unstable and the deformity is likely to recur. Skeletal traction obtained by a transversely placed pin in the distal phalanx and attached by rubber bands to a wire projecting from a forearm cast is necessary in some oblique and comminuted fractures. Union can be expected to take place in four weeks.

Fractures of the distal end and comminuted fractures elsewhere in the bone may require continuous traction and cast (Fig. 9).

Fractures of the Proximal Phalanx. The proximal phalanx is fractured almost twice as often as the middle or distal phalanx.

Figure 8 Drawings showing deformities of fractures of the phalanges and metacarpal bones. Note the methods for correcting the alignment. The interphalangeal and metacarpal-phalangeal joints should be immobilized in some degree of flexion whenever possible.

The fracture is usually transverse through the middle third of the bone but may occur in any portion and may frequently be comminuted or open. It either results from a force directed upward from the distal end of the finger or it may be produced by a blow over the bone. The deformity is usually one of forward angulation due to contraction of the lumbricals and interosseous muscles, which normally flex the proximal phalanx and extend the distal interphalangeal joints (Fig. 10).

Treatment consists of a manual reduction of the fracture under local anesthesia. Alignment is brought about by flexing the extended distal fragment on the proximal one. The finger is then immobilized in a forearm cast which includes the involved digit with the metacarpal-phalangeal and interphalangeal joints in a moderate degree of flexion (Fig. 11). Comminuted but stable fractures may be treated in the same way. Unstable, oblique, spiral or comminuted fractures require continuous rubber-band traction from the ends of a pin which has been inserted transversely through the distal phalanx. The finger is supported on a curved splint which forms part of the forearm cast; it must not be kept in extension on a banjo splint, for this will lead to contractures of the collateral ligaments of the metacarpal-phalangeal joints and permanent crippling of the hand. Proper alignment is important because resulting rotary or angular deformities with overlapping digits may require osteotomy to

restore satisfactory function of the hand. Union is usually effected in four to six weeks, although it takes much longer to mobilize the finger joints and restore full function of the hand. Paraffin baths are perhaps the best and cheapest form of physical therapy for painful, swollen and stiff joints of the fingers. Forceful manipulation delays recovery and must be avoided. The patient should be encouraged to move the digits actively during the period of cast treatment and especially after immobilization is discontinued.

Avulsion of the Extensor Tendon of the Fingers. A common injury which is frequently mistreated is that of an avulsion fracture of the proximal and dorsal portions of the distal phalanx resulting from a blow on the end of the finger while the distal interphalangeal joint is actively extended. The result is the typical drop or mallet finger seen frequently in baseball players. This condition can also result from a tear of the extensor tendon of a finger at the point of its attachment to the base of the distal phalanx. It is usually a subcutaneous injury without an external wound. Roentgenograms may show a separated small fragment of bone. Pain and swelling may be minimal, but the flexed position, the loss of active extension of the distal phalanx and the local tenderness are diagnostic.

Treatment is the same whether a fragment of bone is torn off by the tendon or the tendon is ruptured at its insertion. In both cases the finger is immobilized for six weeks with

the distal interphalangeal joint in maximum extension and with the proximal joint flexed 45 degrees in order to relax the flexor profundus tendon. A molded plaster cast which extends from the tip of the finger to the metacarpal-phalangeal joint is highly satisfactory, although a metal splint will serve just as well. Intramedullary fixation is recommended by some surgeons but should be reserved for exceptional cases. Open reduction and tendon suture are rarely necessary in acute cases but may be necessary to restore extension of the distal phalanx in instances of neglect.

Dislocation of the Metacarpal-Phalangeal Joint of the Thumb. Posterior dislocation of the proximal phalanx on the first metacarpal bone may result from a fall on the hand or a blow on the hyperextended thumb. The anterior capsule is torn and in many instances the proximal end of the metacarpal bone is protruded through the defect and may interfere with the reduction. The patient complains of pain, deformity and loss of function of the metacarpal-phalangeal joint. The proximal end of the phalanx can be palpated prominently posterior to the distal end of the metacarpal bone. Roentgenograms should confirm the finding.

The dislocation can be reduced in most instances by downward traction on the thumb and countertraction on the forearm. The reduction may be facilitated by hyper-

extension of the thumb in order to approximate the end of the proximal phalanx to the metacarpal head, after which the thumb is re-aligned. In other cases, the head must

Figure 10 Fracture of the proximal phalanx. The characteristic volar angulation is seen.

Figure 9 T fractures of the middle phalanges of the long and ring fingers. Note the stippled deformities of the articular surfaces of the middle phalanges of the long and ring fingers. They can usually be reduced by side-to-side compression of the fragments or by traction through the distal phalanx.

Figure 11 Forearm cast which includes one finger with the digit in flexion at all joints. This is a satisfactory means of immobilizing fractures of a metacarpal bone or the proximal and middle phalanges.

be pushed backward through a rent in the anterior capsule to achieve reduction. Occasionally the flexor pollicis longus tendon becomes caught around the metacarpal bone, necessitating open reduction. After open or closed reduction, the thumb is immobilized in a forearm cast which should extend as far as the distal phalanx of the thumb. The cast may be removed after three to four weeks, when active motion can be resumed.

Fractures of the Metacarpal Bone of the Thumb. Fractures of the shaft of the metacarpal bone of the thumb are a common occurrence because of the exposed position of this organ. The fracture takes place in any portion of the bone and may assume a transverse, spiral or oblique direction. Comminution is frequently encountered. There also may be marked angulation or overriding at the site of the fracture.

The diagnosis is based on the history of the injury with resulting pain, swelling, deformity and loss of function of the thumb. Roentgenograms will reveal the exact nature of the fracture.

Simple transverse fractures with overriding

may be reduced by traction and counter-traction or by angulation to engage the ends of the fragments and effect their realignment distally and proximally. Immobilization is obtained by a forearm cast which extends to and encircles the thumb as far as the distal phalanx. Severely comminuted and unstable fractures are treated by skeletal traction similar to that used for the Bennett fracture (Fig. 12). Union occurs in four to six weeks. The final result is usually satisfactory.

Bennett's Fracture-Dislocation of the Thumb. There are two fractures which occur at the base of the first metacarpal which are common and characteristic. One is a fracture about $\frac{1}{2}$ inch from the base (Fig. 12) which may be transverse or comminuted and the other is the so-called Bennett's fracture. The latter is distinct in both diagnosis and treatment from the other types of fractures and is, moreover, a potentially disabling injury of the hand which therefore requires special attention.

Bennett's fracture and resulting dislocation involve the proximal articular surface of the metacarpal of the thumb and the ad-

adjacent bone. The fracture usually results from a force which drives the metacarpal bone up against the multangulum majus and shears off a triangular fragment on the volar side of its base. Consequently the normal stability of the metacarpomultangulum majus joint is lost and the main fragment and the two phalanges dislocate proximally and posteriorly. The small anterior fragment usually maintains its normal relationship to the multangulum majus.

Characteristic signs of this fracture-dislocation are painful motion, local tenderness and marked swelling at the base of the first metacarpal. Roentgenograms are necessary for complete diagnosis.

Reduction is obtained by downward traction on the thumb so that the main fragment of the metacarpal bone approximates the small fractured piece left in situ. Six weeks are required for solid union to occur. It is necessary to maintain continuous skeletal traction during this time. This can be achieved by drilling a wire transversely through the proximal phalanx and attaching it, by means of rubber bands, to a small out-rigger which projects from the forearm cast (Fig. 13). End-to-end approximation can be aided by a pressure dressing over the dorsal aspect of the proximal end of the metacarpal. Roentgenograms should be made two days after traction is commenced to determine whether reduction has been effected and at weekly intervals for three more weeks to make sure that alignment is maintained. Union, as confirmed radiologically, should take place within six weeks.

If the fracture is impacted with downward displacement of the small fragments—which, fortunately, is rare—and both the small and the major fragments are pulled distally by the traction, satisfactory reduction cannot be obtained without recourse to surgery (Fig. 14). The reduction must be accurate

in all cases for incongruous joint surfaces lead to early traumatic arthritis of the metacarpal-carpal joint and marked disability of the thumb.

Fractures of the Metacarpal Bones Exclusive of the Thumb. Fractures of the metacarpal bones are produced indirectly by violence directed upward through the knuckles or directly by a blow to the dorsum of the hand. The most common fracture is a transverse one with impaction and dorsal angulation. Reduction is accomplished by extending the distal fragment into alignment with the proximal portion of the bone. A forearm cast is applied which includes the hand and the finger corresponding to the injured metacarpal.

Transverse fractures of the shaft of the bone with overriding are reduced by manipulation, using the angulation method. The fragments are manually angulated dorsally so as to engage the bone ends, after which reduction is completed by extending the distal fragment. Open reduction is occasionally indicated because not all of these fractures can be adequately reduced by manipulation. Skeletal traction through the corresponding finger cannot usually mobilize the distal fragment sufficiently to effect a reduction.

Oblique or spiral fractures of the metacarpal bone with slight overriding can be treated by continuous traction by means of a threaded wire drilled through the middle phalanx with the interphalangeal and metacarpal-phalangeal joints flexed on a curved wire or metal splint which is incorporated in a forearm cast. The patient is encouraged to move the distal phalanx to prevent fixation of the tendons by adhesions. Traction may be discontinued at the end of four weeks in the presence of adequate early callus, although six weeks or more may be required for complete healing. Open reduc-

Figure 13. Type of cast and skeletal traction used for fractures and fracture-dislocations of the metacarpal bone. The web of the thumb must be well padded to prevent pressure sore.

Figure 14 Bennett fracture treated by open reduction after failure of skeletal traction A, Lateral view showing persistent displacement of small fragment. B, Pin fixation following open reduction C, Final result after removal of pins

Figure 15. Impacted fracture of the neck of the fifth metacarpal bone. A, Before reduction, B, after reduction and application of cast.

tion and internal fixation by screws designed for this purpose are justified in some cases.

Fractures through the neck of the metacarpal bones involve most often the fifth metacarpal (Fig. 15). They result most frequently from a direct blow to the head of the metacarpal bone, as happens especially in fist fights. The distal fragment is forced volarward and usually impacts into the end of the proximal fragment. Reduction is effected, with the patient under local or general anesthesia, by bumping the distal fragment and restoring bone alignment—a procedure which often requires considerable force. It should be emphasized that this deformity cannot be corrected by traction on the extended finger, since the collateral ligaments of the metacarpal-phalangeal joints are relaxed in this position and the traction force is not transmitted to the metacarpal bone. Some surgeons recommend that reduction be effected by applying upward pressure on the distal end of the proximal phalanx after putting the metacarpal-phalangeal and proximal interphalangeal joints in 90 degrees of flexion. In other cases the impaction is best corrected by pressure applied to the volar aspect of the distal fragment by the physician's index finger, while a counterforce is made over the site of fracture with the thumb (Fig. 16). The digit is immobilized in a flexed position following restoration of alignment of the metacarpal bone. A band of plaster is placed

about the wrist. A splint of plaster is made to extend distally from it over the metacarpal bone, around the finger and back to the volar aspect of the wrist. The plaster is molded so as to exert upward pressure on the distal fragment of the metacarpal bone. A pad over the flexed proximal interphalangeal joint avoids pressure necrosis. Roentgenograms are made at the end of ten days because the tendency for the deformity to recur is greatest at that time. Union is usually sufficiently advanced at the end of four weeks so that the cast may be discarded and function resumed. Malunited fractures, with the metacarpal head projecting prominently in the palm, may require surgical correction.

THE WRIST JOINT

Fractures of the Navicular Bone. The navicular bone is the most commonly injured bone in the wrist. Trauma to this bone is especially frequent in young persons who engage in sports and similar physical activities. Fractures result from a fall on the outstretched hand, the force of which compresses the navicular bone between the trapezium distally and the end of the radius proximally. The same type of fall may produce a Colles' fracture in older individuals and a fracture of the distal portion of the shafts of the radius and ulna in young children. Navicular bone fractures offer an excellent prognosis for union and restitution of normal wrist function, provided the injury is recognized early and proper treatment is instituted.

Fractures are of three varieties, based on anatomic location. They are, respectively, fractures through the distal portion or tubercle, through the waist or midportion, or through the proximal third of the bone. Fractures through the waist or midportion are more common than those of the other two varieties (Fig. 17). Nonunion is the rule in fractures of the body, if they are not diagnosed accurately and treated properly.

The pain may be so slight as not to induce the patient to seek medical care. The swelling is most marked in the radial half of the wrist joint and restricts motion. Tenderness is elicited over the navicular and especially the anatomic snuff box, which itself might become obliterated by the swelling. The diagnosis should be suspected when these findings are present and confirmed by adequate roentgenograms, including anteroposterior, lateral and oblique views of the wrist. In some cases the fracture line may

Figure 16 Alternate method of reducing impacted fracture of neck of fifth metacarpal bone

Figure 17. Anteroposterior views of fracture of navicular bone. A, Before treatment; B, the final result

be so faint that it cannot be detected on the x-ray film. In these patients, the diagnosis is usually a sprain of the wrist and treatment is accordingly misdirected.

It is safest, therefore, to treat all so-called sprained wrists as though they were fractures of the navicular bone and apply a forearm cast which encases the hand up to the distal flexion crease and extends to the thumb as far as the distal phalanx. The wrist is placed in dorsiflexion and the thumb in neutral position. The cast will relieve symptoms and also immobilize a fracture when present (Fig. 18). If, after three weeks of immobilization, the x-ray picture again shows no fracture line, the cast is discarded and the wrist is permitted to resume function. If, on the other hand, a fracture is demonstrated, a similar snug-fitting plaster cast is applied and immobilization is continued until union is demonstrated on the roentgenograms. The cast may be changed at intervals of six weeks, at which times roentgenographic checks should be made to determine the degree of healing.

Fractures through the tubercle, or the extra-articular portion of the navicular bone, retain an adequate blood supply and union occurs in about six weeks. Fractures through the body, or waist, of the bone usually require three to six months to unite. Practically all fresh fractures of the navicular bone will heal if uninterrupted immobilization of the wrist is continued long enough,

which may be up to twelve months. Loss of blood supply to the proximal fragment at the time of injury may prevent union and a satisfactory result in some cases (Fig. 19).

Nonunion may be due to one or more of the following factors: failure to recognize an acute fracture or to institute immediate cast immobilization and continue it until union is shown on the roentgenograms, an insufficient blood supply with resulting necrosis of the proximal fragment.

Nonunion with two viable fragments is compatible with normal functioning of the wrist. If pain is present, union may be achieved by means of an intramedullary bone graft obtained from the styloid process of the radius. The styloidectomy will at the same time relieve the navicular bone of pressure which, in some patients, may cause pain at the extremes of flexion and extension.

Nonunion, which is accompanied by aseptic necrosis of the proximal fragment, offers a less favorable prognosis. The clinical diagnosis of the necrosis can be made only with the aid of roentgenograms. Immobilization of the fracture in a cast causes the viable distal fragment and the surrounding living bones to undergo atrophy of disuse, while the dead proximal navicular fragment will retain its original density. After eight to ten weeks of treatment in a cast, x-ray evidence will show the necrotic proximal fragment to have a relatively high and unchanged density, and the living distal frag-

Figure 19. Aseptic necrosis of navicular bone following fracture and union. Note unchanged density of proximal half, compared to atrophic distal portion and other carpal bones, due to osteoporosis from cast treatment of original fracture.

Figure 17 Anteroposterior views of fracture of navicular bone A, Before treatment; B, the final result.

be so faint that it cannot be detected on the x-ray film. In these patients, the diagnosis is usually a sprain of the wrist and treatment is accordingly misdirected.

It is safest, therefore, to treat all so-called sprained wrists as though they were fractures of the navicular bone and apply a forearm cast which encases the hand up to the distal flexion crease and extends to the thumb as far as the distal phalanx. The wrist is placed in dorsiflexion and the thumb in neutral position. The cast will relieve symptoms and also immobilize a fracture when present (Fig. 18). If, after three weeks of immobilization, the x-ray picture again shows no fracture line, the cast is discarded and the wrist is permitted to resume function. If, on the other hand, a fracture is demonstrated, a similar snug-fitting plaster cast is applied and immobilization is continued until union is demonstrated on the roentgenograms. The cast may be changed at intervals of six weeks, at which times roentgenographic checks should be made to determine the degree of healing.

Fractures through the tubercle, or the extra-articular portion of the navicular bone, retain an adequate blood supply and union occurs in about six weeks. Fractures through the body, or waist, of the bone usually require three to six months to unite. Practically all fresh fractures of the navicular bone will heal if uninterrupted immobilization of the wrist is continued long enough,

which may be up to twelve months. Loss of blood supply to the proximal fragment at the time of injury may prevent union and a satisfactory result in some cases (Fig. 19).

Nonunion may be due to one or more of the following factors: failure to recognize an acute fracture or to institute immediate cast immobilization and continue it until union is shown on the roentgenograms, an insufficient blood supply with resulting necrosis of the proximal fragment.

Nonunion with two viable fragments is compatible with normal functioning of the wrist. If pain is present, union may be achieved by means of an intramedullary bone graft obtained from the styloid process of the radius. The styloidectomy will at the same time relieve the navicular bone of pressure which, in some patients, may cause pain at the extremes of flexion and extension.

Nonunion, which is accompanied by aseptic necrosis of the proximal fragment, offers a less favorable prognosis. The clinical diagnosis of the necrosis can be made only with the aid of roentgenograms. Immobilization of the fracture in a cast causes the viable distal fragment and the surrounding living bones to undergo atrophy of disuse, while the dead proximal navicular fragment will retain its original density. After eight to ten weeks of treatment in a cast, x-ray evidence will show the necrotic proximal fragment to have a relatively high and unchanged density, and the living distal frag-

Figure 18. Photographs showing plaster cast used in the treatment of fracture of the navicular bone. The plaster is molded well in the palm and permits full flexion of the fingers.

Figure 19. Aseptic necrosis of navicular bone following fracture and union. Note unchanged density of proximal half, compared to atrophic distal portion and other carpal bones, due to osteoporosis from cast treatment of original fracture.

ment to have a low atrophic density (osteoporosis). In spite of this complication, cast immobilization must be continued without interruption, for consolidation might occur as blood vessels extend across the fracture site and gradually replace the dead fragment by new living bone through the process of creeping substitution. The end result may be very satisfactory.

If union does not occur between a live distal and a devitalized proximal fragment, disabling arthritis of the wrist, which is difficult to relieve, is sure to result. Of the numerous corrective procedures which have been recommended for the treatment of nonunion, radial styloidectomy without excision of the dead fragment combined with an intramedullary bone graft across the fracture site is preferable, provided the dead fragment is intact and the symptoms are relatively mild. If union occurs, it will bring about gradual revitalization of the fragment, this may be checked by serial roentgenograms taken at three- to six-month intervals. The bone fragment will gradually appear mottled or even cystic as the high density necrotic bone is replaced by low density atrophic living bone. This process spreads from the fracture site to the proximal extremity of the fragment. The replacement will be complete when the bone reassumes a more or less homogeneous appearance and trabecular structure, but, in spite of successful union and complete restitution of the

necrotic bone, arthritis of the wrist joint may eventually occur.

In the presence of both nonunion and disabling arthritis (Fig. 20), excision of the devitalized fragment alone is rarely successful in relieving the wrist symptoms. The simple operation of styloidectomy offers a satisfactory prognosis, but arthrodesis is the only procedure which will definitely restore a painful wrist to satisfactory usefulness (Fig. 20).

Dislocation of the Lunate Bone. Although fractures of the carpal bones other than the navicular are uncommon, dislocations of the lunate bone are common (Fig. 21). This bone and the navicular form the junction between the radius and the hand. The proximal convex surface of the lunate articulates with the lower end of the radius medial to the navicular and with the cartilaginous disk of the distal radioulnar articulation. The distal surface of the lunate is deeply hollowed to accommodate the head of the capitate and the adjacent portion of the hamate bone.

Dislocation of the lunate results usually from a hyperextension injury, such as may occur from a fall on the dorsiflexed hand. The injury may cause the ligaments between the capitate and lunate and lunate and radius to rupture, thus permitting the lunate bone to rotate forward. The latter may be partly or wholly dislocated and come to rest anterior to the distal end of the radius and

Figure 20. Advanced arthritis of wrist secondary to nonunion of navicular, with necrosis of proximal fragment. Pain was relieved and motion improved by styloidectomy.

Figure 21. A, Drawing showing anterior dislocation of the lunate bone. B, One method of closed reduction. C, Leather molded cock-up splint used during the convalescent period.

beneath the flexor tendons of the wrist and the median nerve.

Clinically the patient experiences great pain and swelling of the wrist with limitation of movement. The fingers are held in semiflexed position. A characteristic sign which may suggest the diagnosis is that of pain or tingling in the distribution of the median nerve. This is due to direct pressure on the nerve by the forwardly displaced lunate crowding the carpal tunnel. Another characteristic sign, but one which is not always present, is that of alteration in the relative positions of the heads of the second, third and fourth metacarpals. Normally the knuckle of the middle finger is more distal than the others, but, with the dislocation of the lunate, this knuckle may lie on the same level as those of the index and ring fingers because of a proximal shift of the metacarpal bone. The diagnosis is confirmed by roentgenograms. Though the dislocation can be recognized in the anterior view, it is shown more clearly in the lateral exposure. In the severe degrees, the articular surfaces of the lunate are completely separated from the radius and the surrounding carpal bones. In the less severe injuries, the articular surface of the lunate and radius may still be in contact to some extent.

Early reduction is essential. Acute dislocations can be corrected by manipulation, that is, by strong downward traction on the hand and simultaneous countertraction on

the arm. This will pull the capitate bone away from the end of the radius where it has shifted, and restore space into which the lunate can be reduced by applying backward pressure with the fingers. Japanese traps on the fingers may be used to obtain strong traction (Fig. 22). Countertraction is produced by flexing the elbow at 90 degrees and placing a sling over the lower end of the humerus. The lunate can then be easily manipulated back into its normal position. A forearm cast which extends as far as the distal flexion crease of the hand maintains the reduction, the wrist is placed in neutral position. The cast is removed at the end of four weeks, when motion can be resumed,

Figure 22. Photograph showing Japanese finger traps, useful in the reduction of fractures of the bones of the wrist and forearm.

Figure 23 Spontaneous aseptic necrosis of lunate, Kienbock's disease, with secondary deformity and fractures (A and B) treated by excision (C) with satisfactory result

and a removable leather molded splint is used for an additional six weeks to protect the wrist.

Dislocation of the lunate older than three weeks cannot ordinarily be reduced by manipulation, although in injuries not yet three weeks old it may be worth while to apply the Japanese finger traps

Persistent dislocations require excision of the bone. The first step is to make a transverse incision in the flexion crease of the wrist. The flexor tendons and median nerve are then retracted ulnarward after the volar carpal ligament has been sectioned. The lunate bone is isolated and removed because it is separated from its blood supply with resulting aseptic necrosis. A disabled wrist would eventuate if the lunate were retained.

The first symptoms of Kienbock's disease frequently follow trauma to the wrist with fracture of the lunate bone (Fig. 23). This condition is spontaneous aseptic necrosis which produces compression deformities, pain, limitation of motion and marked disability. A leather molded, metal-reinforced splint should be used in early cases to protect the wrist during replacement of the dead bone. Excision of the lunate is required when the bone is badly deformed.

Perilunar Dislocation of the Wrist. A perilunar dislocation of the wrist joint consists of posterior dislocation of all the carpal bones with the exception of the lunate, which retains its normal position. The navicular bone may be fractured at the same time, and in some cases the proximal half of the bone may remain in situ along with the lunate bone (Fig. 24). These injuries are frequently misdiagnosed and therefore are either inadequately treated or missed entirely, resulting in grave crippling of the hand.

Physical signs include marked deformity of the wrist with swelling, pain and loss of function. Roentgenograms must be carefully studied for minute details.

Reduction of the dislocation is effected by strong traction and countertraction, with sudden forward flexion of the wrist. In some instances, open reduction is required, particularly if the proximal fragment of the navicular bone has become rotated and blocks closed reduction. Simple perilunar dislocations are immobilized in a forearm cast with the wrist held straight for a period of six weeks. If there is an associated fracture of the navicular bone immobilization in the cast must continue.

until roentgen ray evidence confirms the consolidation of the fracture. This may sometimes require from six to nine months.

Old and unrecognized perilunar dislocations of the wrist are best treated by open reduction and arthrodesis of the wrist joint.

Colles' Fracture. This is the most common of all fractures. It is frequently transverse and situated within an inch of the distal articular surface of the radius (Fig. 25). In the majority of cases either the triangular cartilage between the radius and

ulna is torn or the styloid process of the ulna is fractured. The injury results from indirect violence and most commonly from a fall on the outstretched hand. It may occur at any age but is common in persons of the older age groups. The same injury in young and active adults will more likely produce a fracture of the navicular bone and in adolescent children a fracture-dislocation of the distal radial epiphysis.

Clinically the typical Colles' fracture produces a so-called silver-fork deformity and

Figure 24. Posterior perilunar dislocation of the wrist with a simultaneous fracture of the navicular bone. A, Anterior view, showing injury. B, Lateral view before treatment. the usual symptoms of a fracture. The deformity is due to the posterior displacement of the distal fragment and is demonstrated clearly in lateral roentgenograms of the wrist. These lateral views also will show that the articular surface of the radius faces the dorsum of the hand, rather than being

directed slightly into the palm. An anteroposterior view will reveal, moreover, that the radius is shortened, as will be evident when the level of the styloid process of the radius is compared with that of the ulna. Normally the radial styloid should extend distally from $\frac{3}{8}$ to $\frac{1}{2}$ inch farther than that

of the ulna. Not infrequently the distal fragment is displaced a little to the radial side and may be angulated in the direction of supination. Finally, it should be noted whether or not the fracture lines have entered the wrist joint and, also, to what degree the posterior cortex of the radius at the fracture site has been comminuted.

Reduction of the Colles' fracture may be performed with the patient under local or general anesthesia. The latter is preferable whenever possible, since it avoids the necessity of adding additional fluid to the already swollen fracture site. It also affords a better opportunity to obtain maximum reduction because of more complete muscle relaxation.

There is more than one way of reducing a Colles' fracture, but there are certain definite steps which must be carried out. First, the fracture must be disimpacted, which is done by forcible dorsiflexion of the distal fragment to effect its separation from the proximal one. Strong downward traction is simultaneously exerted on the hand and countertraction on the forearm. When the distal fragment has been brought down to length, the wrist is moved forward and ulnarward to engage the end of the proximal fragment. The wrist is next placed in moderate flexion to tighten the radial collateral ligament and the posterior capsule, which are attached to the distal fragment, and thus to safeguard against the possibility of having the deformity recur in the cast. Japanese finger traps offer one means of obtaining steady traction during the reduction and application of the cast.

The plaster dressing used for immobilization may be a circular cast or anterior and posterior plaster splints, which have the additional advantage of being easily adapted to the degree of swelling (Fig. 26). If the fracture is comminuted or unstable, the plaster dressing should reach above the elbow. Roentgenograms must be made immediately to check the accuracy of the reduction. If it is unsatisfactory, the cast must be removed and the manipulation repeated before the anesthesia wears off or the patient awakens. The aim should be to obtain as accurate a reduction as is possible and to do so with the least amount of trauma to the soft tissues.

Ordinarily it is best to hospitalize the patient overnight, for then the swelling can be kept down by elevating the arm and the state of circulation in the fingers can be checked. In case of marked swelling, it will be necessary to split the cast along the ulnar

side and to cut through the underlying dressings to the skin to restore adequate circulation. Roentgenograms must be repeated at the end of ten days and again after two weeks to determine whether reduction is being maintained, so as to make remanipulation unnecessary. Union of the fracture ordinarily takes place in six weeks, at which time the cast may be removed and function resumed.

Fractures which alter the articular surface of the radius, as well as those with severe comminution of the posterior cortex of the radius, are best treated by continuous traction. This can be done while the patient is ambulatory, by introducing a threaded wire through the midportion of the metacarpal bone of the thumb and another wire through the proximal crest of the ulna. The two wires are then incorporated in a forearm cast which is applied after the fracture is reduced by manipulation. Wrist and hand are immobilized with slight ulnar deviation but little flexion. This method avoids the Cotton-Loader position of marked flexion and extreme ulnar deviation of the wrist, while at the same time maintaining a wide space be-

gauze roll molds the plaster to the contour of the extremity.

Figure 27 Malunited Colles' fracture with permanent shortening of the radius and dorsal angulation of the distal fragment. Note the extreme osteoporosis of the bones. Motion of the wrist was limited and painful.

tween the fragmented surface of the radius and the articular surfaces of the proximal row of carpal bones. It is unlikely that fibrous adhesions which may grow across the joint surface will cause marked and permanent limitation of motion of the wrist joint.

Finally, it should be noted that the Colles' fracture is frequently considered to be a simple therapeutic problem and consequently is poorly treated (Fig. 27). This attitude is deplorable, because it is really a difficult fracture to treat successfully.

Smith Fracture (Reverse Colles'). This interesting but rather rare fracture is most commonly the result of direct violence which forces the hand volarward. It may also be caused indirectly by a fall on the dorsum of the strongly flexed hand. The line of fracture is somewhat variable but is usually roughly similar to that of the Colles' fracture, except that the distal fragment is displaced volarward and proximally (Fig. 28). The deformity is characteristic but in most instances it is less obvious than the silver-fork appearance of the hand and wrist seen in Colles' fracture (Fig. 29). Comminution is often present and makes it difficult to maintain the proper position of the fragments after reduction.

The signs and symptoms are much the same as for a Colles' fracture and the general deformity has aptly been called "spade-handle deformity."

Reduction may be effected with the aid of local or general anesthesia. The treatment

follows principles which are similar to those employed for the Colles' fracture, except that the movements of reduction are reversed. Strong traction is exerted on the hand and countertraction on the lower end of the humerus with the elbow in 90 degrees of flexion. Impaction, if present, is disengaged by exaggerating the flexion position of the small fragment, following which the fracture is reduced by strong traction. The wrist is next brought into dorsiflexion with ulnar deviation of the hand and is immobilized by means of anterior and posterior plaster splints or by a circular plaster dressing which extends from the elbow to the distal flexion crease of the hand, thus permitting full use of the fingers and thumb.

Roentgenograms should immediately be made to check the accuracy of the position of the fragments. They should be repeated after ten days. If no displacement has occurred, the cast is left in place for six weeks and then discarded. No sling is allowed during that time and full use of the fingers, elbow and shoulder is encouraged as in all wrist fractures. If, on the other hand, reduction has not been maintained, as evidenced by roentgenograms taken at the end of ten days, the fracture must be remanipulated. In some of these fractures, the difficulty encountered in maintaining good reduction is more troublesome than in Colles' fractures. But, if in these patients the best alignment possible is obtained, if the wrist is put in extension with some ulnar deviation and if active use of the fingers is . . .

ed from

the first, a very good functional result will be obtained.

Marginal Fractures of the Distal End of the Radius. These fractures may occur along the anterior or the posterior margin of the distal end of the radius. They result from forceful flexion or extension of the hand,

causing the carpal bones to impinge against one of the marginal ends just noted, and splitting off a segment. The fracture fragment, whether from the anterior or the posterior margin, always includes a portion of the joint surface. Upward displacement is rarely marked, however. The injury is char-

Figure 29 Photograph of unreduced Smith fracture showing reverse Colles' deformity. Note prominence of ulna.

acterized by pain, swelling, and limited motion of the wrist joint. Local tenderness and crepitus may also be present. Roentgenograms will confirm the diagnosis.

These fractures are not difficult to reduce but must not be neglected or treated lightly. The reduction is accomplished, with the patient under local anesthesia, by exerting moderate downward traction on the hand and countertraction on the elbow and by molding the fragment. Both anterior and posterior marginal fractures should be immobilized with the wrist held in slight dorsiflexion. Plaster splints applied along the front and back of the forearm from the elbow to the distal flexion crease of the hand offer adequate fixation. The plaster is molded from front to back at the site of the fracture to close such gap as may remain between the fragment and the radius. Union usually takes place within six weeks, at which time the cast may be discarded and full use of the arm resumed.

Fracture-Dislocation of the Distal Radial Epiphysis. An injury in adolescent children, which is more or less comparable to the Colles' fracture in adults, is the fracture-dislocation of the distal radial epiphysis (Fig. 30). The injury results from forceful hyperextension of the wrist, such as in a fall on the hand. The fracture occurs through the radius just proximal to the distal epiphyseal growth plate. The fragment consists of the distal articular surface, the epiphyseal

ossification center, the cartilaginous growth plate and varying amounts of the adjacent metaphysis of the radius. The degree of dorsal displacement of the epiphysis varies from none in some cases to complete posterior dislocation in others.

The usual symptoms of a fracture are present. They consist of deformity, swelling, pain on attempted movement, muscle spasm and local tenderness.

A fracture-dislocation of the distal radial epiphysis is reduced by the same type of manipulation as that used for the Colles' or other extension fractures of the wrist. Downward traction is exerted on the fingers and countertraction is obtained at the elbow region. When the distal small fragment clears the lower end of the radius, the hand, including the distal fragment, is brought forward to re-align the radius. A long arm cast is applied with the wrist in moderate flexion and ulnar deviation.

The reduction is best performed with the patient under general anesthesia. Roentgenograms are obtained before the patient is allowed to awaken. If the reduction is unsatisfactory, it is repeated. There should be no difficulty in obtaining accurate reduction of this fracture. It is, however, best to accept some degree of persistent displacement of the distal radial epiphysis rather than to perform an open reduction, for this provokes a premature closure of the epiphyseal growth zone with resultant shortening

of the radius and overgrowth of the ulna. Growth arrest rarely occurs when the fracture is reduced gently by closed methods, even when the reposition is not complete.

Follow-up care is the same as for other fractures of the wrist. Sufficient union is present at the end of six weeks to allow the removal of the cast. No physical therapy is necessary. The patient should be followed

for several years to determine if arrest of growth of the radius has resulted from the fracture. Yearly roentgenograms will show whether longitudinal growth of the radius is occurring at the normal rate. Premature closure of the epiphysis may require surgical obliteration of the corresponding growth plate of the ulna and a shortening of the bone to the level of the radius, de-

acterized by pain, swelling, and limited motion of the wrist joint. Local tenderness and crepitus may also be present. Roentgenograms will confirm the diagnosis.

These fractures are not difficult to reduce but must not be neglected or treated lightly. The reduction is accomplished, with the patient under local anesthesia, by exerting moderate downward traction on the hand and countertraction on the elbow and by molding the fragment. Both anterior and posterior marginal fractures should be immobilized with the wrist held in slight dorsiflexion. Plaster splints applied along the front and back of the forearm from the elbow to the distal flexion crease of the hand offer adequate fixation. The plaster is molded from front to back at the site of the fracture to close such gap as may remain between the fragment and the radius. Union usually takes place within six weeks, at which time the cast may be discarded and full use of the arm resumed.

Fracture-Dislocation of the Distal Radial Epiphysis. An injury in adolescent children, which is more or less comparable to the Colles' fracture in adults, is the fracture-dislocation of the distal radial epiphysis (Fig. 30). The injury results from forceful hyperextension of the wrist, such as in a fall on the hand. The fracture occurs through the radius just proximal to the distal epiphyseal growth plate. The fragment consists of the distal articular surface, the epiphyseal

ossification center, the cartilaginous growth plate and varying amounts of the adjacent metaphysis of the radius. The degree of dorsal displacement of the epiphysis varies from none in some cases to complete posterior dislocation in others.

The usual symptoms of a fracture are present. They consist of deformity, swelling, pain on attempted movement, muscle spasm and local tenderness.

A fracture-dislocation of the distal radial epiphysis is reduced by the same type of manipulation as that used for the Colles' or other extension fractures of the wrist. Downward traction is exerted on the fingers and countertraction is obtained at the elbow region. When the distal small fragment clears the lower end of the radius, the hand, including the distal fragment, is brought forward to re-align the radius. A long arm cast is applied with the wrist in moderate flexion and ulnar deviation.

The reduction is best performed with the patient under general anesthesia. Roentgenograms are obtained before the patient is allowed to awaken. If the reduction is unsatisfactory, it is repeated. There should be no difficulty in obtaining accurate reduction of this fracture. It is, however, best to accept some degree of persistent displacement of the distal radial epiphysis rather than to perform an open reduction, for this provokes a premature closure of the epiphyseal growth zone with resultant shortening

Figure 32. Photograph showing position of surgeon's hands during the manipulation of a green-stick fracture.

muscle, it is necessary to hold the forearm distal to the fracture in midposition between supination and pronation during the manipulation. In case of doubt as to the degree of supination of the proximal fragment of the radius, an anteroposterior x-ray film of the forearm should be compared with films of the normal radius taken in known positions of rotation.

Fractures of the Radius and Ulna in Children. Most fractures of the radius and ulna in children can be treated effectively by manipulative reduction and application of a long arm cast. Green-stick fractures, most common in children, represent an incomplete break through the bone; they are characterized by extreme degrees of angulation which is most commonly in a volar direction (Fig. 31). Except for the presence of pain and the obvious angular deformity, such common fracture signs as crepitus and false motion are absent. Roentgenograms in the anteroposterior and lateral projections should be taken prior to reduction.

The treatment of an incomplete or green-stick fracture of the radius and ulna consists essentially of re-aligning the distal fragment on the proximal one. No general or local anesthesia is necessary and sedation with codeine or morphine will suffice if properly adjusted to the child's age and temperament. The surgeon grasps the extremity distal and proximal to the fracture while placing his thumbs along its apex (Fig. 32). Reduction is accomplished by pushing forward firmly with the thumbs and by simultaneously levering the distal fragment backward until the bone snaps in two. The completely fractured bone can then be brought into normal

alignment. Care must be taken to avoid loss of the end-to-end position of the fragments. It is possible that the ulnar deformity may correct itself while the radius is being manipulated, but more often it is necessary to repeat the maneuver just described. Immobilization is effected by means of a long arm cast with the elbow in 90 degrees of flexion and the wrist in moderate flexion and ulnar deviation. The cast should be made to fit snugly and yet allow for the swelling which occurs during the first twelve to twenty-four hours. Angulation in the cast is less apt to take place if the plaster is well molded from front to back over the fracture site. Roentgenograms should check the accuracy of the reduction. If some angulation has occurred, or the reduction has otherwise become unsatisfactory, the cast may be wedged or, if necessary, removed and the manipulation repeated. An x-ray examination must be made ten to fourteen days after reduction because of the tendency at that time for angulation to recur as the swelling subsides and the cast becomes loosened.

Wedging is accomplished by making parallel cuts, spaced $\frac{3}{4}$ inch apart, through the sides of the cast, the cuts being centered over the fracture site. A window is then made in the front (or back) of the plaster between the adjacent cuts with its location on the side to which the cast is to be wedged. A single saw cut is finally made transversely across the cast opposite the window connecting with the parallel cuts. The distal portion of the cast which encases the lower fragment is then angulated sufficiently to open a wedge and to close the window at the same time that the alignment of the

pending upon the age of the patient at the time of injury. This, fortunately, is not a common injury, but carries a guarded prognosis—a fact which should at once be explained to the parents

THE RADIUS AND ULNA

Fractures of the shafts of the radius and ulna usually are the result of a direct blow to the bones or, indirectly, a fall on the outstretched hand. In adults, the resulting fracture has a tendency to be comminuted and to be oblique with overlapping. The result is a fracture which is most difficult to maintain by closed manipulation. In children, the same fracture is frequently of the green-stick variety, although complete separation of the bone fragments is not uncommon and the combination of these two in one and the other bone is rather frequent.

The displacement of fragments following fractures of the forearm bones is dependent on muscle action as well as on the force of the injury. More specifically, the nature of the deformity depends largely on the location of the break in relation to the pronator teres muscle. This muscle, it may be recalled, has its origin above the elbow medially and inserts near the middle of the radius. When the fracture occurs proximal

to the insertion of this muscle, the upper fragment of the radius assumes a position of supination, because of the unopposed action of the supinator muscle which passes from the ulna around the upper fourth of the radius. The distal fragment is then pronated by the pronator teres and the pronator quadratus. The latter muscle is located anteriorly in the distal fourth and its fibers pass transversely from ulna to radius. In order to re-align this fracture, the distal fragment must be strongly supinated with steady traction throughout the maneuver.

If the fracture is distal to the insertion of the pronator teres, the proximal fragment of the radius assumes a neutral position because the action of the supinator muscle is countered by that of the pronator teres. The distal end of the radius, on the other hand, is pronated by the pronator quadratus muscle and pulled toward the ulna. Reduction is accomplished by obtaining end-to-end alignment of the fragments, with the hand in neutral position between pronation and supination.

In summary, when the fracture is proximal to the insertion of the pronator teres muscle, the distal fragment must be maintained in supination during reduction. When the fracture is distal to the insertion of this

Figure 31. Green-stick fractures of the midportion of the radius and ulna. A, Anterior view showing site of fracture but no deformity. B, Lateral roentgenogram showing marked volar angulation. C and D, Final result. Note some persisting angulation in the lateral view. The cosmetic and functional results were good.

sum of the forearm from the elbow to the metacarpal-phalangeal joints of the fingers. Several turns of sheet wadding are placed beneath the plaster and the splint is held in position by gauze. Roentgenograms are made in the anteroposterior and lateral positions and, if the reduction is shown to be satisfactory, a circular long arm cast is applied to incorporate the dorsal plaster splint.

The patient must be hospitalized for at least twenty-four hours to permit a close check of the circulation in the affected arm. An x-ray examination should be made at the end of ten days and again ten days later, to make sure that the alignment has been maintained. Forearm fractures may angulate in the cast when the swelling subsides during the third week and as the child becomes increasingly active. Green-stick fractures will consolidate in six weeks, but displaced fractures of the radius and ulna require eight to ten weeks for sufficient callus to form so that the child, especially young ones, may be given full use of the extremity when the cast is removed.

Open reduction of a fracture of the shaft of the radius or ulna, or both, is rarely indicated in children. It is important, however, to explain to the parents that the persistence of some residual deformity until corrected by growth is preferable to subjecting the child to open reduction.

Transverse Fractures of the Shaft of the Radius and Ulna in Adults. These fractures are commonly accompanied by angulation and overriding. They may be reduced by

direct traction and countertraction or by the method of angulation just described for forearm fractures of children. For traction on the hand with the elbow flexed at 90 degrees, Japanese finger traps may be used, and for countertraction a padded sling over the distal end of the arm. As much as 25 to 30 pounds of continuous traction can thus be exerted, without the need of help from assistants. The arm is suspended from an overhead pulley by means of the finger traps, which permits the operator to use both hands as he attempts to interlock the ends of the fragments to align the bones. With the arm in this position, anteroposterior and lateral roentgenograms should be obtained to ascertain if reduction has been satisfactorily accomplished. A circular cast or anterior and posterior molded plaster splints are applied from below the axilla to the metacarpal-phalangeal joints if the fragments are reduced. The postoperative care is the same as that for closed reduction of fractures in children. The patient is encouraged to flex and extend the fingers and to exercise the shoulder each day through the full range of motion.

Oblique or Comminuted Fractures of the Radius and Ulna. These fractures must be treated by open reduction or by continuous traction because they have a tendency to become displaced when in the cast (Fig. 35). Fixed traction may be obtained by means of two threaded wires which are inserted, respectively, through the midshaft of the metacarpal bone of the thumb and

Figure 34 Incomplete reposition of bone ends but with good alignment is satisfactory treatment of forearm fractures in children, residual deformities correct with growth. A and B, Before treatment; C and D, following union.

Figure 33 Fracture in the distal fourth of the radius and ulna in a child. A and B, Views showing displacement of radius and angulation of ulna. C, Lateral x-ray film, showing reduction and the dorsal plaster splint. D, Lateral view, showing good reduction and circular cast which included the splint.

arm is corrected. A piece of wood is placed in the resulting opening in the cast so as to maintain the corrected position. An x-ray picture is taken immediately to determine the accuracy of the alignment. After final adjustment of the cast, the plaster is repaired.

Transverse fractures of the radius and ulna in children with complete separation and displacement of the fragments are best reduced by the angulation method rather than by strong traction and countertraction (Fig. 33). Satisfactory end-to-end position is difficult to obtain by traction alone, for the soft tissues become tense and appear to lock the fragments in their displaced positions.

The manipulation is performed with the patient under general anesthesia. If the distal fragment is dorsal to and overlaps the end of the proximal fragment, reduction is accomplished by angulating the distal fragment, wrist and hand into an exaggerated position which will then be considerably behind the plane of the upper segment of bone. At the same time, the proximal end of the distal fragment is pushed distally by the thumbs of the surgeon until it engages the lower end of the proximal one. The lower fragment is now brought into alignment with the upper one. If the degree of

overriding of the displaced fracture is marked, it may be helpful for an assistant to pull downward on the hand while a second assistant provides countertraction by pulling upward on the elbow as the surgeon manipulates the fracture.

If motion is observed, it may warrant the conclusion that the reduction has been successful.

If there is an associated fracture of the ulna, it must also be reduced. Green-stick fractures should be corrected before manipulation of the radius. If the ulnar injury is a fracture-displacement, it should be manipulated by angulation in a manner similar to that described for the radius. Occasionally, the reduced radius can serve as a fulcrum for manipulation of the ulna. End-to-end reposition of the radius is essential but is less exacting with the ulna. Anatomic reduction is not required of the radius and ulna in children as long as the alignment is satisfactory, since growth will overcome imperfect end-to-end position (Fig. 34). In adults, however, these fractures require the most accurate reduction if satisfactory results are to be obtained.

Following manipulation, a posterior molded plaster splint is applied to the dor-

ry or the superficial branch of the radial nerve. The ulna is exposed by a dorsal incision over its crest. No important structures will be encountered if the dissection is kept subperiosteally. For internal fixation, many surgeons are still using metal plates and screws, but the intramedullary rod is preferable because, in addition to providing fixation, it often obviates the necessity for the additional protection of a plaster cast (Fig. 36). The intramedullary rod is inserted into the shaft of the radius by the retrograde method. For this purpose, the distal end of the bone is exposed dorsal and lateral to the radial styloid process. The rod is introduced through a hole drilled in the cortex and driven upward through the medullary canal to the fracture site and then continued into the proximal fragment after the fracture is reduced under direct vision. The length of the rod is determined by measuring the radius in the other arm. The insertion of the rod into the ulna is performed by the retrograde technique. After exposure of the site of the fracture, the rod is passed proximally into the medullary canal of the upper fragment through the olecranon process and a small incision in the overlying soft tissues until the rod is flush with the distal end of the upper fragment. The fracture then is re-

duced and the rod is driven into the canal of the distal fragment. The end of the rod projects slightly beyond the olecranon but is buried under the soft tissue to minimize the possibility of infection. Bone grafts should be used for the added stimulus they give to callus formation when fractures four or more weeks old are subjected to open reduction. Finally, a long arm cast should be applied for about one month if the fracture remains unstable in spite of the intramedullary rod. Complete union may not be achieved for four months or more, but the patient may be able to resume suitable work soon after the cast is removed.

Fractures of the Shaft of the Radius. Either one of the two forearm bones may be broken. Fractures of the shaft of the radius alone are rare, however, for this part of the bone is dense and compact. These fractures are usually the result of direct violence. In children, they are very common and are most often of the green-stick type. In adults, the fracture is, as a rule, oblique or comminuted and often somewhat displaced toward the ulna. If the fracture is accompanied by overriding and shortening of the radius, it will be necessary to obtain roentgenograms of the entire forearm to confirm the presence of either an associated fracture or a dislocation of the ulna.

Figure 36. An unstable oblique fracture of the middle third of the radius and ulna in an adult treated by open reduction and intramedullary rods after unsuccessful closed manipulation. A, Before treatment. B, Soon after open reduction. C and D, State of healing after four months.

Figure 35. Oblique and comminuted fractures of the radius.

through the proximal end of the ulna. These wires then are incorporated in a long arm cast after the fracture has been manipulated. If, in spite of accurate reduction, the radius or the ulna becomes displaced or angulated in the cast as the swelling subsides, then open reduction must be attempted. Many surgeons recommend recourse to operative reduction as the acceptable treatment for

all unstable fractures of the shaft of the radius and ulna in adults.

Open reduction must not be attempted by exposing both of these bones through one incision. It is, moreover, a difficult operation which should be performed only by an experienced surgeon. The shaft of the radius is exposed through an appropriate incision. Care must be taken not to injure the radial

Figure 37. Comminuted fracture of radius treated by manipulation and cast (A and B). Double pin fixation maintained alignment, although anterior part of cast was removed for skin grafting of extensive burn of forearm. Final result of fracture was excellent (C and D).

Closed reduction of fractures of the radius displaced ulnarward is very difficult. It may at least be attempted, however, by lifting the radius manually away from the ulna and by using Japanese finger traps to reduce the fracture by strong traction, countertraction at the elbow and angulation of the bone fragments so that their ends may be locked. It remains, however, that these fractures have a tendency to redisplace or angulate in the cast, thus making it necessary to check the reduction at frequent intervals with roentgenograms. If displacement occurs, the cast must be removed and recourse must be had to continuous traction utilizing a thread wire through the metacarpal bone of the thumb and a second pin inserted across the proximal end of the ulna. These are incorporated in a long arm cast (Fig. 37). Open reduction followed by internal fixation with an intramedullary rod may be an alternative method of treatment. The result should prove completely satisfactory. Union of the fragments usually requires eight to twelve weeks. It is not exceptional to apply a bone graft at the time of surgery because of the high incidence of nonunion.

Fractures of the Shaft of the Ulna. These fractures are most often due to direct violence and occur usually in the lower third of the bone. They may be transverse, oblique or comminuted, except in children, in whom they are usually of the green-stick variety. Closed reduction and immobilization in a long arm cast with the elbow in 90 degrees of flexion may be attempted, however, there is a tendency for the ulna to angulate toward the radius during immobilization in the cast. Fractures, therefore, which either cannot be reduced by manipulation or cannot be maintained after closed reduction must be treated by surgery, preferably followed by fixation with an intramedullary rod. The rod is inserted by the retrograde technique, it may make a plaster cast unnecessary. A heavy Steinmann pin or a Rush rod may be used. Union occurs in about ten weeks. It need hardly be emphasized that malunited fractures of the ulna with bowing of the forearm are most disabling and must be avoided.

Fracture of the Shaft of the Ulna and Dislocation of the Head of the Radius (Monteggia Fracture). This is a fracture in the shaft of the ulna accompanied by either an anterior, posterior or lateral displacement of the upper end of the radius. It is usually due to direct violence applied to the ulna. The injury is important because the disloca-

tion of the radius is often overlooked and only the obvious fracture of the ulna receives treatment. The inevitable result is a deformity with restriction of motion and disability. The accident is common in children, in whom closed reduction is usually satisfactory and a good position can be maintained with a plaster cast. In adults this is not the case and the need for perfect reposition of the ulna and radius often requires open reduction. The shaft of the ulna may fracture at any level from the lower third to just below the olecranon process.

There are in general two types of deformity: an anterior angulation of the ulnar fragments associated with anterior dislocation of the radial head, and posterior angulation of the ulnar fragments associated with posterior dislocation of the radial head. The fracture may be transverse, oblique or comminuted or of the green-stick variety in children. The ulna is with forward and radial head. The annular ligament is always torn as the radial head dislocates.

On physical examination, there is often a depression over the posterior aspect of the shaft of the ulna at the site of the fracture of the anterior type. Palpation of the radial head reveals its position. In partial rotation. Examination for posterior interosseous nerve palsy should be made, since this is found in about one-fourth of the cases. Roentgenographic examination which shows the angulated fragments of the ulna only, and does not include the elbow joint in lateral projection, is inadequate to rule out dislocation of the radial head. It is very easy to determine on a lateral view of the elbow whether the radial head is dislocated or not. A line drawn through the long axis of the radius and projected upward past the humerus normally passes through the center of the capitellum. If it does not, there is dislocation of the radial head.

Treatment of Monteggia injuries may be either conservative or surgical, depending upon the nature of the fracture and the reducibility of the radius. Many of these fractures can be satisfactorily treated by closed methods, for example, transverse fractures. Closed reduction of the ulna is accomplished by traction followed by manipulation of the head of the radius. Immobilization is obtained by means of a plaster cast extending from the metacarpals to the axilla.

is not, for it will delay recovery and lead to permanent loss of motion. The prognosis should always be guarded in patients in whom the head of the radius is excised, for recovery of a painless joint with full flexion and extension capacity is difficult to accomplish.

In children, fractures of the neck of the radius with severe lateral angulation or displacement of the head fragment require special treatment. In adults, these conditions should be treated by excision of the head of the radius; in children, the head must be replaced accurately by manipulation or surgery. Excision of the head will permit an undesirable upward displacement of the remaining portion of the radius during subsequent growth, with resulting subluxation of the distal radioulnar joint, accompanied by pain and marked disability of the wrist joint.

Fractures of the Olecranon Process. This injury occurs almost exclusively in adults. It usually follows a fall on the elbow, resulting in a transverse, oblique or, more often, a comminuted fracture and occasionally with anterior dislocation of the elbow (Fig. 38). It may also occur from a violent pull of the triceps muscle, for its tendon is attached

to the tip of the olecranon process, thus producing a true avulsion fracture. In the majority of subjects, there is some, and often considerable, separation of the fragments.

The diagnosis is suggested by the history and the pain and swelling over the olecranon process. It is confirmed if a gap can be felt between the fragments or if the normal relationship between the process and epicondyles of the humerus is disturbed. Roentgenograms will reveal the exact nature of the fracture.

Fractures of the olecranon without separation of fragments should be immobilized in a long arm cast with the elbow at an angle of between 90 and 135 degrees and with the forearm in midpronation. Roentgenograms should be made at the end of the first and the second week to determine whether the smaller fragment has not been displaced by the triceps muscle. If no displacement has occurred, the cast can be discarded at the end of five weeks to permit gradual resumption of elbow motion.

Some fractures of the olecranon with separation of fragments may be satisfactorily reduced by complete extension of the elbow and can be maintained by the application

Figure 38. Anterior dislocation of the elbow and associated fractures of the olecranon process and head of the radius. A and B, Anteroposterior and lateral aspects before treatment. C, Lateral view following open reduction of dislocation, internal fixation of olecranon and excision of radial head.

In patients having anterior dislocation, the elbow should be put up in 90 degrees of flexion, while in those with posterior dislocation the elbow should be placed in incomplete extension (135 degrees or more). Frequent roentgenographic check-ups must be made in the following two weeks to determine whether the ulnar fragments and the radial head are maintaining their reduced position. If the deformity recurs or the initial treatment is not satisfactory, then open reduction must be performed.

Surgery is accomplished by exposure of the fracture site and the radial head through two separate incisions, except in the proximal third of the forearm where both may be made through a posterior incision, as described by Speed and Boyd. The fracture of the ulna is reduced and fixed by means of an intramedullary rod, following which the radial head is replaced and the annular ligament is repaired. A plaster cast is applied for six weeks to permit healing of the ligament, after which motion is resumed. At the same time, the intramedullary rod will maintain alignment of the ulna until final consolidation of the fracture has been achieved. If, on the other hand, internal fixation has not been resorted to for treatment of the ulna, it will be necessary to continue the use of the cast until roentgenograms confirm union of the fracture. This

In these patients, the fracture of the ulna is reduced, an intramedullary rod is utilized for fixation and bone grafts are placed about the fractures to stimulate union. The head of the radius is reduced and the annular ligament repaired with a strip of adjacent triceps tendon or of fascia lata. If this is not possible, the radial head is resected. In some instances, satisfactory function of the elbow and forearm is present in spite of persistent dislocation of the upper end of the radius.

The prognosis of patients having Monteggia fractures is favorable, provided the acute injuries are immediately recognized and treated. It is difficult to restore function of the radius in neglected cases, although satisfactory union and alignment of the ulna may be obtained.

THE ELBOW

1. II. Neck of the
and neck of
the capsule

of the elbow joint. Clinically, the importance of these fractures varies with the degree of their interference with the function of articulation between the radial head and the capitellum or between the radius and the ulna. Treatment must accordingly be adjusted to the extent of functional disability which may be expected in the elbow and radial-ulnar joints.

Fractures of the head and neck of the radius are extremely common in adults but less so in children. They usually result from a blow directed upward through the forearm, forcing the radial head to strike against the distal end of the humerus and producing one of the following main types of fracture: fissure, marginal, comminuted fractures of the head, and fractures of the neck of the radius with impaction or displacement of the head.

The symptoms are usually characteristic. The patient complains of pain and swelling of the elbow, local tenderness over the head of the radius and loss of the movements of pronation and supination, depending upon the degree of deformity of the head. An accurate diagnosis must make use of roentgenograms.

Linear cracks across the radial head or impaction of the head into the neck without significantly altering the position of the articular surface is not an important injury and may be treated adequately by putting the arm in a sling and early resumption of motion. On the other hand, fractures with marked comminution and separation of the fragments or with displacement of one or more fragments into the elbow joint should be treated by complete excision. The same treatment should be applied to impacted fractures in which the head of the radius is tilted to such a degree as to cause it to impinge upon the adjacent articular surfaces of the ulna and humerus.

Excision of the head of the radius is effected through an incision between the anconeus and the extensor carpi ulnaris muscles. The capsule of the elbow joint is exposed and the radial head is laid bare by an appropriate incision through it. The line of resection should be just proximal to the annular ligament. All loose fragments must be removed from the elbow joint. Trauma must be kept at a minimum, for otherwise considerable ossification will occur in the capsule and produce stiffness of the joint.

Elbow motion is permitted as soon as the wound is healed. Active exercise may be helpful, but passive stretch the elbow

wire suture. A cortical bone graft is applied on the ulnar side of the fracture, while cancellous grafts are placed on the other side. The proximal end of the radius must not be exposed in the wound, for otherwise cross-union and synostosis may result. Motion of the elbow is resumed after the wound has healed and internal fixation has been adequately procured. Union occurs in ten to twelve weeks with results which are, as a rule, highly satisfactory.

Dislocation of the Elbow Joint. This injury is particularly frequent in children and adolescents, because of the undeveloped state of the coronoid process. The dislocation is most often in the posterior direction (Fig. 40) and usually is the result of a fall on the hand in which the forearm is forced backward while the elbow is flexed. The appearance of the arm, if not obscured by

swelling, is typical. The patient holds the forearm in incomplete extension. The elbow appears broadened from behind and the forearm is shortened; the olecranon may be palpated posterior to the medial and lateral epicondyles of the humerus. Normally the two humeral epicondyles and the tip of the olecranon process form an equilateral triangle when the elbow is flexed to a right angle, and the three landmarks are at the same level when the elbow is in extension (Fig. 41). Crepitus is absent unless there is an associated fracture. Marked lateral or medial displacement is rare because of the strong collateral ligaments and the broad articular surface of the distal end of the humerus.

Reduction should always be preceded by a careful roentgenographic examination to rule out the possible presence of other in-

Figure 41. Drawings illustrating the relationship between the external and internal epicondyles of the humerus and the olecranon process when the elbow is in flexion and extension (Ehason: *Fractures of the Humerus, Radius and Ulna*. D. Appleton-Century Company, Publishers.)

Figure 40. Roentgenograms showing a posterior and lateral dislocation of the elbow joint

of a cast for six weeks. But the position of the elbow is discomforting to the patient and the development of edema may pose a real problem. Another difficulty is in mobilizing the elbow after it has been in extension for six weeks. Manipulation with the patient under general anesthesia is frequently necessary.

By contrast, open reduction with adequate internal fixation, by use of multiple threaded wires, a long wood screw or wire suture, makes active motion of the elbow immediately possible and, as a rule, justifies the expectation of regaining a painless elbow with full flexion and extension.

Avulsed fragments of not more than one-third the length of the olecranon process are best treated by excision of the fragment and suture of the triceps tendon to the raw bone at the proximal end of the ulna. Motion can be resumed at the end of two weeks with the likelihood that full extension power of the elbow will be regained.

Comminuted fractures with separation should be re-aligned accurately by open reduction and fixed internally to maintain their normal relationship with the rest of the ulna (Fig. 39). Accurate restoration of the articular surface of the olecranon, even to the extent of replacing small fragments, is a requisite if arthritis due to incongruous joint surfaces is to be avoided.

Ununited fractures of the olecranon process are productive of pain and weakness of extension motion of the elbow and are best treated by open reduction and a bone graft. For this, a linear incision is made over the subcutaneous border of the olecranon process, beginning proximal to its tip and extending downward for about 3 inches. The bone is exposed subperiosteally. The ulnar nerve is left alone and preserved from injury. The fracture surfaces are freshened and reduced accurately if they are not in adequate alignment. Fixation is obtained with multiple threaded wires, screw.

Figure 43. Fracture of the capitellum due to a force transmitted upward through the radius. A and B, Note comminuted fracture with one large fragment displaced anteriorly. C and D, Condition after manipulation and application of arm cast with elbow in extension for three weeks.

wrist and shoulder frequently. Six months, more or less, may be required to regain maximum motion.

The prognosis should always be guarded, because it is not infrequent that deposition of bone in the collateral ligaments entails some permanent limitation of motion, especially in extension. Old or neglected dislocations of the elbow must be treated by open reduction. Recurrent posterior dislocations may be stabilized by a bone graft which is inserted through a hole drilled from the posterior surface of the ulna. The end of the graft is made to project beyond the coronoid process to buttress the joint.

Fractures of the Capitellum of the Humerus. These fractures may be produced by a forceful impact of the head of the radius on the opposing articular surface of the humerus (capitellum), resulting in the breaking off of either a single fragment or multiple fragments of cartilage and bone (Fig. 43).

The immediate symptoms include swelling of the elbow due to hemorrhage, accompanied by pain and limitation of motion of the elbow and forearm. Stereoscopic roentgenograms taken in the anteroposterior and lateral directions will disclose the location of the fragments.

Fractures which involve either a single or, at most, two large segments of the capitellum should be reduced by open surgery and the articular surfaces restored as accurately as possible. Comminuted fractures which cannot be reassembled require excision of the fragments. Removal of the major portion of the capitellum, including the adjacent condylar bone, will result in lateral instabil-

ity of the elbow, permanent valgus deformity and functional disability.

Closed reduction of a large fragment with upward displacement, but without rotation, may be attempted in selected cases. This can be done with the patient either under local or general anesthesia. With the elbow in extension and the forearm adducted, pressure is exerted against the fragment to push it back in its normal position. Following this the elbow is placed in 90 degrees of flexion in a posterior molded splint. Roentgenograms are made immediately. If the reduction is not successful, the splint must be removed and manipulation repeated. A posterior splint then is applied with the elbow in complete extension and roentgenograms are again made. If the reduction is now satisfactory, the elbow is immobilized in extension for a period of three weeks, following which it is gradually brought into a flexed position in the course of the following two weeks.

Open reduction is performed through a lateral oblique incision between the anconeus and the extensor carpi ulnaris muscles. The incision is extended proximally along the epicondylar ridge. The anconeus is retracted posteriorly and the extensor muscles of the forearm anteriorly. The tendon of the anconeus is severed proximally and the soft tissues are stripped from the epicondylar ridge to gain access to the joint and to the adjacent posterior aspect of the humerus. The fracture then is reduced accurately and held in position by two screws which are inserted through the intact posterior portion of the condyle and into the fracture fragment. The screws must not protrude to the articular surface of the capitellum. Fol-

Figure 42. Posterior dislocation of the elbow with an associated comminuted fracture of the head of the radius. juries, such as a fracture of the head of the radius or the medial epicondyle of the humerus (Fig. 42) A general anesthetic should ordinarily be administered, although it may on rare occasion be necessary to attempt reduction by skillful manipulation following an adequate dose of a sedative.

Care must be exercised while effecting the reduction to avoid additional trauma. Downward traction is applied to the forearm while an assistant holds the upper arm. The medial or lateral displacement is corrected and then the forearm is extended to disengage the coronoid process from the back of the humerus. Further gentle downward traction on the forearm will bring the articular surface of the radius and ulna to the level of the distal end of the humerus, following which the elbow is flexed to effect final reduction. A posterior molded plaster

splint is then applied, with the elbow joint in 90 degrees or more of flexion. The flexion, as well as the swelling which ensues, must not be permitted to obliterate the radial pulse. Roentgenograms must be obtained before the anesthesia has subsided to determine the success of the reduction. If it is shown to be unsuccessful, the splint must be removed and manipulation repeated until a satisfactory result is obtained.

The adequacy of the circulation in the arm should be checked carefully for thirty-six to forty-eight hours and roentgenograms should be obtained again at the end of ten days and after two weeks. Active flexion motion may be resumed fourteen days from the time of injury when the arm is transferred from the cast to a sling. The patient is urged to close and open the hand vigorously immediately after reduction to move the

ment. The fragment maintains a good blood supply through the soft tissues attached to it, which facilitates rapid union. Aseptic necrosis of the avulsed portion of the humerus rarely occurs.

A posterior molded plaster splint is applied for four weeks, after which the patient is permitted active use of the elbow. The prognosis for recovery of full motion and maintenance of normal longitudinal growth should be guarded.

Adults are occasionally seen with untreated fractures of the lateral humeral condyle which had occurred in childhood. The function of the elbow joint is usually superior to

that of the normal joint. The fragment was excised.

An increasing valgus deformity of the elbow occurs in children when the fracture is neglected or the distal lateral humeral epiphysis undergoes premature closure while growth of the trochlear epiphysis continues. This produces stretching of the ulnar nerve with partial or complete paralysis of those muscles of the hand supplied by it. The angular deformity of the bone can be corrected by supracondylar osteotomy. Transplantation of the ulnar nerve to the anterior surface of the elbow before irreparable damage to the nerve has occurred offers a good prognosis for recovery of function.

Fracture of the Medial Epicondyle of the

Humerus. The medial epicondyle epiphysis of the humerus may be avulsed (Fig. 45) and rotated downward by the pull of the flexor muscles of the wrist and fingers which are attached to it. The displacement may amount to a few millimeters in some patients and requires for treatment only a protective circular cast or a posterior plaster splint applied for four weeks. In others, the fragment may be significantly displaced downward along the side of the medial condyle of the humerus, and in still others it may become incarcerated in the elbow when the joint is wedged open by a continuation of the force of the injury. This may likewise occur when the fragment fails to leave the joint as an associated dislocation is reduced (Fig. 46).

Open reduction of the epicondyle is indicated in all patients in whom there is a significant degree of displacement of the fragment. In this approach, a linear incision is centered over the medial side of the elbow. The deep fascia is opened and the ulnar nerve, which is stretched excessively at times by the injury, is identified and protected from further damage. The avulsed fragment is then isolated outside or inside the joint, replaced in its normal position and fixed with two threaded wires. In some selected cases, the ulnar nerve is transplanted to the anterior aspect of the elbow during closure of the wound. A posterior molded splint is applied for three weeks and motion is re-

Figure 45. Avulsion fracture of the medial epicondyle of the humerus in a child with slight displacement treated by a long arm cast with the elbow in 90 degrees of flexion A, Anteroposterior x-ray film showing original condition. B, View of final result C, Normal arm for comparative purposes.

lowing closure of the wound, the elbow is flexed to 90 degrees and immobilized in a posterior molded plaster splint for about three weeks. Full flexion and extension of the elbow joint may be recovered if the reduction has been performed accurately. In many instances, however, this goal is not attainable and some permanent decrease in the range of motion will persist.

Fractures of the Lateral Condyle of the Humerus in Children. This relatively rare fracture is produced by a valgus injury of the elbow. A comparable fracture is not seen in adults. The fracture extends from the lateral cortex of the humerus just above the epiphyseal plate obliquely downward across the growth cartilage plate and lateral condyle, to emerge at the joint surface near the trochlea. The fragment may be pulled laterally and backward out of the joint by contraction of the attached extensor muscles. In some cases, the fragment is also rotated outward and forward through an arc of 90 degrees, thus causing its articular surface to face proximally and medially rather than distally.

Swelling and ecchymosis are confined more or less to the lateral half of the elbow joint. The articulation appears broader than normal and the abnormal relationship between the olecranon process and the epicondyles of the humerus at the lateral side of the joint should suggest the nature of the fracture. Roentgenograms made in the anteroposterior, lateral and oblique views will

show the details of the fracture and establish the diagnosis.

Closed reduction of this fracture is usually unsuccessful, although McLearn and Mereson have reported two successful cases. They believe that the elbow is dislocated posteriorly and laterally by the injury and carries the fractured lateral condyle fragment with it. The elbow dislocation, they assume, reduces spontaneously but leaves the fragment in its dislocated position. Therefore they redislocate the elbow laterally and the condyle fragment resumes its normal position as the dislocation is again reduced.

Surgery is indicated for those patients in whom the reduction cannot be accomplished manually (Fig 44). The fragment and the elbow joint are exposed through an oblique incision between the anconeus and the extensor carpi ulnaris muscles. The distal, lateral aspect of the adjacent humerus is exposed subperiosteally as the incision is extended upward along the epicondylar ridge. All blood clots are removed from the joint and the fragment is rotated into its normal position where it is either sutured to the surrounding soft tissues or fixed to the humerus with two threaded wires. Accurate reduction must be maintained to prevent a bridge of bone from forming across the cartilaginous epiphyseal plate with resulting arrest of longitudinal growth. It is less dangerous to use two small-caliber threaded wires to secure accurate internal fixation than to permit the fragments to unite with displac-

diately of the accuracy of the reduction. If reduction is unsatisfactory, the cast must be removed at once and the manipulation repeated until normal repositioning is obtained. If this cannot be achieved, then continuous skeletal traction is necessary. Hospitalization after manipulative reduction is desirable for immediate detection of possible circulatory embarrassment.

If, as has been stated, the distal fragment cannot be held in position in the cast or if the swelling around the elbow is excessive and prevents immediate and adequate reduction, skeletal traction through the crest of the ulna may be used. An ordinary wood or eye screw is inserted into the olecranon just distal to the elbow joint. The injured arm is then extended over the side of the bed with the elbow at an angle of 90 degrees and 5 pounds of traction is applied to the screw attached to the olecranon process. The forearm is at the same time suspended overhead by means of 3 pounds of skin traction. A well-padded sling, to which a weight of 1 pound is attached, is placed over the lower end of the humerus to pull it backward to approximate the small condylar fragment as it comes forward. Medial or lateral displacement of the condyles is corrected by manual pressure if they do not assume a satisfactory position by traction. Pronation of the forearm may correct a medial shift of the small fragment.

Roentgenograms should be obtained at appropriate intervals during the first week to check the progress of the reduction. Sufficient callus will have developed in twelve to fourteen days to permit application of a

posterior molded splint with the elbow in as much flexion as can be tolerated. The patient then is discharged from the hospital.

Follow-up care is the same for both the manipulative and the continuous traction methods of reduction. Roentgenograms should be repeated at seven-day intervals on two or three occasions to check for possible rotation or posterior displacement of the distal fragment. The fracture may be re-manipulated at any time before much callus has formed if a change in alignment points to an unfavorable end result. Bony union should be sufficiently advanced in six to eight weeks to permit removal of the cast. Recovery of full motion may require several months. The elbow must not be stretched, for this will delay full recovery and may even lead to permanent fibrosis with limitation of joint extension.

United fractures with loss of the normal carrying angle are unlikely to correct with subsequent longitudinal growth of the humerus. In these patients it may be necessary to perform transverse supracondylar osteotomy to obtain proper functioning of the extremity. The procedure is carried out through a lateral epicondylar incision. The supracondylar portion of the humerus is exposed subperiosteally all around its circumference. A wedge of bone is then removed so that the distal fragment can be angulated outward into a corrected position. Six weeks are required for union.

It is of the utmost importance to observe the circulation in the fingers at frequent intervals for forty-eight to seventy-two hours after reduction, for this injury is most prone

humerus in a small child. A and B, reduced fracture in a cast. D and E,

Figure 46. Fracture of the medial epicondyle of the humerus with posterior and lateral dislocation of the elbow joint. sumed. The pins are removed at a convenient time. Motion of the elbow joint should be fully recovered unless there is associated dislocation of the joint with fibrosis of the collateral ligaments and capsule.

Supracondylar Fractures of the Humerus in Children. These fractures (Fig. 47) occur through the thin transverse plate of bone between the condyles and the shaft of the humerus. They result from a fall on the outstretched hand with the elbow in varying degrees of flexion, leading to anterior or posterior displacement of the condylar fragment as related to the shaft of the humerus. The posterior or extension type is most common because the fracturing force is usually upward and backward rather than upward and forward.

The diagnosis is based on physical examination and roentgen ray findings. There is diffuse swelling of the elbow with obvious shortening of the arm. The relationship between the epicondyles of the humerus and the olecranon process remains normal, although they lie posterior to the shaft of the humerus, in contrast to their relationships in posterior dislocations of the elbow, in avulsion fractures of the epicondyles and in fractures of the olecranon process with upward displacement. The olecranon process can be palpated posteriorly to the condyles of the humerus in dislocations, whereas one epicondyle will be asymmetrically placed in fractures which involve it or one condyle. A careful neurologic examination is essential, because the radial, ulnar or medial nerves often show paralysis from which recovery is spontaneous in three or four months.

The circulatory status of the forearm and hand must also be studied prior to the re-

duction. Pressure upon or spasm of the brachial artery may present a serious therapeutic problem before or after reduction of the fracture, which may predispose to the development of a Volkmann's contracture.

Roentgenograms will disclose the direction of the fracture line and the degree of displacement of the distal fragment.

Some controversy exists as to which is the best method for the reduction of supracondylar fractures of the humerus, that is, whether reduction should be undertaken immediately after injury and the cast applied, or whether it is safer to apply continuous skeletal traction and reduce the fracture gradually.

Successive objectives in the manipulation of supracondylar fractures are correction of the proximal displacement of the condyles and of the medial and lateral shift, following which the distal fragment is brought forward to engage the end of the shaft of the humerus.

In patients with complete backward displacement with overlapping of the fragments, general anesthesia is necessary. Gentle downward traction is exerted on the forearm, while the distal fragment is aligned with the proximal one by the operator. After the condyles have cleared the end of the shaft, they are lifted forward by one hand, while the surgeon's other hand places the patient's forearm in moderate flexion. Reduction is maintained by the tension exerted by the triceps muscle attached to the olecranon process. The fracture is immobilized in a posterior molded plaster splint, with the elbow flexed at the maximum degree, which will leave the radial pulse intact. Roentgenographic studies should be made im-

by marked swelling of the elbow region and discoloration of the skin due to hemorrhage. The radial and ulnar nerves frequently become contused sufficiently to produce temporary paralysis. It is therefore important to check the condition of these nerves before proceeding with the reduction. If the surgical approach is contemplated, the extremity should be immobilized for ten to fourteen days in a posterior metal or plaster splint with the elbow in 90 degrees of flexion and a large pressure dressing on the arm to give the swelling a chance to subside. If closed

reduction is to be tried, skeletal traction can be instituted immediately after the accident.

For open reduction of comminuted fractures of the lower end of the humerus (Fig. 49), a posterior linear incision is made over the proximal end of the olecranon process and extended upward on the back of the arm for several inches. The olecranon process is then cut about 1 inch distal to its tip and the proximal segment is separated from the triceps tendon and removed. When the elbow is flexed an excellent exposure of

Figure 48 A serious comminuted fracture of the distal end of the humerus in a sixty-seven-year-old patient. Treatment by skeletal traction, using a threaded wire through the ulna, was unsuccessful. Open reduction was performed with recovery of full motion. A and B, Original fracture. C and D, Unsatisfactory reduction by traction.

to be followed by *Volkman's ischemic contracture*. Immediate treatment is necessary in all patients and especially if poor circulation is due to spasm of the brachial artery which follows initial trauma or is induced by manipulation.

The earliest signs are those of obstruction to the arterial circulation, with pallor, absence of the distal pulse and lowered skin temperature, terminating in paralysis and contracture. When this condition has fully developed, the hand is so useless that little if any amelioration is possible. Therefore the importance of carefully observing the condition of the circulation cannot be too strongly emphasized.

At the first sign of an impending *Volkman's contracture*, all dressings must be loosened down to the skin and, if necessary, the cast removed. The elbow should be extended sufficiently to permit recovery of the radial pulse. In some patients it may be necessary to allow the fracture to redisplace temporarily in order to restore adequate circulation. A superior cervical sympathetic ganglion block should be performed and, if successful, may be repeated at appropriate intervals to maintain an optimum degree of vasodilatation and blood flow.

If the condition remains refractory to these measures, the surgeon must quickly proceed with an exploration of the brachial artery, followed by correction of any abnormality that may be discovered. At the same time, the fascia of the forearm should be split longitudinally to relieve all pressure on muscles, blood vessels and nerves.

THE HUMERUS

Fractures of the Distal End of the Humerus in Adults. Some of the most difficult fracture problems are encountered in this region. There are four types. T fractures, transcondylar, fractures of the medial or lateral condyles and comminuted fractures with wide displacement and rotation of the fragments. They may occur in the young, but are most frequent and common in older adults.

A T fracture is caused by a fall directly upon the elbow and consists of a transverse break across the supracondylar region of the humerus with an extension downward between the two condyles into the elbow joint. In the milder forms of displacement or deformity, the fracture can be treated satisfactorily by means of a hanging cast left in place for four weeks. The arm is then carried

in a sling and a satisfactory range of motion is gradually recovered. Transcondylar fractures are treated similarly.

Displaced T fractures of the humerus require continuous traction for reduction. This can be obtained with the patient lying supine in bed by means of skeletal traction with a pin inserted through the proximal end of the ulna. Traction can also be carried out while the patient is ambulatory. The arm is then supported on an abduction splint to which the skeletal traction is attached. T fractures which do not adequately reduce by closed methods should be treated by open reduction and internal fixation.

Fractures of the medial or the lateral condyle of the humerus are infrequent. They result from shearing forces which produce a fracture which begins at the joint surface and extends upward to emerge at the outer aspect of the medial or lateral cortex of the humerus. The fracture can frequently be reduced by strong traction, although in many cases open reduction and internal fixation are necessary to restore alignment of the articular surface.

Comminuted fractures of the distal end of the humerus with wide displacement and rotation of fragments tax the ingenuity and skill of the surgeon to the utmost. The fracture frequently is of the comminuted variety and may include fragments of bone from the medial epicondylar ridge, the trochlea and medial condyle, varying portions of the capitellum and the lateral condyle and also pieces of the contiguous bone. Some of these fractures look hopeless in the roentgenograms but reduce quite accurately when skeletal traction is applied through the crest of the ulna with the elbow placed in 90 degrees of flexion. Recourse to open reduction may be advisable, however, if the articular surface of the humerus is not satisfactorily restored by skeletal traction (Fig. 48). Highly fragmented fractures of the articular surface are almost impossible to reduce accurately, even by surgery, so that it may be wise to accept the best position which can be obtained by skeletal traction. On the other hand, when the fragments are large and not more than three or four in number, open reduction offers a much better prognosis than an inaccurate closed one. Motion can be permitted three weeks after surgery if the fragments are rigidly secured by internal fixation with threaded wires, screws, bolts or plates.

Comminuted fractures are characterized

depends more upon the direction of the fracturing force than upon muscle action. Spasm of the biceps and triceps muscles pulls the distal fragment proximally and may produce shortening, but neither the distal nor proximal fragment is deviated significantly from the midline by muscle action.

The physical signs of a shaft fracture of the humerus consist of swelling, deformity, crepitation, false motion and, in some cases, wristdrop due to injury of the radial nerve (Fig. 51). Roentgenograms must be made not only in the anteroposterior but also in the lateral projection in order to obtain a complete understanding of the deformity.

Most fractures of the shaft of the humerus distal to the deltoid insertion can be treated successfully by the hanging cast (Fig. 52). This consists of application of a long arm cast with the elbow in 90 degrees of flexion, the forearm in supination and the wrist in a neutral position. The cast extends from the level of the fracture to the distal flexion crease of the palm. The thickness of the cast depends upon the amount of overriding of the fracture which must be corrected by the weight of the cast. If the cast is too heavy, it will distract the fragments—a complication which is difficult to correct. The cast must hang freely from a rope which passes around the patient's neck and is attached to the cast

near the wrist. It is important to caution the patient against resting the cast on a chair arm or other support, for this will defeat the purpose of the cast by causing shortening or angulation of the fracture.

Roentgenograms should be made twenty-four hours after application of the cast, with the patient standing and the cast hanging down freely, for in this way the optimum position of the reduction can be demonstrated. The radiologic check-up is repeated as often as necessary for evaluating the course of the reduction and the degree of union.

The crepitus, which is at first associated with movement of the bone fragments, should not be a cause of worry to the patient, since it disappears at the end of ten to fourteen days as fibrous tissue covers the end of the fragments. Union is achieved in six to twelve weeks.

If an acceptable reduction cannot be obtained with the hanging cast in seven to ten days, the fracture should be manipulated with the patient under general or local anesthesia. The hanging cast is continued in order to maintain the reduction.

Some fractures of the humerus distal to the deltoid muscle are best treated by a shoulder spica cast. This is especially applicable to patients in whom the proximal

Figure 50

the interior of the joint can be obtained and as much of the lower fourth of the humerus as necessary can be uncovered by reflecting the triceps muscle and tendon upward. The ulnar nerve must be isolated at the beginning of the exposure. In some instances it may be desirable to transplant it to the front of the elbow at the time of closure. The radial nerve need not be exposed in the wound, although its location must be kept in mind to avoid its injury. The triceps tendon is sutured to the exposed end of the ulna at the end of the operation. The procedure is a highly specialized one and should not be undertaken by anyone except an experienced surgeon. It is important to understand that this fracture problem can be resolved in

spite of the hopeless appearance of the roentgenograms.

Fractures of the Shaft of the Humerus. Fractures of the shaft of the humerus may be grouped according to their location into those which occur between the humeral condyles and the insertion of the deltoid muscles, those between the insertions of the deltoid and the pectoralis major muscles and those which occur proximal to the attachment of the pectoralis major tendon.

Fractures of the shaft of the humerus distal to the deltoid tubercle (Fig. 50) may be produced by direct or indirect violence. The fracture may be transverse, oblique, spiral or comminuted. They are rarely open fractures. Displacement of the fragments

The radial nerve because of its proximity to the shaft in its middle is one of the nerves at risk.

fragment remains abducted because of excessive obesity of the arm. Alignment, however, can be obtained in some of these patients with a hanging cast by placing enough padding on the inner side of the forearm to lever the lower fragment of the humerus away from the body and align it with the upper fragment. Tendencies toward adduction of the proximal fragment can be similarly corrected by padding the inner aspect of the arm proximal to the hanging cast, for in this way the upper fragment is levered outward.

Fractures located between the attachments of the deltoid muscle and the pec-

Figure 52. Photograph of hanging cast effectively used in the treatment of fractures of the surgical neck and the shaft of the humerus. The arm must hang freely at the side.

toralis major tendon may show considerable deformity. The distal fragment will be pulled proximally and become slightly abducted by the action of the deltoid, biceps and triceps muscles. The deforming force acting on the upper fragment is the unopposed pectoralis major muscle. This fragment assumes a position of adduction and slight internal rotation (Fig. 53).

Reduction of these fractures may be difficult because the proximal portion of the humerus must be abducted so that it can engage the end of the lower fragment. After the fracture is reduced, a hanging cast will usually maintain the corrected position. Open reduction is occasionally necessary.

Fractures of the shaft of the humerus proximal to the attachment of the pectoralis major tendon result in a deformity opposite to the one produced by a fracture distal to the pectoralis major insertion. The proximal fragment of the humerus, consisting of the head and that portion of the shaft between the neck of the humerus and the fracture site, is abducted and externally rotated by the supraspinatus, infraspinatus and teres minor muscles (Fig. 54). The distal fragment, consisting of the major portion of the shaft of the humerus, remains in a more or less neutral position. The adduction force of the pectoralis major balances the abduction action of the deltoid muscle.

For re-alignment of the humerus, the distal fragment must be brought into sufficient abduction to approximate the upper fragment. Some degree of external rotation of

Figure 57. Abduction fracture of the surgical neck of the humerus with separation and proximal displacement of the shaft followed by open reduction and wire fixation. A, Before reduction B, Good anatomic result following surgery.

of the humerus is characterized by varying degrees of separation and displacement of the shaft fragment. This type of fracture is divided into two subgroups, depending upon whether the shaft is in an abducted or adducted position in relation to the proximal fragment.

In abducted fractures the proximal end of the shaft of the humerus usually is displaced proximally and medially to its head and may encroach on the axilla. The head fragment may at times be broken.

Reduction is accomplished by strong downward traction on the arm while the proximal end of the shaft is manually levered outward from the axilla so as to cause the humeral shaft to engage the end of the small head fragment. If the fracture is a transverse one, a hanging cast will ordinarily maintain end-to-end position until union occurs.

Oblique abduction fractures of the humerus may redisplace and require continuous traction, such as was described in the treatment of comminuted fractures of the distal end of the humerus, or else the fracture must be surgically reduced and secured by internal fixation (Fig 57).

Adduction fractures of the humerus result in outward angulation of the proximal end of the shaft as well as of the head fragment. These fractures have a greater tendency to be impacted than do abduction fractures. Treatment consists of the application of a heavy hanging cast which will, as a rule,

correct the lateral angulation and maintain good relationship between the two portions of the bone. In some patients it may be necessary to manipulate the fracture in order to disimpact it. Union is achieved in six to eight weeks, when the patient may resume abduction of the shoulder and use of the arm.

THE SHOULDER

Fractures of the Head of the Humerus.

Fractures of the head of the humerus may involve one or both tubercles or a combination in which the tubercles as well as the remaining portion of the head are fractured.

Fractures of the greater tubercle of the humerus may be of the avulsion type, due to contraction of the supraspinatus, infraspinatus, teres minor or a combination of these muscles. The fragment will usually be pulled upward and outward. The fracture is reduced by approximating the main portion of the humerus to the displaced small fragment. This is accomplished by abduction and external rotation of the humerus, so that the fragment resumes its normal relationship with the rest of the head. In some patients it may be necessary to change the degree of external rotation several times before stereoscopic roentgenograms show optimum reduction. Open reduction will occasionally be indicated.

In another type of fracture of the greater tubercle, the broken segment is impacted into the adjacent bone by forced abduction

Fig. 55 Compound fractures of the humerus with residual nonunion and partial defects (A) may be treated successfully by late application of bone grafts (B) across the pseudarthrosis

the forearm and elbow is necessary, since the small humeral fragment is usually externally rotated as well as abducted. The reduction is best performed with the patient under general anesthesia and is maintained by an abduction splint or a shoulder spica cast with the arm in 90 degrees of abduction and an appropriate degree of external rotation. If sufficient union is demonstrated by roentgenograms at the end of six weeks, the

spica cast can be discarded. Use of an adjustable abduction metal splint then will permit the arm to be brought gradually to the side of the trunk. Abduction exercises can at the same time be instituted, beginning with a small range of motion and gradually increasing it as the power of the deltoid muscle improves and the angle of the splint is decreased. Nonunion of this fracture is rare and the end results are very good (Fig. 55).

Fractures of the Surgical Neck of the Humerus. Fractures of the surgical neck of the humerus are of two general types. The most common is an impacted fracture (Fig. 56) in which the shaft is driven upward so that the head becomes impaled on the metaphysis as the force expends itself against the glenoid. Varying degrees of rotation of the head may be associated with this injury. Ordinarily it is not necessary to disimpact the fracture in an effort to correct the rotation, unless the impaction is extreme.

Treatment should consist of immobilization of the arm at the side of the trunk for seven to ten days, following which it is placed in a sling and circumduction exercises are begun. These exercises are performed several times daily and the patient is permitted to resume active abduction motion of the shoulder against gravity as soon as he is able to do so. Sufficient union is present by the end of three weeks and precludes separation of the fragments.

The second type of surgical neck fracture

Figure 56. Fracture of the surgical neck of the humerus with backward rotation of the head and impaction into the shaft. The greater tubercle is fractured off as a third fragment. A, Before treatment. B, After therapy. Function was good in spite of persistent angulation.

greater and lesser tubercles should indicate the true nature of this interesting fracture.

With a few exceptions, full function of the shoulder cannot be obtained without recourse to open reduction. The head is disimpacted from the shaft and rotated upward to restore its proper angle with the shaft. The greater and lesser tubercles are brought into their normal position between the head fragment and the metaphysis. The tubercles are stabilized by being sutured together with heavy chromic catgut. This will in many cases offer sufficient stability between the fragment of the head and shaft without the necessity of internal fixation with metal. The arm is bandaged to the side of the trunk for three weeks, following which motion is permitted. A satisfactory range of shoulder motion is recovered in four to six months.

Comminuted fractures involving the head of the humerus may not always result in the three large fragments just described. It is considerably more difficult to reassemble multiple fragments representing the articular portion and the tubercles of the humerus and restore some of the normal anatomy. Fortunately the shoulder is not a weight-bearing joint and the prognosis may be excellent even in patients in whom there is some deformity.

Dislocations of the Shoulder Joint. The most frequently dislocated joint in the body is the shoulder, for the shallowness of the glenoid cavity and the absence of strong ligaments evidently favor freedom of movement at the price of stability. The shoulder dislocates most frequently anteriorly, although on occasion the displacement is in a posterior direction (Fig. 59). Forced ab-

duction of the arm causes the humerus to impinge against the acromion process and will, in some cases, lever the head of the humerus out of the glenoid cavity and through the capsule of the shoulder joint. The head of the humerus comes to lie in front of the scapula beneath the subscapularis muscle. When the force is continued, the displacement may carry the head of the humerus beneath the clavicle. On rare occasions the dislocation may be directly beneath the lower margin of the glenoid and the axillary border of the scapula. Sometimes the capsule is not only torn from its attachment to the scapula, but, in addition, the glenoid labrum is severed from the margin of the glenoid cavity.

The patient presents a typical appearance. The arm is held in a position of abduction and supported by the opposite hand. The shoulder appears flat and on palpation the proximal end of the humerus cannot be felt beneath the deltoid muscle. A marked prominence can usually be seen anterior to the shoulder and beneath the clavicle. It is caused by the displaced proximal end of the humerus.

A neurologic examination should precede reduction of the dislocation, as associated nerve injuries are not uncommon. Not infrequently the axillary nerve is injured and the patient loses active use of the deltoid muscle. This can be detected by requesting the patient to try to abduct the arm. Even faint contractions of the deltoid muscle revealed by palpation suffice to indicate that the axillary nerve is intact. Injury of the other components of the brachial plexus is less frequent.

Roentgenograms of the shoulder should

Figure 59. Roentgenogram showing a subglenoid dislocation of the shoulder.

fracture of the humerus with backward displacement of tubercles A, View showing deformity. B, Final result.

injury. There is pain and hesitancy to initiate shoulder motion. Roentgenograms will disclose the impacted nature of the fracture. No treatment other than the use of a sling is usually required. The patient is encouraged to perform swinging circumduction exercises immediately and to resume abduction motion as early as possible, for rarely will the fracture disimpact or fail to heal. Roentgenograms should be made frequently during the first three weeks to make sure the fragment has not displaced. If it has separated from the shaft, then the extremity should be immobilized in a cast in abduction and external rotation.

Fractures of the greater tubercle are also encountered in association with anterior dislocations of the shoulder. The fragment usually remains in its normal position and falls into its defect in the humeral head as the dislocation is reduced. Union occurs to a sufficient degree in four weeks to allow resumption of motion. In many patients the arm must be abducted and externally rotated in order to obtain reduction of the fracture, although this position carries within it the danger of recurrence of the dislocation. The arm should therefore be kept in as much adduction and forward flexion as possible to minimize the tension on the anterior capsule of the shoulder without jeopardizing the reduction.

Isolated fractures of the lesser tubercle of the humerus are infrequent and usually of the avulsion type, because of the subscapularis muscle. The fracture is treated by rotating the arm internally and keeping it mobilized at the side of the trunk for four weeks to permit the humeral head to approximate the lesser tubercle.

An injury of unusual interest is a comminuted fracture of the humerus in which the articular portion of the head is driven backward with such violence that the greater and lesser tubercles are forced to give way and the head becomes impacted on the upper end of the shaft (Fig 58). The fracture results from an injury in which the humerus is forced violently against the glenoid portion of the scapula. The roentgenograms show a characteristic appearance. The articular cortex which outlines the head of the humerus in the roentgenogram will be found to lie horizontally across the end of the shaft instead of at an angle of 45 degrees to the longitudinal axis of the humerus. There is, moreover, considerable displacement between the head and the glenoid fossa.

The first interpretation of the roentgenogram showing marked displacement of the tubercles suggests dislocation of the shoulder, but the characteristic displacement of the head and the associated fractures of the

ularis muscle is next detached from the humerus. The humeral head is replaced and fixed to the shaft by loops of wire or staples. Following this, the capsule is repaired, the muscles are replaced and the wound is closed. The arm is then bandaged to the side of the trunk for three weeks, after which time motion is resumed. The fact that the humeral head undergoes aseptic necrosis from loss of the blood supply has prompted some surgeons to advocate its excision. However, since the head usually unites with the shaft and is in most instances gradually replaced by new bone, it is better to retain the head rather than to incur a flail shoulder which results from its removal.

THE SHOULDER GIRDLE

Fractures of the Clavicle. The clavicle is most frequently fractured in its middle third. The injury results from a fall onto the shoulder as well as a direct blow against the clavicle. It occurs most often in children.

The symptoms consist of pain, swelling and deformity at the site of the fracture. A fracture of the clavicle should always be suspected when a small child has sustained a fall from a chair or bed and subsequently hesitates to use the extremity. The presence of local tenderness over the clavicle, together with the demonstration of crepitus or deformity when present, should establish the diagnosis. The fracture is more easily recognized in adults who will refer the symptoms to the clavicle.

The deformity of displaced fractures of the clavicle is characteristic. The medial

fragment is pulled proximally and backward by the sternocleidomastoid muscle. The outer portion, the scapula and upper extremity fall forward, downward and toward the midline (Fig. 60), because of the weight of the extremity and loss of the normal support provided by the intact clavicle. Stereoscopic roentgenograms will reveal the nature of the deformity.

Reduction of fractures of the clavicle is accomplished by approximating the displaced outer fragment to the medial one. This is achieved by elevation and retraction of the shoulder girdle which will mobilize the outer fragment. Strong backward pressure on both shoulder girdles is required to correct marked overriding. Numerous methods have been devised for immobilization of these fractures, but a figure-of-eight plaster dressing is preferred. It is applied as follows: The patient is seated on a stool or a table and local anesthesia is induced at the fracture site. One assistant then elevates the patient's right arm and retracts it as far posteriorly as possible. At the same time a second assistant places the patient's left arm in a similar position. The operator stands between his assistants and behind the patient. Sheet wadding and then plaster are applied in a figure-of-eight manner, crossing the clavicles, passing under the armpits and crisscrossing posteriorly. As the plaster begins to set, the patient is placed in the supine position on a table with a small sandbag between the scapulae. Backward pressure is exerted on the shoulders by the surgeon to obtain maximum retraction,

Fig. 60

be obtained in all these patients, since there are associated fractures of the head or neck of the humerus, the most common being avulsion of the greater tubercle

Several methods are available for reduction of simple anterior dislocation of the shoulder. The oldest, often referred to as the hippocratic method, consists of downward traction on the arm while the unbooted foot of the physician is placed in the axilla. Gradual adduction of the extremity will usually effect a reduction. Care must be exercised that the pressure exerted in the axilla does not injure its contents

The technique of the Kocher method is safe, provided it is carried out gently. It is quite easy to fracture the proximal end of the humerus if the shoulder muscles are not relaxed or if too much force is applied. Manipulation is ordinarily carried out with the patient under general anesthesia. It can be done equally well following an adequate dose of morphine or Demerol, permitting the patient actively to perform the maneuvers as directed by the surgeon.

The patient is supine on the table and an assistant places an arm around the chest near the axilla so as to provide upward and outer pull for countertraction. The surgeon flexes the patient's elbow, obtains a strong hold on the arm just above the flare of the distal humeral condyles and pulls strongly downward. The arm is kept in about 20 degrees of abduction. The patient is instructed to rotate the arm externally. When his hand approximates the surface of the bed or table, he is to move his elbow toward the front of his chest. As the elbow reaches the side of the trunk, his hand is placed on his opposite shoulder. Invariably the dislocation will be reduced on the first attempt. There is little pain during the maneuver because the muscle spasm which would ordinarily act to oppose the manipulation is absent. If the humerus is not replaced after two attempts, the patient should be given a general anesthetic and the manipulation repeated. Restoration of the normal contours of the shoulder will indicate that reduction has been successful. The arm is then bandaged to the trunk with the hand in front of the thorax. It should be held there for three weeks after roentgenograms have confirmed the accuracy of the reduction.

Patients with recurrent dislocations are permitted to use the extremity without an intermediate period of immobilization, for it will not preclude the possibility of subsequent dislocations.

Posterior dislocations of the shoulder are relatively rare. They are manifested by flattening of the shoulder, a prominence posterior to the joint and an adducted position of the arm. Reduction is accomplished by downward traction on the extremity and forward pressure on the head of the humerus

Neglected dislocations of the shoulder cannot generally be reduced by closed manipulation. The head of the humerus should be replaced in the glenoid cavity by surgery even though the result is not wholly satisfactory because of persisting limitation of motion.

Fracture-Dislocations of the Shoulder Joint. Anterior dislocations of the shoulder, with simultaneous fracture of the surgical neck of the humerus, occur most commonly. Dislocations accompanied by fractures of the coracoid process or the glenoid cavity also occur, although very infrequently. A fracture-dislocation of the shoulder which involves the neck of the humerus occurs mainly in older people. The fracture takes place while the arm is in abduction; the shaft of the humerus then drops alongside the trunk while the head of the humerus remains displaced beneath the subscapularis muscle

The diagnosis is usually suggested by the pain, loss of shoulder function, flattened deltoid region, palpable swelling under the clavicle and crepitus on passive motion. The exact level and type of fracture are not easy to gauge except by means of roentgenograms.

Replacement of the head of the humerus should be the first step in treatment. With the patient under general anesthesia, downward traction is made on the arm, and thereby on the humerus, to make room between it and the scapula, thus making possible the replacement of the humeral head into the glenoid cavity. Care must be taken that contents of the axilla are not injured during the manipulation. If manual reduction is not successful, traction is applied to the arm while it is in 90 degrees of abduction, and an attempt is made to pull the head into the capsule by way of the untorn soft tissues between the head and the shaft. Open reduction must be performed if the head is still dislocated

The shoulder is exposed through an anterior deltoid incision. The short head of the biceps and the coracobrachialis muscles are reflected downward following osteotomy of the tip of the coracoid process. The subscap-

terposed between the articular surfaces of the outer end of the clavicle and the acromion gives additional stability to the articulation and permits greater range of motion.

Dislocation of the acromioclavicular joint (Fig. 62) may displace the outer end of the clavicle upward, backward or forward. The degree of displacement will depend upon the severity of the injury to the restraining soft tissues. Rupture of the acromioclavicular ligament may permit the clavicle to dislocate, but it is only in the presence of rupture of the coracoclavicular ligament that wide displacement occurs.

The injury results either from a fall on the shoulder or from forces directed upward through the arm to the acromioclavicular joint. The patient usually experiences little pain, while the physical examination discloses local swelling and a palpable deformity at the acromioclavicular joint.

For minor subluxations of the acromioclavicular joint, adhesive dressing may suffice (Fig. 63). On the other hand, it is difficult to maintain adequate downward pressure on the outer end of the clavicle for six weeks by means of adhesive to correct major dislocations and to permit repair of the ligaments and capsule.

A satisfactory result can often be obtained by the use of a body and arm cast, but this entails immobilization of the corresponding extremity for at least six weeks. A circular body cast which extends from the mid-thorax to below the iliac crests is applied to

the trunk. It is joined with a second cast which encases the arm on the side of the injury with the elbow in 90 degrees of flexion. The dislocation is then reduced and held by a strap of webbing which crosses over the clavicle and is attached in front and back to the top of the body cast.

Some surgeons prefer open reduction for treatment of complete dislocations of the acromioclavicular joint. This is accomplished by a curved incision made along the outer portion of the clavicle and around the shoulder. The skin is reflected to expose the acromion and the adjacent clavicle. The dislocation is corrected and maintained by drilling two threaded wires through the acromion process into the outer fourth of the clavicle (Fig. 64). The capsule and ligaments are repaired and the wound is closed. The arm is bandaged to the side of the trunk for two weeks, after which cautious use of the extremity is allowed. The threaded wires are removed at the end of ten weeks.

Some chronic dislocations of the acromioclavicular joint are compatible with full use of the extremity. In the presence of pain and marked disability, the symptoms may be relieved by resection of the clavicle lateral to the coracoclavicular ligaments, provided these are intact. This type of resection is particularly effective in relieving the pain

Figure 62. Roentgenogram showing proximal dislocation of the outer end of the clavicle at the acromioclavicular joint.

Figure 63. Photograph of a patient with an acute acromioclavicular dislocation treated by adhesive dressing (Key, J. A., and Conwell, H. E.: *The Management of Fractures, Dislocations and Sprains* C. V. Mosby Company)

Figure 61. Intramedullary fixation of comminuted fracture of clavicle, which could not be reduced adequately by manipulation

at the same time permitting the plaster dressing to mold itself over the sandbag and between the scapulae. The cast is trimmed to maintain a buttress in front of the outer end of the clavicle but is cut away sufficiently in the axillae to prevent excessive pressure upon their contents.

Roentgenograms are obtained following application of the cast and if reduction is not satisfactory, it should be repeated. Accurate end-to-end repositioning of fractures of the clavicle is not necessary in the average patient. A considerable degree of persistent overriding may be accepted in young children, since the clavicle will be remodeled as growth continues, with a satisfactory end result. Some overriding may be accepted in adults, provided there is no undue prominence to cause pressure symptoms when the patient carries objects on his shoulder. A cosmetically acceptable result is, of course, important in women and may require continuous arm traction in abduction with the patient at bed rest.

Comminuted fractures of the clavicle can in most instances be reduced satisfactorily by the methods just described. In a few patients, open reduction is necessary, espe-

cially when one of the lesser fragments rotates and becomes caught in the adjacent soft tissues. An appropriate incision is then made just below the site of fracture. The bone is exposed subperiosteally and internal fixation is obtained by means of a heavy intramedullary threaded wire (Fig. 61). The wire is first drilled outward through the medullary canal of the lateral fragment, permitting it to emerge through the skin in the suprascapular region. The fracture is then reduced and the threaded wire is drilled medially for a sufficient distance into the inner fragment. The smaller fragments are brought into their normal position and fixed with circular loops of heavy chromic catgut. The wound is closed and the arm is bandaged to the side of the trunk. Sutures are removed at the end of ten days, when the arm is placed in a sling and shoulder motion is resumed gradually. Union occurs in young children in about six weeks, in adults it may take eight to ten weeks.

Dislocations of the Acromioclavicular Joint. Stability of the acromioclavicular joint is dependent upon the intactness of the acromioclavicular and the coracoclavicular ligaments. A cartilaginous disk which is in-

crepitus of air in the subcutaneous tissues will be felt and the condition may spread over the whole of the chest, even up to the neck and down to the abdomen. Muscular violence due to heavy lifting, sneezing or coughing may also cause rib fractures, although the incidence is low. The upper two ribs are infrequently broken because of the protection afforded by the clavicle. The lowest, or floating, ribs are freely movable and difficult to break.

The fracture may be transverse, oblique or comminuted (Figs. 65 and 66). Displacement is usually slight. Open fractures, except those from gunshot wounds, are rare.

Symptoms include severe pain in the chest, with aggravation by deep breathing and coughing or straining; swelling and tenderness will localize the site of the fracture. When crepitus cannot be detected by palpation, it may be heard at times with the stethoscope. Crepitus is ordinarily present for ten to fourteen days, by which time fibrous tissue and some callus will have covered the ends of the fragments and eliminated movement.

Roentgenograms must be taken after every chest injury. Portable films are satisfactory if they are taken with the patient in the upright position and are overexposed to demonstrate fractures, collapse of lung tissue

and a fluid level. Occasionally a linear fracture without displacement is not visible in the x-ray film, thus leaving the diagnosis of fracture uncertain until callus is seen in a later roentgenogram or until palpable. Fracture or separation of a costal cartilage cannot be demonstrated on the x-ray film and its detection must be made by physical signs alone.

Multiple fractures with collapse of the chest wall may produce shock and dyspnea, the intrathoracic damage being so severe as to cause death. It is therefore necessary to begin immediate administration of intravenous fluids while the patient's blood is being crossmatched for transfusion. At the same time it is imperative to evaluate the status of the respiratory mechanism in these patients and to make every effort to restore its normal functioning, first by aspiration or intubation. Tracheotomy and skeletal traction should be employed to stabilize the chest wall if necessary. Steinmann pins can be passed parallel to the ribs beneath the pectoral muscles on one or both sides of the chest and attached by means of spreader bows to weights suspended from an overhead frame. Definitive treatment of other injuries must be delayed until this is effected.

Both single and multiple fractures, if uncomplicated, may be treated by restricting the respiratory excursions, which can be

Figure 65 Roentgenogram showing fractures without displacement of the lower four ribs. This type of fracture can usually be treated by adhesive strapping or an Ace bandage which encircles the lower portion of the chest so as to restrict inspiration movements.

Figure 66 Crushing injury to chest with multiple fractures of ribs and collapse of lung frequently requires lifesaving measures in treatment.

Figure 64 Dislocation of the acromioclavicular joint unsuccessfully reduced by closed method and subsequently treated by open reduction and pin fixation. The ligament and capsule were repaired at the same time. Wires were removed at the end of three months. The result was good.

and limitation of motion associated with arthritis which often follows injuries to the acromioclavicular joint. Arthrodesis should never be performed since it restricts elevation of the arm.

Dislocation of the Sternoclavicular Joint. Dislocations of the clavicle occur much less frequently at its inner than at its outer end. The sternoclavicular joint is reinforced by the sternoclavicular and the costoclavicular ligaments. A cartilaginous disk is interposed between the articular surfaces of the joint and facilitates movement of the clavicle on the sternum.

In dislocations of this joint, the displacement is usually in an upward direction and is the result of a fall on the shoulder. The displacement may be forward. Little, if any, pain is associated with the dislocation and the patient notices only a firm prominence at the base of the neck. In many patients, early medical care is not sought because of the minimal disability produced by the dislocation.

The diagnosis is easily established by physical examination but is difficult to demonstrate by roentgenograms.

Acute dislocations of the sternoclavicular joint are hard to reduce by conservative means. There is no satisfactory method of

maintaining the clavicle in its normal relationship with the manubrium following closed reduction. Open reduction is probably the most satisfactory means of correcting the dislocation. Heavy wire must be used to anchor the inner end of the clavicle to an adjacent rib, while at the same time the ligaments are repaired. The arm is immobilized in a Velpeau dressing for three weeks.

Chronic dislocations of the sternoclavicular joint are best left untreated unless they cause considerable disability, in which case the inner end of the clavicle can be resected.

Fractures of the Scapula. Fractures of the scapula may involve its spine, the glenoid portion of the bone, the supraspinatus or infraspinatus fossae. They are the result of direct violence, such as a blow to the shoulder blade. Comminution may be marked, but the displacement is usually minimal.

No special treatment is required for these fractures other than the support of the arm in a sling and a bandage around the trunk to immobilize the scapula against the chest wall. Function of the extremity can be resumed in about three weeks.

On rare occasions, a fracture of the scapula is seen in which a portion of bone is angulated to such a degree that it cannot be reduced by manipulation. In these patients, open reduction is required to relieve the prominence, if the bone fragment is not too large or represents a sizable portion of the glenoid cavity, it may be removed without impairing the normal function of the scapula or the shoulder.

Fractures which involve the neck or the glenoid cavity require more careful treatment. Frequently the fractures are impacted and require a sling only until the pain and reaction from the injury subside, following which function can be rapidly resumed. Skeletal traction with a pin through the proximal end of the ulna is necessary to reduce some displaced fractures involving the glenoid portion of the scapula. Open reduction is rarely indicated.

THE THORAX

Fractures of the Ribs. An injury to the front of the chest compressing the thoracic cage commonly results in fractures of the ribs along their axillary aspects. A severe direct blow which fractures the ribs may damage the pleura and the lungs, causing pneumothorax, hemothorax or surgical emphysema. With the latter, the characteristic

be necessary to stop uncontrollable hemorrhage, relieve tension pneumothorax or to remove large blood clots. If empyema occurs, it must be treated either by antibiotics or surgery as may be indicated.

Open fractures of the chest wall require immediate débridement, closure of the wound, continuous aspiration and re-expansion of the lung. Elderly patients should be kept in the sitting position out of bed as soon as their condition will permit.

Pain usually disappears in two to three weeks. Rapid and satisfactory union occurs, as a rule, in even the untreated patients, in six to eight weeks. Nonunion rarely occurs and malunion hardly ever causes undesirable symptoms. Finally, in the more severe chest injuries the prognosis must depend primarily on the complications.

THE SPINE

Any patient who complains of pain in the neck or back after a fall from a height, a severe blow to the shoulders, an automobile accident or similar injuries should be assumed to have sustained a fracture of the spine until examination proves otherwise. Fractures of the spine may be associated with dislocation of the facets while displacement of one vertebra on another may not be accompanied by a concomitant fracture. The spinal cord may be injured at the same time by displaced bone fragments, by lacerations, hemorrhage or a complete transection as one vertebra dislocates forward on the one below.

Patients with fractures of the spine must

receive expert care from the moment of the accident until the fracture or dislocation has been diagnosed and appropriate treatment instituted.

Fractures and Dislocations of the Cervical Spine. Fractures of the cervical vertebrae are best treated by skeletal traction using Crutchfield tongs. The tongs can be inserted with the patient under local anesthesia and without placing him on the operating table, while gentle manual or halter traction is maintained on the head. Fifteen pounds of traction is adequate for the treatment of the average cervical fracture.

The head is kept in a neutral position at first, and then is gradually brought into hyperextension in order to obtain maximum reduction of the fracture. A Minerva jacket is applied at the appropriate time and its use is continued for a period of three months. A removable cervical collar is then substituted and motion of the head and neck is gradually resumed. The collar is discarded after the spine is mobilized and muscle tone has been recovered.

The best procedure for reduction of dislocations of the cervical spine is continuous skeletal traction (Fig. 69). Fifteen pounds of straight traction is applied and portable roentgenograms are obtained after thirty minutes. If the inferior articulating facet of the displaced vertebra has not been pulled upward beyond the level of the superior articulating facet of the body below, an additional 5 pounds is added to the traction. Roentgenograms are repeated at intervals of thirty minutes and further weights are added

successfully treated by Crutchfield tongs. A, 15 lb. traction was applied. C, Final result. Note which increased the stability of the spine.

Figure 67 Front and back photographs of a patient, showing the vertical method of adhesive strapping for fractures of the upper four ribs (Key, J. A., and Conwell, H. E. *The Management of Fractures, Dislocations and Sprains* C. V. Mosby Company)

Figure 68. Strapping ribs The adhesive extends from the opposite side of the chest posteriorly to well past the midline anteriorly. The skin is first painted with tincture of benzoin in order to avoid reaction from the adhesive tape.

done by a local strapping that crosses the midline in front and back or by a circular dressing around the lower portion of the thorax. The material used for this purpose may be adhesive (Figs. 67 and 68), elastic bandage or a rib belt. Adhesive strapping should not be too tightly applied in patients with multiple displaced fractures, so as not to increase the deformity. Instillation of 1 per cent Novocain into the hematoma at the fracture site will relieve pain and muscle spasm. Often a dry and persistent cough is

present from pleural irritation which may be relieved by a sedative cough mixture or codeine.

Emphysema usually does not require treatment and disappears in a few days. Pneumothorax with severe dyspnea can be relieved by aspiration of the air. If necessary, a catheter may be inserted and an air seal and a water bottle used for continuous aspiration. Blood in the pleural cavity should be removed as demanded by its interference with lung function. Open surgery may

Open reduction of fractures and dislocations of the cervical spine must be performed while skeletal traction is maintained on the head. The laminae and facets are exposed in the usual manner; traction is then increased with the facets under direct vision. When the articulating processes clear each other the head is gently extended and traction is released as the upper vertebrae is brought into proper alignment with the body below. A loop of wire is placed around the spinous processes of the two vertebrae to maintain the reduction. Many surgeons feel that a spinal fusion should be done at the same time.

Fractures of the odontoid process are usually associated with dislocation of the atlas on the axis (Fig. 70) and are produced by falls in which the head is thrown violently forward. Treatment consists of skeletal traction with the head in a neutral position. After the first cervical segment has cleared the axis, the head is gradually extended until reduction is accomplished and the odontoid fragments assume their normal relationship. Skeletal traction is maintained for four weeks, following which a head and body cast is applied for an additional eight weeks.

Dislocations of the atlas on the axis without an associated fracture of the odontoid process are of grave danger to the patient, because transection frequently occurs when the cervical cord is forced against the pointed end of the process as the atlas moves forward. Here, too, treatment consists in the immediate application of skeletal traction and gradual reduction of the dislocation by extension of the head. The subsequent treatment is the same as that for a fracture-dislocation of the odontoid process.

Fractures of the Dorsal Spine. These

by the conservative attitude of many surgeons. These patients are therefore provided with a Taylor-type back brace or a lumbodorsal corset, reinforced with heavy stays to relieve the strain on the fractured body and to maintain maximum posture of the spine during the three months required for healing. Some surgeons prefer a body cast which extends upward from the pelvis and over the tops of the shoulders.

Fractures of the Lumbodorsal Spine. Fractures of the lower thoracic vertebrae and those involving the upper lumbar bodies are due to severe flexion motion of the spine in which the patient assumes a so-called

jackknife position. These are the most common fractures which occur in the spine. An effort should be made to reduce the involved body accurately.

The resulting deformity of the vertebral body may be of two general types. If the pressure which is applied to the body is evenly distributed to the superior surface of the vertebra below, the latter will become wedge shaped as its anterior height is shortened and the posterior portion remains unchanged (Fig. 71). If, on the other hand, the angulation of the spine at the time of the injury is more acute, the vertebral body will likely be broken into several segments and result in a comminuted fracture. The adjacent intervertebral disks are usually also injured and the prognosis is less favorable than in patients having simple wedge fractures.

Patients with deforming fractures of the lumbodorsal vertebrae must be treated in the hospital. If there are no associated injuries, the patient may be taken to surgery for reduction of the fracture and application of an adequate body cast. Many surgeons

Figure 71 Roentgenogram of the lumbodorsal spine showing depressed superior surface of the first lumbar vertebra. The fracture was treated by means of a lumbodorsal corset reinforced with heavy stays. No further collapse occurred.

Figure 70 Fracture of the odontoid process with anterior displacement of the atlas on the axis. E and F, Final anatomic result.

if indicated. As soon as the facets have cleared each other, the head is placed in hyperextension and roentgenograms are again made. If the anteroposterior and lateral views show the facets to be in proper alignment, the traction is gradually decreased to permit reduction of the dislocation as the two vertebrae approximate each other and the facets lock. After accurate replacement has been accomplished, traction

include the head. Some surgeons apply the cast immediately after reduction of the dislocation with the head placed in moderate hyperextension, provided the reduction is stable. The patient can then become ambulatory.

Roentgenograms must be repeated at intervals of two to three weeks to make sure that the dislocation has not recurred. The

cast is discarded after three months, at the end of which period a cervical collar is used until painless motion has been restored.

Dislocations and fracture-dislocations of the cervical spine which cannot be adequately reduced by skeletal traction require open reduction. Manipulation of acute bilateral dislocations of the cervical vertebrae is not recommended, although there is no objection to careful manipulation of a unilateral dislocation of a cervical facet. This is accomplished by applying firm traction to the chin, while angulating the head and neck toward the side of the intact joint. After the articulating process of the dislocated vertebra has cleared the one below, the head is gently rotated toward the side of the dislocation so as to bring the facets in realignment. The traction is then released and reduction is completed. Roentgenograms will show whether manipulation has been successful. Persistent dislocations require surgery.

on the psoas muscles and may at the same time allow some reduction of the fractures. A plaster cast can be applied after seven to ten days if several of the transverse processes are fractured and the patient's condition warrants fixed immobilization. Most indi-

viduals with only involvement of one or two processes will recover satisfactorily after local infiltration of the fracture sites with Novocain and protection of the back from lifting and other strenuous activities for six weeks.

Figure 100

Figure 72 Diagram showing the type of plaster jacket used in fractures of the lumbodorsal vertebrae

recommend bed rest for several days until the abdominal distention which invariably accompanies a fracture of the spine is relieved. Others believe that the distention is more easily controlled if the fracture is immediately reduced.

Numerous methods have been devised for reducing compression fractures of the lumbodorsal region, but the two-table technique, as described by Watson-Jones, is preferable. This consists in suspending the patient in the supine position between two tables. The table which holds the upper end of the body should be about 6 inches higher than the one which supports the legs. The patient is allowed to assume a position of maximum degree of hyperextension of the spine without actual manipulation of the back by the surgeon. Reduction of the fracture is accomplished by the corrective force exerted on the fracture by the tension generated in the anterior longitudinal ligament and the annulus fibrosus of the intervertebral disks. The patient is given an adequate dose of a sedative, but a general anesthetic should not be used. A plaster cast is finally applied which must extend from the sternal notch to the symphysis. The cast is trimmed posteriorly so that the scapulae are free, but the lower margin of the cast should extend well down to the gluteal areas posteriorly and the symphysis anteriorly (Fig. 72).

The patient is then returned to bed. Some

surgeons favor a period of recumbency of from four to six weeks and others recommend ambulation as soon as the patient becomes adjusted to the cast and is relieved of pain in the spine and of abdominal distention.

Other methods of reducing fractures of the lumbodorsal region consist of suspension of the patient by the ankles in a supine position on the fracture table (Davis' method), correction of the deformity by means of a hyperextension jack as described by Ryerson, the use of the Goldthwaite irons or gradual correction of the deformity by progressive hyperextension of the spine with the Gatch bed in reverse.

The goal of treatment of fractures of the lumbodorsal spine is complete restitution of the normal height and shape of the vertebrae regardless of the way reduction is accomplished, immobilization in a properly fitting plaster cast, institution of a supervised exercise program to maintain good tone of the muscles of the back and abdomen and, after removal of the cast, a rehabilitation program to enable the individual to resume his usual form of employment.

Healing of wedge-shaped fractures of the lower thoracic and upper lumbar vertebrae is complete by the end of four months, at which time the cast is removed. Comminuted fractures unite more slowly and the deformity has a tendency to recur (Fig. 73) and, therefore, immobilization in a cast for four months should be followed by the use of a Taylor back brace for two months.

Fracture-Dislocations of the Lumbodorsal Region. These are best treated by open reduction. The facets are exposed through an adequate incision. The patient then is cautiously flexed on the table and longitudinal traction is applied in order to free the facets and to permit reduction of the dislocation by extension. A spinal fusion should be performed at the same time to insure stability of the back. A cast is applied and left in place for four months.

Fractures of Transverse Processes of the Lumbar Vertebrae. These fractures are common. They represent avulsion fractures in which the tips or other portions of the transverse processes are separated as a result of spasm of the psoas muscles. Following the injury, these patients demonstrate the findings characteristic of acute low-back strain. The fractures are discovered on routine roentgen ray examination.

The patient is best treated by bed rest in a sitting position, for this relieves the tension

on the psoas muscles and may at the same time allow some reduction of the fractures. A plaster cast can be applied after seven to ten days if several of the transverse processes are fractured and the patient's condition warrants fixed immobilization. Most indi-

viduals with only involvement of one or two processes will recover satisfactorily after local infiltration of the fracture sites with Novocain and protection of the back from lifting and other strenuous activities for six weeks.

Fractures and Dislocations of the Pelvis and the Lower Extremity

By HAROLD A. SOFIELD, M.D.

HAROLD AUGUSTUS SOFIELD, born in New Jersey, received his education by geographically covering the United States. Columbia University, Northwestern University and San Francisco City-County Hospital have contributed to his experiences. He chose to receive his orthopedic training in the Midwest, where he has remained as Chief Surgeon, Shriners' Hospital for Crippled Children, Chicago Unit. He is Professor of Orthopedic Surgery at Northwestern University Medical School.

FRACTURES OF THE PELVIS

Pelvic fractures fall into four general types: fractures of the rim of the pelvis, acetabular fractures, fractures of the pelvic ring, and fractures of the sacrum and coccyx.

These fractures are common and are increasing in number, because so many injuries are received while persons are in sitting positions in automobiles and airplanes. The most serious fractures are those of the ring of the pelvis, practically all of which are compression fractures. When disruption of the pelvic ring, which is formed by the bones surrounding the pelvic opening, is severe, viscera present inside the pelvic ring may be punctured by sharp spicules of the fractured bones. The bladder and the rectum are most commonly punctured, but tears of the urethra are frequent and injuries of the ureters are not uncommon. In all persons having fractures involving the pelvic ring in which significant displacement of fragments is present it is imperative that the condition of the urinary tract be ascertained as promptly as possible. If the patient voluntarily voids clear urine with no blood, the chances are against any serious damage being present. A small amount of blood in the first specimen followed by clear, bloodless urine usually means injury to the mucous membranes, but no serious damage. When the patient cannot void, he should be carefully catheterized with a small, soft catheter. If the catheter cannot be introduced into the bladder and if blood is present at the tip of the catheter, injury to the urethra may be suspected. If the catheter passes into the blad-

der and blood is persistently found in the urine, injury to the bladder may be surmised. Once the catheter is in place, it should not be removed, for it may be very difficult to reinsert later. Whenever injury to the urethra, bladder or ureter is suspected, immediate steps should be taken to treat the injury. All patients with pelvic ring fractures should have a rectal examination to see whether a sharp fragment of bone may have punctured the lining or may be lying close to the rectum. Occasionally a sharp fragment may be moved away from danger by digital pressure. Shock accompanying violent fractures of the pelvic ring which produce severe displacement is often profound and sometimes fatal. Gentle manipulation to reduce marked displacement should be attempted because gross displacement adds to the shock.

Fractures of the Rim of the Pelvis. Almost the entire outer surface, or rim, of the pelvis serves for the attachment of muscles. Strong muscle contractions, particularly when the individual is participating in athletics, cause avulsion type fractures. Certain areas of the rim where strong muscle groups are attached to relatively small areas of bone are most vulnerable. Avulsion fractures of the rim occur most commonly at the anteroinferior iliac spine, the anterosuperior iliac spine, the crest of the ilium and the tuberosity of the ischium. Treatment consists of bed rest for a week or two until pain is reduced, then limited activities for several weeks. Even though displacement seems rather marked, closed manipulation is useless and open re-

placement with fixation is not required because none of these fractures seems to have any effect on ultimate function.

Acetabular Fractures. Two groups of fractures may be identified in consideration of fractures of the acetabulum: fractures of the rim of the acetabulum and fractures of the floor of the acetabulum.

Acetabular fractures are frequently grouped under dislocations of the hip because so-called central dislocations of the hip often accompany fractures of the acetabular floor. There are, however, many acetabular fractures in which there is no displacement of the head of the femur and, in common with pelvic fractures in general, the number of acetabular fractures is increasing. In about one-half of the patients with acetabular fractures, other pelvic fractures are present (Fig. 74). Marked displacement of the acetabular floor into the pelvis may, in rare instances, cause injury to viscera or nerves occupying the pelvis. These fractures are most apt to appear in young and middle-aged adults; in older persons the same type of force is more likely to cause fractures of the upper end of the femur.

Fractures of the rim of the acetabulum may occur with or without dislocation of the hip. They are usually caused by the head of the femur being forcibly driven against the acetabular rim as is found in the mechanism producing posterior dislocation of the hip. Most frequently the rim fractures are at the posterosuperior border of the acetabulum, but, on rare occasions, practically the whole rim may break loose. Customarily the piece, or pieces, of the posterior rim are driven

Figure 74 Fracture of the floor of the acetabulum pushing the ischial portion inward. There is an associated fracture of the pubis near the symphysis.

backward and if the head of the femur follows, producing a posterior dislocation, the fractured portion of the rim may stay closely connected to the femur and may reduce satisfactorily when the dislocation is reduced. If, however, there is no dislocation and the fractured fragments are large and significantly displaced from their anatomic position, or if large fragments accompanying a dislocation do not come into place when the dislocation is reduced, open reduction with fixation by a screw or screws is indicated (Fig. 75). Provided the pieces are small and are not displaced into the acetabulum, they may be ignored.

If the fractured pieces of the rim are large, light traction on the leg should be instituted and continued for about four weeks. This is true whether there was no significant displacement to begin with or whether open

Figure 75. A, Fracture of posterior rim of the acetabulum with persistent displacement. B, Open reduction and screw fixation of fracture of acetabular rim. Traction should be continued for several weeks.

reduction and internal fixation were required. Every effort should be made to keep the acetabulum as near normal as possible. After removal of balanced Russell traction the patient is permitted to exercise in bed for one week and is then given crutches for two weeks. In most instances a good result can be expected.

Fractures of the floor of the acetabulum occur from force applied to the greater trochanter in line with the neck of the femur. If the floor of the acetabulum cannot resist the force, it bursts inward, usually splintering from the pubis and separating near the junction of the acetabular portions of the ilium and pubis. Most often the iliac portion of the acetabulum remains in place while the pubic portion is shoved inward. Occasionally both iliac and pubic portions are displaced inward and in very rare instances the pubic portion remains in place and the iliac portion pushes outward.

If there is a stellate type of fracture with no appreciable amount of displacement, balanced Russell traction may be applied for four to six weeks with moderate traction on the injured side and light traction on the other leg. The results in such patients are usually good although, if there is a fracture across the weight-bearing portion of the acetabulum, disabling arthritis is apt to eventuate.

When moderate inward displacement of the acetabular fragments occurs, heavy skeletal traction for five or six days with a wire through the lower femur or upper tibia, followed by moderate traction, is indicated. The leg should be in about 45 degrees of abduction and slight flexion at the hip. If, after several days, x-ray examination shows that the displaced acetabular floor has not returned to its normal location, open reduction should be done. Surgical approach is made by an incision along the iliac rim near the anterosuperior iliac spine. By dissecting subperiosteally against the inner surface of the ilium and the pubis, the region of the acetabulum can be reached. The fragments are manipulated into place and fixed with wire or screws. Heavy traction is again continued for several days before moderate traction is used.

Grossly displaced acetabular fractures, in which the head of the femur has remained driven into the pelvis, require heavy skeletal traction for several days and, if reduction is not satisfactory and the head of the femur has not returned to its normal position, manipulation with the patient under anes-

thesia may be tried. Caution must be exercised not to displace further the fragments and cause intrapelvic damage. If the floor of the acetabulum does not follow the head of the femur into good reposition, open reduction as described above should be done. This likewise should be followed by heavy traction.

Traction outward in line with the neck of the femur by applying a sling or adhesive traction to the upper, inner thigh combined with longitudinal traction is occasionally useful. Some surgeons prefer to use a pin or a screw through the greater trochanter fastened to a lateral traction device. Others find a well-leg type of traction helpful. Regardless of the apparatus, traction should be directed outward at 45 degrees or a little more.

Severely displaced acetabular floor fractures, even when adequately replaced, carry a doubtful prognosis (Fig. 76). Disabling arthritis is prone to intrude and it is wise to keep in mind that a hip fusion operation may be necessary later.

Fractures of the Pelvic Ring. The pelvic ring consists of a right and left pubis, ischium and ilium, and a single sacrum. The coccyx, while attached below the sacrum, carries no body weight and is not an integral functioning portion of the pelvic ring. The ring, made up of its various bony components, transmits all the body weight from above to the lower extremities. Pelvic ring fractures may be divided into three types: incomplete fractures of the ring, complete fractures without displacement and complete fractures with displacement.

Incomplete fractures cause little trouble. This type is represented by isolated fracture of the superior ramus of the pubis, partial fracture in a vertical direction into the wing of the ilium, isolated fracture through the ramus of the ischium and isolated fracture of the inferior ramus of the pubis. In no instance is the pelvic ring entirely broken. Because of the strong enveloping muscles and ligaments, little displacement occurs and treatment consists of bed rest for one or two weeks followed by limited activity for another two weeks.

Complete fractures of the pelvic ring without displacement may be single or multiple. These are represented by fractures through both rami of the pubis, unilateral or bilateral (Fig. 77), fractures through the sacroiliac region on one side combined with fracture of the ischium, fractures through the region of the symphysis pubis either alone or com-

A

tip and marked lump.

ward. Head of femur also after injury. Note persistent
2. The patient has a painful

combined with fractures in or near the sacroiliac joint on one side, and fractures through the ilium. These are fairly common examples, but any single fracture or combination of pelvic fractures which severs the pelvic ring, but does not cause recognizable displacement, may be treated the same way. Patients having single fractures need only be put at bed rest for about three weeks, then be permitted limited activity for three more weeks. Commuted fractures of the ring, in which there are two or more breaks, particularly if the combination is that of fracture near the pubic symphysis or across both pubic rami with fracture in or near the sacroiliac joint, require special attention. They must be guarded so that displacement does not occur. For patients having these fractures it is wise to use balanced traction with the leg on the uninjured side suspended without traction and with the leg on the side having the pel-

components of the pelvic ring in this type of injury, the most representative being fracture in or near the symphysis pubis associated with fracture in or near the sacroiliac joint on the same side (Fig. 78). This is termed the double vertical fracture of Malgaigne. The strong upward pull of muscles displaces the separated portion of the ring superiorly and, according to the force applied, the loose fragment may either be pushed outward, causing separation in the region of the symphysis pubis, or inward, causing overriding in the symphysis region. Shock is frequently dangerous to life and if the crushing force was severe enough to

Figure 77 Fractures of superior and inferior rami of pubis without significant displacement (anteroposterior view). The pelvic ring, though broken, had no displacement and healing occurred without trouble.

steps must be taken to keep the portion of the ring that has been freed of its support from becoming displaced proximally. Traction is continued for three or four weeks, then bed rest for another two weeks, before permitting the patient to resume limited activity.

The third type, complete fracture of the pelvic ring with displacement, is a very serious type of injury. While visceral damage may occur in association with other types of fractures, in this type it is fraught with most serious consequences. There may be many combinations of fractures of the

reduction and internal fixation were required. Every effort should be made to keep the acetabulum as near normal as possible. After removal of balanced Russell traction the patient is permitted to exercise in bed for one week and is then given crutches for two weeks. In most instances a good result can be expected.

Fractures of the floor of the acetabulum occur from force applied to the greater trochanter in line with the neck of the femur. If the floor of the acetabulum cannot resist the force, it bursts inward, usually splintering from the pubis and separating near the junction of the acetabular portions of the ilium and pubis. Most often the iliac portion of the acetabulum remains in place while the pubic portion is shoved inward. Occasionally both iliac and pubic portions are displaced inward and in very rare instances the pubic portion remains in place and the iliac portion pushes outward.

If there is a stellate type of fracture with no appreciable amount of displacement, balanced Russell traction may be applied for four to six weeks with moderate traction on the injured side and light traction on the other leg. The results in such patients are usually good although, if there is a fracture across the weight-bearing portion of the acetabulum, disabling arthritis is apt to eventuate.

When moderate inward displacement of the acetabular fragments occurs, heavy skeletal traction for five or six days with a wire through the lower femur or upper tibia, followed by moderate traction, is indicated. The leg should be in about 45 degrees of abduction and slight flexion at the hip. If, after several days, x-ray examination shows that the displaced acetabular floor has not returned to its normal location, open reduction should be done. Surgical approach is made by an incision along the iliac rim near the anterosuperior iliac spine. By dissecting subperiosteally against the inner surface of the ilium and the pubis, the region of the acetabulum can be reached. The fragments are manipulated into place and fixed with wire or screws. Heavy traction is again continued for several days before moderate traction is used.

Grossly displaced acetabular fractures, in which the head of the femur has remained driven into the pelvis, require heavy skeletal traction for several days and, if reduction is not satisfactory and the head of the femur has not returned to its normal position, manipulation with the patient under anes-

thesia may be tried. Caution must be exercised not to displace further the fragments and cause intrapelvic damage. If the floor of the acetabulum does not follow the head of the femur into good reposition, open reduction as described above should be done. This likewise should be followed by heavy traction.

Traction outward in line with the neck of the femur by applying a sling or adhesive traction to the upper, inner thigh combined with longitudinal traction is occasionally useful. Some surgeons prefer to use a pin or a screw through the greater trochanter fastened to a lateral traction device. Others find a well-leg type of traction helpful. Regardless of the apparatus, traction should be directed outward at 45 degrees or a little more.

Severely displaced acetabular floor fractures, even when adequately replaced, carry a doubtful prognosis (Fig. 76). Disabling arthritis is prone to intrude and it is wise to keep in mind that a hip fusion operation may be necessary later.

Fractures of the Pelvic Ring. The pelvic ring consists of a right and left pubis, ischium and ilium, and a single sacrum. The coccyx, while attached below the sacrum, carries no body weight and is not an integral functioning portion of the pelvic ring. The ring, made up of its various bony components, transmits all the body weight from above to the lower extremities. Pelvic ring fractures may be divided into three types: incomplete fractures of the ring, complete fractures without displacement and complete fractures with displacement.

Incomplete fractures cause little trouble. This type is represented by isolated fracture of the superior ramus of the pubis, partial fracture in a vertical direction into the wing of the ilium, isolated fracture through the ramus of the ischium and isolated fracture of the inferior ramus of the pubis. In no instance is the pelvic ring entirely broken. Because of the strong enveloping muscles and ligaments, little displacement occurs and treatment consists of bed rest for one or two weeks followed by limited activity for another two weeks.

Complete fractures of the pelvic ring without displacement may be single or multiple.

the ischium, fractures through the region of the symphysis pubis either alone or com-

mon but occur more frequently in women than in men. Displacement usually is minor, but, if present, digital pressure in the rectum may effect some reduction of angulation. Adhesive strapping across the buttocks or a snug binder may give comfort. A supporting low-back belt is of some value in the relief of symptoms. Unless pain is present there is no reason to enforce bed rest. Occasionally, severe injury to the sacrum may damage the lower sacral nerves and cause incontinence and local anesthesia.

Fractures of the coccyx are rare but painful. Adequate x-ray visualization is difficult and interpretation of the x-ray films is frequently a matter of conjecture. When fracture does occur, displacement is usually slight, but in all patients having suspected fractures a rectal examination should be performed and, if displacement forward is found, efforts to reduce the forward angulation by digital pressure should be made. The treatment is the same as that used for fractures of the lower sacrum. In addition to support across the buttocks, the following measures are useful in relieving pain: an air pillow or ring to make sitting less painful, warm baths, and medication to keep the contents of the rectum soft so that straining at defecation may be minimized.

Symptoms of pain in the region of the coccyx may persist for many months following fracture, but most cases of coccydynia are not due to fracture. Surgical removal of the coccyx to relieve pain is frequently in vain, because pain in the region may persist, may return or may increase after surgery. Certainly one should not resort to removal of the coccyx until more than a year has passed after fracture and all conservative measures to relieve pain have been exhausted.

FRACTURES OF THE FEMUR

Fractures of the femur may be divided into six types: fractures of the head of the femur, fractures of the neck of the femur, intertrochanteric fractures, trochanteric and subtrochanteric fractures, fractures of the shaft of the femur and fractures of the lower end of the femur.

The necessity of transmitting weight through the bones and joints of the lower extremities influences the conformations and functions of the joints and the shape of the bones. In the shoulder joint the head of the humerus fits against a shallow rim of fibrocartilage which encircles a flat disk of bone which acts as a buttress. Only a very small

area of the head of the humerus is ever in contact with buttress bone at any one time and when the shoulder is performing its most specialized functions, the entire joint, with its ligaments and muscles, is loosely held together so that maximum range and rapid changes of motion may be attained. On the contrary, the hip joint has stability as one of its major attributes. When it is performing its most specialized functions, it requires firm transmission of weight from one supporting bone to another weight-transmitting bone. This necessitates relatively broad bone contact across joint surfaces and, in addition, it requires strong ligaments, muscles and tendons enveloping the joint in order to keep the articular surfaces within strict limits of motion so that the forces and pressures accompanying weight transmission can be confined to act only on those areas of the articular cartilages which are developed to sustain weight-bearing without premature wearing of the cartilaginous surfaces. For this reason the hip joint has a much deeper socket than has the shoulder joint and relatively little leeway can be permitted in alterations of the opposing articular surfaces if smooth, durable function is to be expected. In treating fractures of the lower extremities it therefore becomes of prime importance to preserve or restore anatomic relationships to the highest degree possible.

Fractures of the Head of the Femur. Fractures of the head of the femur, in which a portion is completely separated from the rest of the head, occur infrequently. Sometimes a violent force pushing the femur posteriorly shears off a portion of the head at the point where pressure is brought against the posterior rim of the acetabulum (Fig. 79). More frequently the posterior portion of the

Figure 79. Fracture of head of femur and of acetabular floor (anteroposterior view). This combination carries poor prognosis for function.

Figure 78 A, Markedly displaced fractures of pelvic ring, principally of the double vertical type (anteroposterior view), associated fractures including the upper shaft of the femur. The patient had profound shock. B, Partial reduction of severe pelvic ring fractures. In order to establish effective strong traction on the pelvis it was necessary to plate the fracture of the femur. The patient has no pain and only a slight limp. He plays football and participates in all other sports.

cause marked displacement, blood vessels, nerves and viscera in the region may be hopelessly damaged.

It is important to restore something approaching anatomic relationship, if possible, although it is surprising to see what good function frequently results in patients in whom marked displacement was never corrected. Many patients retaining displacement subsequently develop pain and disability. In the female, it is necessary to restore the pelvic ring as accurately as possible so that difficulty in parturition may be minimized. The most useful method of reducing displaced pelvic ring fractures is continuous skeletal traction through the employment of a wire in the lower end of the femur or in the upper end of the tibia. Strong traction with heavy weights is indicated at the start, but if later x-ray study reveals that the upward displacement has been corrected, the traction load may be reduced. In order to keep the heavy traction effective, it is often necessary to tip the foot of the bed well up in the air and pass a sheet between the legs, placing it against the perineum on the uninjured side and fastening it to the head of the bed. This provides good counter-traction. It may also be necessary to place another sheet or a binder around the body and secure it to the bed frame on the uninjured side to keep the body straight and the traction functioning to maximum advantage. The use of pelvic hammocks or slings whereby the pelvic region is elevated from

the bed by attachment of the sling to the overhead frame is not as general as it was a few years ago. It still has a place in the treatment of fractures which are widely separated at the symphysis region, but it must be watched carefully so that displacement in the opposite direction does not occur. Experience has shown that the use of overhead pelvic slings frequently either checks the efficiency of longitudinal traction or causes even more displacement than existed previously. A snug binder around the pelvis may bring about improved position of fragments as well as maintenance of reduction. In addition, the patient often feels better with the support of a binder. In a few difficult fractures, well-leg traction applied by the method of Hoke or Roger Anderson may be effective when reduction is not accomplished by ordinary skeletal traction. Comminuted pelvic ring fractures, like practically all pelvic fractures, heal rapidly. Traction for four to six weeks followed by recumbency for three or four weeks is a good program.

Fractures of the Sacrum and Coccyx. The upper three segments of the sacrum are an integral part of the pelvic ring. The most common fracture of the lower sacrum is a transverse one at the level immediately below the third sacral segment. In this region the protection of the almost rigid sacroiliac joint is absent and the bone is most vulnerable to forces which may cause it to snap. Fractures of the lower sac are unco-

and frequently more than ten years. This fact led Phemister and his associates to attempt to hasten replacement by inserting a bone graft through the viable neck into the necrotic head. Evidence shows that replacement is hastened by such method, but the time of complete resubstitution, so that safe weight bearing can be resumed, is still several years. It is difficult to keep persons in the advanced age group walking on crutches for several years and the wisdom of such a procedure may be in doubt. This fact has led many surgeons to discard the necrotic head as soon as definite evaluation of the condition can be made, which is usually between six and eighteen months. Some surgeons and some radiologists profess to be

able to assess the viability of the head before six months, but the general opinion is that action taken on such assessments may lead to numerous mistakes. One may strongly suspect aseptic necrosis at three months in some patients and be quite correct, but in general it is safer to make definite evaluations at a later date.

In the presence of a nonviable head and nonunion through the fracture area, one of several procedures may be employed. The insertion of a bone graft through the viable neck with the added agent of immobilization through the employment of multiple nails may be tried. Such operations, while frequently successful, take a long time before weight bearing can be safely permitted.

Figure 81. I, Sources of blood supply for the femoral neck. A, From the ligamentum teres, scant and sometimes missing; B, from the capsular attachments, numerous large vessels, C, from the capsular reflection and synovia, small short vessels D, nutrient vessels, numerous and small; E, from the femoral artery and vein.

Figure 82. A, Recent fracture of femoral neck. Head in moderate varus position. B, Nonunion of femoral neck fracture. Aseptic necrosis of femoral head revealed by increased density of bone as compared to surrounding bone. Tri-flanged nail extruded and was removed.

Figure 80. A, Fracture of head of femur and posterior dislocation of hip (anteroposterior view). A portion of the head of the femur has remained in the acetabulum. B, Condition of fracture-dislocation of hip one year after reduction and removal of fractured fragment of head of femur. The patient has marked pain and disability.

acetabulum is broken, but when it remains intact the head itself may break and leave a portion in the acetabulum while the rest of the head continues posteriorly with the neck and shaft and becomes dislocated (Fig. 80). There are numerous variations of fractures of the head, but they seem to have one feature in common and that is the rather extreme disability which results. It may be possible to bring about manipulative reduction or it may be necessary to open the hip joint widely in order to effect reduction of a dislocation. If the hip is opened, it seems wise to remove the isolated fragment from the joint, but then a rough surface is left to articulate against the acetabulum. The remaining head may be smoothed and, if it appears worthy of trial, nothing more need be done. If the remaining head is jagged and comminuted, some type of arthroplasty or replacement should be considered or a hip fusion may be judged the best solution. In practically all instances in which the remaining portion of the head reveals comminution, the prognosis for good, painless motion is very questionable. It is advisable to anticipate an unsatisfactory result unless some type of arthroplasty or fusion is performed.

Fractures of the Neck of the Femur. There is little question but that fractures of the neck of the femur continue to be the most speculative and controversial of all fracture injuries. Entirely within the last half century, comp fractures to union 80 per cent solid bone unions. This has been

accomplished principally by the recognition that firm immobilization of fractures of the neck of the femur is the primary requisite for promotion of solid union of viable fragments. It has been known for some years that the blood supply to the head of the femur is rather precarious in the event of injury (Fig. 81). Fractures of the neck of the femur frequently cause sufficient damage to the blood vessels to impair seriously the circulation to the head and bring about a gradual aseptic necrosis (Fig. 82). Thus necrosis progresses slowly and invasion of the necrotic areas with new bone-forming elements starts rapidly. The two processes proceed simultaneously, but the new bone-forming elements must grow upward from the viable neck, so it is only logical that the areas of bone close to the articulating surfaces of the head are the last to be revascularized and replaced with living bone. This process of revascularization and replacement with living bone appears to vary considerably as to its speed of occurrence. There is no doubt that replacement follows a definite time schedule which is under control of natural conditions, but there are so many variables in the assessment of such conditions that it is almost impossible at the present time to predict the speed of replacement or the time of completion of restoration of good bone. It may be stated that in fractures of the neck of the femur in the age group in which they are most common, namely, in persons between sixty and seventy years old, replacement of necrotic bone with good bone in the head of the femur is usually a matter of more five years

Figure 85 A, Aseptic necrosis of head following femoral neck fracture. The multiple pins have been removed. Nonunion is evident. B, Necrotic head removed. An Eicher prosthesis has been inserted.

Figure 86. Judet type prosthesis in place. The plastic head occupies the acetabulum but does not show in x-ray film.

Subcapital fractures and vertical fracture lines through the neck seemed to indicate eventual bad results. Valgus position, either prevailing immediately after fracture or obtained in reduction, was considered a forerunner of good results. It now appears that the crux of the problem is not the position of the fragments or the angle of the fracture line, but the efficiency of the immobilization of the fragments. Subcapital fractures and vertical line fractures through the neck are difficult to immobilize securely, while valgus fractures are more easily immobilized. Evidence now tends to show that true anatomic reduction with secure immobilization offers the best opportunity for successful results in the presence of a viable head.

Reduction of most fractures of the neck of the femur can be obtained by extension, moderate abduction and marked internal rotation. Occasionally when the neck of the

femur on the shaft side is displaced backward in relation to the head, it may be necessary to flex the thigh and knee to right angles and lift upward, before resorting to extension, abduction and internal rotation. Ordinarily in the aged, a spring-scale reading of between 40 and 50 pounds is sufficient to maintain reduction. This position may be maintained on a fracture table or by a Soutter-type apparatus. Nailing or pinning is usually done by x-ray control, care being exercised to obtain satisfactory lateral views. The tri-flanged, cannulated nail of Smith-Petersen is most popularly employed (Fig. 87). Multiple nails of various sorts are frequently used (Fig. 88). There are many methods employing many types of screws, nails and bolts. All methods, if properly used, seem to give comparable results. In none of the methods does immediate, unassisted walking seem to be safe. The use of wheel chairs and walkers, followed by crutches, with full weight bearing withheld until evidence of beginning union is demonstrated by x-ray film, is a less dangerous procedure. One must study x-ray pictures taken at frequent intervals in order to judge the viability of the head, the maintenance of reduction and the progress of union.

The diagnosis of impacted fracture of the neck of the femur is made with more frequency than is justified by facts. There are numerous impacted fractures, but often the diagnosis is made without thorough x-ray study and the resulting dissolution of the fracture is almost inevitable when impaction is not actually present. In fact, even with

Figure 83 McMurray osteotomy, illustrating a medial shift of the upper shaft of the femur in an attempt to remedy nonunion of a femoral neck fracture with a viable head.

Osteotomies below the neck with medial shifting of the upper end of the shaft to a position under the necrotic head seem to improve the mechanics of weight distribution and the necrotic head seems to revascularize more rapidly (Fig. 83). Frequently, however, union does not occur between the neck and the head and the condition is not materially improved. Other forms of reconstruction are employed using the upper end of the shaft placed directly into the necrotic head after moving the muscular attachments of the greater trochanter distally. None of these methods is successful in a significantly high percentage of patients to indicate preference. The same methods are used when there is nonunion of a viable head. In these patients a higher percentage of successful results ensues, but there is still little choice between the various operations.

Because of the numerous failures of the above operations to produce painless, functioning hips for many patients in whom necrotic heads are present, metal replacements and metal cups or caps have become popular. Because of the usual reduction in size of the neck of the femur, the placement of a metal cup on the stub of the neck does not produce good mechanical results and leads to instability (Fig. 84). The use of a cup on the end of a trimmed shaft, after moving the trochanteric muscular attach-

Figure 84 Smith-Petersen cup on fractured neck of femur. Instability due to short neck and varus position.

ments distally, gives only fair stability and frequently limited motion in many patients. At present, the popular attack on the problem is removal of the necrotic head and replacement with an intramedullary type of stem prosthesis (Fig. 85). Previously a straight short-stem type of prosthesis was used extensively (Fig. 86). While this seemed to work well for a short time, many of the stems did not maintain their original valgus positions, which resulted in unsatisfactory, unstable varus positions. The intramedullary-stem type prosthesis comes in many models and has many names, indicative of the fact that none is completely satisfactory and that no one model is significantly better than another type. The complications of such prostheses are multitudinous, yet there is gradually growing a substantial group of aged patients who, a few weeks after insertion of a prosthesis, walk with little pain and only moderate limp. When successful, the operations have the advantage of enabling the aged patients to walk in a shorter time than by any of the other procedures and, while the procedures may not stand the test of time, these aged patients frequently do not have a great deal of time to spend. The best advice is that

is instituted. One should not become dogmatically addicted to one type of procedure.

With all possible complications in mind, treatment of fresh fractures of the neck of the femur takes on added significance. It has been thought that the position of the fracture or the angle of the fracture line entered into the prognosis of possible union.

offers the slightest chance of surgical survival, nail or pin fixation should be used.

Some surgeons, conscious of the appreciable number of nonunions which result with casual nailing in femoral neck fractures, prefer to remove the fractured heads immediately and substitute prostheses; others per-

form immediate osteotomies. In view of the relatively high percentage of unions obtained by adequate nailing and the uncertain results of prostheses and osteotomies, it does not appear that such procedures, done immediately, have sufficient percentages of success to justify their adoption.

Intertrochanteric Fractures. Any fracture or combination of fractures which interrupts the continuity of bone between the greater and the lesser trochanters may be termed intertrochanteric (Fig. 89). Such fractures are often found in combination with other fractures through the neck of the femur and with fractures of the subtrochanteric region. A great variety of intertrochanteric fractures occurs. In some, merely the lesser trochanter is broken off, while, in others, there are six or more complete fracture lines between the trochanters. Displacement may be slight or severe. It is no longer necessary to describe in detail the diagnostic differences of various types of fractures in clinical examinations. Whenever the possibility of a fracture exists today, an x-ray study is indicated. Fractures are no longer diagnosed by clinical observations. Now, even in the most remote hamlets and close to the battle lines in times of war, x-ray facilities are available.

The treatment of intertrochanteric fractures, differing from that of femoral neck fractures, may be successful either by opera-

Figure 90. Russell traction. The thigh and leg are supported on pillows. A is a sling underneath the knee and upper calf. From this a rope passes through an overhead pulley, B. Skin traction is applied to the leg, and incorporated in the spreader is a pulley, E. Attached to the foot of the bed is a board holding a double pulley, CF, or two pulleys close together. The traction cord from B passes through one side of the double pulley C, then through the pulley on the spreader E, and back through the other side of the double pulley F, to the traction weight. The pull is a multiple of the weight, because of the double-pulley arrangement. The resultant of the two pulls is indicated by the large dotted arrow. Lowering the level of the pulley CF or placing the pulley B nearer the foot of the bed will alter the pull toward the horizontal. Raising the level of pulley CF or shifting pulley B will alter the pull toward the vertical.

— Anchner wire traction through the fibula and tibia 1 inch above the ankle is preferable.

Figure 88. Femoral neck fracture Fixation with Sofield-Potts nails.

good impaction and bed confinement, the fracture fragments not infrequently fall apart. Such cases of failure become tragedies, because, subsequently, nailing often does not result in promotion of union. The part of wisdom would seem to be primary nailing even in impacted fractures, for the

patient can then be permitted much more liberty of motion in and out of bed and the fear of late disruption of the so-called impacted fragments is minimized. Needless to state, there is no place today for the treatment of neck fractures by casts or sandbag positioning. If the condition of the patient

markedly upward by its strong muscle attachments, it is probably the part of wisdom to perform an open reduction and maintain fixation with screws or small nails. One can then permit crutch walking in a few days. Markedly comminuted fractures of the greater trochanter are treated by keeping the limb abducted and extended until a safe degree of union exists.

Subtrochanteric fractures are often transverse and occur in combination with intertrochanteric or neck fractures. When iso-

lated, or when they occur in combination with other fractures which are amenable to treatment by nail-plate fixation, they are treated by the same method (Fig. 93). The only difference is that the plate must be long

but often they resist reduction by any means short of open methods. If satisfactory reduction can be obtained in younger adults, continued traction until union occurs is an excellent method of treatment.

Fractures of the Femoral Shaft. The past ten years have seen what amounts to a revolutionary change in the treatment of femoral shaft fractures. Fifteen years ago, Kuntscher started to popularize a method of intramedullary support for femoral shaft fractures and this method has made great strides. True it is that Rush and his followers had been using a type of intramedullary rod fixation for many years, but the method had not been widely adopted. The exigencies of the war years, the advances in metal alloys and the improvements of operative techniques combined to bring the method to the foreground. Numerous complications occurred and still prevail, but, in spite of difficulties, intramedullary fixation continues to

Figure 92. Recent fracture, top of greater trochanter. Displacement slight.

Figure 91. McLaughlin nail-plate fixation for intertrochanteric fracture

preferable to long traction treatment. Such a method has been successfully utilized in recent years and is particularly applicable to the treatment of the aged person. In its most common form, the method utilizes a tri-flanged or flat femoral neck nail to which is attached either integrally or by screw connection a plate which extends distally along the lateral side of the shaft for a distance of about 4 inches below the greater trochanter (Fig. 91). The firm attachment of the plate by screws through the bone provides strong support for the nail or blade which extends across the fractured fragments of the intertrochanteric region into the neck of the femur. Unless the fragments are very soft or the comminution extreme, the combination of nail or blade and plate gives adequate support. A few days of traction following the insertion of the intertrochanteric fixation apparatus are frequently employed in order to let the fresh fracture fragments adjust and become established in their positions. After a few days the patient is permitted up in a wheel chair and, if of sufficient physical and mental vigor, he is soon allowed to use a walker and then crutches. Most intertrochanteric fractures become well united in from eight to twelve weeks. The common position for application of the nail-plate is extension, moderate abduction and neutral rotation of the thigh. The use of a fracture table so that traction may be maintained during fixation is a requirement. Very frequently the lesser trochanter is completely separated from the shaft and occupies a place medial and proximal to its anatomic position. Seldom does reduction of the fractured lesser trochanter occur, but experience has shown that bone usually bridges the gap to the displaced trochanter and function is satisfactorily restored.

Trochanteric and Subtrochanteric Fractures. Isolated fractures of the greater and lesser trochanters occur, although single fracture of the lesser trochanter is not frequent. It is seldom necessary to perform open reduction and replacement of fractures of the lesser trochanter, although some surgeons advocate such procedure when displacement is marked. In most instances, rest in bed with the thigh flexed and adducted and in neutral rotation suffices for treatment. Fractures of the greater trochanter are common and variegated (Fig. 92). They may be of a type that shears off the greater trochanter as a whole unit or they may splinter the trochanter into many pieces. When the greater trochanter is sheared off and pulled

tive or nonoperative methods. The chance of nonunion of intertrochanteric fractures, while present, is slight. Most intertrochanteric fractures progress to firm bony union and the only problem from the mechanical viewpoint is that of obtaining and maintaining satisfactory reduction of the fractures. Even this problem is not difficult. Traction, either of the Buck's type or by the Russell method (Fig. 90), or even by skeletal application, customarily brings about good reduction and satisfactory maintenance of position to permit good healing. In patients of the younger age group, treatment by traction may well be the method of choice. Certainly, in children it is practically never necessary to resort to anything but traction for the treatment of intertrochanteric and shaft fractures of the femur. In persons of the military age group, traction is still the method of choice, but as one approaches the older age group the dangers of long bed confinement necessitated by traction methods make one question the propriety of this type of treatment. It is well recognized that persons of advanced years react poorly to long confinement in bed, so, if a method of treatment which has a fair assurance of success and which permits the patient to get up in a wheel chair and then become ambulatory in a short time can be perfected, it should be

viewing of the fractured bone ends. The fracture area is opened and customarily the rod or nail is inserted in a retrograde manner by starting it upward in the proximal fragment and permitting the upper end to emerge from the skin in the buttock area; then, when the fracture is reduced, the nail is driven downward to about 1 inch above the intercondylar notch. The nail should be only moderately snug; if the diameter is too large to pass the isthmus and wedging occurs, a most difficult situation of not being able to move the nail in any direction ensues. It is remarkable and discouraging to learn how firmly a nail may become jammed when improper choice of equipment has been made. Two general types of fairly rigid nails are in common use: the clover leaf of Kuntzsch and the diamond shape of Street. In the southern part of the United States, the more flexible Rush rods enjoy considerable popularity (Fig. 96). All rods should be left in place until there is x-ray and clinical evidence of firm bony union. Usually one year is considered a minimum time for removal of rods. There is usually no difficulty in extracting the rods after a year of use, even though they may have been fitted quite snugly at the time of fixation.

Fractures of the Lower End of the Femur. Condylar and supracondylar fractures in the lower one-fourth of the femur can often be treated by either adhesive traction or insertion of a skeletal pin through the upper or

lower end of the tibia. A frame holding the thigh upward at 45 degrees and the leg horizontal is useful. After adequate reduction and about six weeks of maintenance of position by traction, a snug, long-leg cast fitted well up into the groin may suffice to hold the fragments in good alignment. If satisfactory reduction cannot be had by traction and manipulation, open reduction may be necessary. Fixation with two Rush rods by starting the rods toward the medullary canal and upward from the lateral surfaces of both condyles may work well (Fig. 97). Bending a blade plate to right angles and molding the plate to fit the contour of the shaft, then driving the blade across both condyles and screwing the plate to the shaft are useful. Sometimes screws may suffice, or a circular band of steel or wire, which is later removed so that ring sequestra may be avoided, can be employed. In most instances good union is obtained in ten to fourteen weeks.

Fractures of the femur which split into the knee joint are frequently troublesome. If satisfactory reduction can be maintained by either adhesive or skeletal traction through the tibia, it is the method of choice. The use of screws, bolts, wires and other foreign materials in the lower femur, close to the knee joint, does not encourage good joint function. Occasionally, satisfactory reduction is not possible by traction and open reduction must be employed. In such cases, metal should be kept to a bare minimum and only the fewest required screws or bolts to maintain reduction should be used. Subsequent traction and plaster-cast support may be required. It is, of course, important to restore proper joint conformation.

FRACTURES OF THE PATELLA

The important feature of patellar fractures is injury to the extensor mechanism of the knee. Actually the patella is a sesamoid bone in the quadriceps tendon and, while very useful for smooth knee-joint function, it can be discarded when deemed necessary and joint function is only moderately impaired, although long-term results of patellectomy are not as encouraging as might be desired. All efforts in treating fractures of the patella should be channeled into the task of restoring the damaged extensor mechanism and re-establishing a smooth-gliding component. When it is possible to repair the fractured patella and restore a smooth articular surface, the result is better than when the patella is removed. Only in comminuted

Figure 97. Application of Rush rods in fracture of lower femoral shaft.

Figure 95 Comminuted fracture of the femoral shaft Nail fixation is impractical This is best treated by traction

gain favor (Fig 94). Not all femoral shaft fractures are amenable to treatment by rod fixation and, until the definite limits of proper application of such fixation are recognized, errors will continue to occur. An intramedullary rod can only be as large in diameter as the smallest area of the medullary canal of a bone. If one exaggerates the shape of a medullary canal and visualizes it as an hour-glass, it can be realized that firm fixation can be had only near the narrow portion of the canal and the efficiency of fixation decreases rapidly as the extremities are reached. For this reason, intramedullary rod fixation is practically useless in the proximal

and distal fourths of the femoral shaft. Fixation is best at the junction of the middle and upper thirds of the shaft, where the medullary isthmus is located. The more comminuted the fractures and the more oblique the break, the poorer will be the case for rod fixation (Fig. 95). Traction for femoral shaft fractures is still an excellent method of treatment, but it suffers from the necessity of keeping the patient confined to bed for eight to twelve weeks with the attendant danger of stiffness of joints, pressure areas, atrophy of muscles and medical and surgical complications of long bed confinement. Young adults usually take bed confinement without too much trouble and children's femoral shaft fractures should practically always be treated by traction. Once again it is the aged who benefit most by methods designed for early ambulation and return to accustomed surroundings. Ideally, one should not be influenced by economic or, in some instances, military considerations. Still it is necessary to view conditions in their true perspective and, if so considered, the value of being able to apply a rod and get a patient ambulatory with crutches in a week or ten days, in comparison with being confined to bed with traction for two or three months, makes a potent argument for rod fixation whenever applicable. The use of plates and screws in such fractures has largely been supplanted by the employment of rods, although, for certain types of fractures, plates may be superior. However, it must be warned that two plates facing each other on opposite sides of a bone frequently lead to the tragedy of necrosis and nonunion.

On the North American continent, most intramedullary rods are applied with direct

Figure 96 Intramedullary femoral rods Top, Kuntscher nail Middle, Hansen-Street nail. Bottom, Rush rod.

diately. It usually takes six to ten weeks for safe union to occur and frequently the patella undergoes extensive atrophic changes during that time and has to rebuild itself into a solid-appearing bone over the course of months. On rare occasions a longitudinal fracture will occur in the patella. This seldom requires open reduction unless the split surfaces are widely separated and the longitudinal soft tissue tears are of slight consequence. Frequently the common transverse fractures are not complicated by adjacent tears into the ligaments and separation of the fragments is minimal. In such cases, open reduction is not indicated and cast support suffices.

Whenever the patella is split into more than three large pieces, it seems inevitable that considerable roughness of the articular surface will result and it is considered wise to perform primary patellectomy (Fig. 99). When this excision is performed, one should avoid damaging the remaining soft tissue strands which preserve the integrity of the quadriceps-patellar ligament mechanism. If, as frequently happens, the mechanism is severely damaged and appears quite loose and elongated after attempted approximation, it is better to take a tuck in the ligament and tendons so as to provide proper stability.

On many occasions fractures occur only at the proximal or distal portions of the patella where the quadriceps tendon inserts proximally or at the attachment of the patellar ligament distally. Such fractures are of the avulsion type and are frequently comminuted. The rule of restoration of the extensor mechanism as the primary object continues in force in such instances, so it is best to remove and discard the small fracture fragments, leaving the main body of the patella, and then carefully repair the tendinous or ligamentous attachments. This may require drilling holes in the outer surface of the patella in order to obtain a firm anchor for the soft structures.

FRACTURES OF THE TIBIA AND FIBULA

Fractures of the tibia may be divided into three types: fractures of the anterior spine of the tibia and of the tubercle, fractures of the tibial plateau and fractures of the shaft of the tibia.

Because the blood supply to the shaft of the tibia is apt to be seriously curtailed by fractures, delayed union and nonunion may occur in fractures anywhere in the shaft. However, the most dangerous area by far

is the region of the junction of the middle and lower thirds of the shaft.

Fractures of the Anterior Spine of the Tibia and of the Tubercle. Fractures of the anterior spine of the tibia occur and, because of the danger of resulting ligamentous instability as well as malposition of the fractured bone, open reduction is indicated when the piece of bone is of enough size to justify operative intervention. This is particularly true when the spine fractures at the base and has marked displacement. Anteromedial incision, extending from the upper pole of the patella and running close to the medial aspect of the patella straight distally to the upper rim of the tibia, then turning laterally to the region of the tibial tubercle, is made. The knee joint is entered and the anterior tibial spine becomes evident. A small hole is drilled through the base of the spine and then a hole is drilled from the region just above the tibial tubercle obliquely upward to emerge into the joint just anterior to the anatomic base of the tibial spine. Wire is passed upward through the main body of the tibia, then through the base of the loose fragment and back through the anterior area of the tibia to the initial insertion area near the tubercle. The wire is permitted to extrude through the skin during closure and then the knee is extended. The wire is then pulled taut and fastened to a button or other material outside the skin. After six or eight weeks, the wire is pulled out. This method usually effects satisfactory replacement of the tibial spine. The posterior tibial spine is seldom fractured.

Fractures of the tibial tubercle occur and are quite painful. The tubercle, being the principal anchor of the patellar tendon, is subjected to almost continuous upward displacement force. When definite diagnosis of tubercle fracture is made, and one must be careful not to confuse ununited tubercle epiphyses with fracture, treatment for an undisplaced fracture consists of immobilization in extension for four to six weeks. If there is displacement of a sizable fragment, open reduction is performed and fixation with a screw or screws is necessary. When considerable comminution exists, the fragments should be removed and the patellar tendon firmly attached to the underlying bone.

Fractures of the Tibial Plateau. The articulating surface of the tibia at the knee joint is known as the tibial plateau. Its two major components are the medial and lateral tibial condyles. Fractures frequently

Figure 98 A, Transverse fracture of patella. The wide separation of fragments denotes extensive tears of the lateral expansions of the patellar tendon. Torn lateral expansions must always be repaired with strong sutures. B, Fixation of patellar fragments with wire and threaded pins. Anteroposterior x-ray view. C, Lateral x-ray view. The wire does not touch the articular surface of the patella.

Figure 99. A, Comminuted fractures involving large portion of articular surface of patella. Patellectomy advised. B, Patella excised because of extensive comminution of fracture. Quadriceps tendon firmly sutured to patellar ligament. Lateral expansion tears repaired.

fractures, when it is evident that the multiplicity of articular fractures militates against the restoration of smooth function, should the patella be sacrificed.

Transverse fractures are most common in injuries to the patella. The disabling tears in the ligaments on both sides of the patella must be repaired and the fractured fragments carefully apposed. When it is evident

that good restoration of articular surfaces is possible, holes are drilled from the outer surfaces of the fragments into the fractured

together and the wire is twisted securely. A posterior splint is applied for only a few days. Quadriceps exercises are started imme-

Figure 102. Severe "bumper" fracture with marked comminution of upper end of tibia and fibula. Prognosis for knee-joint function is poor.

all the fragments and prognosis of a poor result is foreseen (Fig. 102). Initial knee fusion, however, is seldom indicated because clinical trial in such cases has shown that occasionally fairly good joint function may result and last for a considerable time. Of course, the prognosis for long-term function is poor and eventual knee fusion should be anticipated.

Fractures of the Shaft of the Tibia. Most single fractures in the upper two-thirds of the shaft of the tibia can be well treated by closed manipulation or by traction, when necessary, followed by application of a plaster cast. Very oblique fractures may require traction to prevent shortening, but the more oblique the fracture, the more raw, bleeding surface there is available for promoting successful union. In general, it may be stated that the chances of successful union in any given fracture are increased in proportion to the degree of obliquity of the fracture—the more transverse the fracture, the smaller the amount of raw surface there is available for promoting bony union.

Single fracture at the junction of the middle and lower thirds of the shaft of the tibia is usually only moderately oblique and is frequently transverse (Fig. 103). The blood supply to this region is seriously impaired by injury and nonunion or delayed union is common (Fig. 104). All efforts should be bent to secure good apposition and firm immobilization of the fragments. If the patient is in good general health and the fracture is

not compound, open reduction and internal fixation may be the treatment of choice. With oblique fractures in this region, one or two screws may suffice for fixation. Up to the present time, a popular method of fixation has been the application of a metal plate to the lateral surface of the tibia. Slotted plates, which theoretically permit the screws and bone fragments to move toward each other as the fragments are influenced by strong muscle pull, have acquired many advocates. Under ideal situations, such slotted plates keep the fractures in good alignment while permitting the fragments to be snugly pressed together. If plates are used, they should not be put on the anteromedial aspect of the tibia because of its relatively superficial position, which leads to the danger of breakdown of skin and poor healing. Most surgeons prefer to place their plates on the anterolateral surface of the tibia, although some believe that the posterior surface is better. In both instances, good coverage by muscles is obtained and the dangers of superficial irritation are minimized. Many surgeons have been disappointed with the results of plate fixation for fractures of the tibial shaft and some have

Figure 103 A, Comminuted fractures of lower shafts of tibia and fibula. At this region union is frequently slow. Firm immobilization is required for a long period. Anteroposterior view. B, Lateral x-ray view. Such fractures may be treated by closed reduction and plaster casts, traction followed by casts, open fixation with a plate and screws or by intramedullary fixation of the tibia.

Figure 100 A, Comminuted fracture of lateral condyle of tibia Anteroposterior x-ray view. B, Lateral x-ray view. Closed reduction by compression made with the hands is satisfactory. Reduction is maintained by a snug plaster cast. A carpenter's clamp could have been used for compression.

Figure 101 A, Comminuted depressed fracture of lateral condyle of tibia. B, Lateral x-ray view. Closed manipulative reduction has been unsuccessful. C, Bone graft from 2 inches down on the tibia has been used as a prop to support the lateral articular surface of the tibia. A fracture bolt is used to hold the fragments together. D, Lateral x-ray view. The defect below bolt is the area from which bone for supporting upper articular surface was removed.

extend distally from the region of the anterior tibial spine and extend medially or laterally to break through the cortices at about the level of the tubercle or below. The tubercle is usually left intact. The displacement of condylar fractures may be slight or marked. When displacement is slight, little need be done except elimination of weight-bearing to prevent it. When displacement is severe, restoration of anatomic position is required if good subsequent function is to be expected. Closed manipulative reduction of slightly displaced

fractures is frequently successful (Fig 100). If displacement is marked, open reduction should be attempted. Provided the fractures are not too comminuted, reposition can usually be obtained by prying the fragments up into place, then immobilization may be secured by long screws or fracture bolts (Fig. 101). Healing requires about ten to twelve weeks, but knee-joint motion should be

that it is impossible to replace successfully

type and the vertical compression type. Internal and external rotation causes variations of the three types. Frequently a combination is present such as the abduction and external rotation fracture complex.

The important goal in treatment of fractures about the ankle is restoration of the anatomic mortise of the joint. This mortise is formed by the articular surface of the lower end of the fibula laterally and the articular surfaces of the lower end of the tibia superiorly and medially (Fig. 106). The lower projection of the tibia medially forms the medial malleolus and the lower extremity of the fibula forms the lateral malleolus. The talus fits into the mortise formed by the distal ends of the tibia and fibula. This fit must be preserved if full, painless rocking motion is to be expected. Proper alignment of the ankle joint with the knee joint must be maintained.

The different varieties of fractures depend upon the position of the foot in relation to the leg when irresistible force is applied to the ankle joint. If the foot is everted beyond the ability of the ankle joint structures to resist disruption or if the foot is fixed to the ground in weight bearing and a strong force is applied to the outer aspect of the lower leg forcing the tibia medially, an abduction fracture may occur (Fig. 107). If a twisting motion is added to the force, a combination-

type fracture may eventuate. The rupture of the ligaments and the degree of displacement of the fractures from minor to complete dislocation depend upon the amount of force applied. When vertical compression occurs with the foot in plantar flexion, the posterior lip of the tibia may be fractured and, when the foot is in dorsiflexion, vertical compression may cause fracture of the anterior lip of the tibia. Falling from a height or having a force suddenly applied upward, as from an explosion, may cause a compression fracture in which the main portion of the tibia breaks from the medial malleolus and the fibula fractures just above the lateral malleolus, while the horizontal portion of the lower tibial articular surface and the talus are pressed together so forcefully that displacement occurs. This may result in the talus being forced upward so strongly as to cause lower tibial shaft fractures and displacement of the talus to a position proximal to the malleoli. At other times the tibia is driven downward into the talus. If adduction or abduction is also a factor, even more severe displacement may occur.

Ligaments are of the utmost importance in ankle injuries and efforts to insure repair in anatomic position must not be neglected. Inferior tibiofibular diastasis, if not reduced by manipulation and casting, should be reduced and immobilized by a long screw.

Figure 106 a, Diagrammatic illustration of the ankle joint and its ligaments. Note the position of the tibiofibular ligament b, Abduction fracture with (1) fracture of internal malleolus, (2) laceration of tibiofibular ligament and separation of tibiofibular articulation, (3) fracture of shaft of fibula, and (4) lateral displacement of astragalus. c, Abduction fracture with intact tibiofibular ligament. Note: (1) fracture of internal malleolus, (2) fracture of external malleolus near its base and (3) lateral displacement of astragalus.

Figure 104 A, Old nonunion of the shaft of the tibia under treatment with an onlay bone graft. Anteroposterior x-ray view. B, Lateral x-ray view. Note the atrophy of bone that usually occurs with restricted weight bearing due to nonunion.

Figure 105 A, Fracture of tibia and fibula treated by Lottes' intramedullary nail. Anteroposterior x-ray view. B, Lateral x-ray view, showing Lottes' nail in the tibia. If union is satisfactory, the nail is usually removed at about the end of one year.

turned to intramedullary fixation. The preliminary reports of the results obtained by intramedullary fixation have been encouraging for some types of nails, but sufficient time has not elapsed to permit mature evaluation. The Kuntscher type tibial nail has not gained wide acceptance in the United States and the Rush tibial rods continue to enjoy their popularity principally in the South. A newer type of tibial nail by Lottes, which is more rigid and provides firmer fixation, is now being given clinical trial in some surgical centers (Fig. 105). If this nail fulfills its early promise, it may in many cases supplant the use of plates and screws.

Markedly comminuted fractures of the tibia are frequently best treated by skeletal traction until sufficient union occurs to permit immobilization in a plaster cast. This often takes about six weeks. The use of the cast is continued until union is solid. There is no advantage in applying large amounts of various types of devices to a comminuted fracture of the tibia just to gain some degree of metal fixation; skeletal traction applied by a wire through the lower end of the tibia or

just above the calcaneus is a more satisfactory method of treatment.

Fractures of the shaft of the fibula usually occur in conjunction with fractures of the tibial shaft but also occur alone. If a fibular fracture accompanies fracture of the shaft of the tibia, it is usually satisfactorily reduced and immobilized during treatment of the fractured tibia. The shaft of the fibula is not a direct weight-bearing structure and therefore is not of prime importance in a weight-

to make little difference. In patients having an isolated fracture of the fibular shaft, alignment and contact of the fragments is invariably good and treatment consists of relief of pain. A light plaster cast extending upward to just below the knee may be required, although frequently the use of crutches for about one week suffices.

FRACTURES OF THE ANKLE

There are three principal types of ankle fractures: the abduction type, the adduction

nation is graphic. When both malleoli are fractured, the condition is called a bimalleolar fracture and when the posterior lip of the tibia is added, the condition is termed a trimalleolar fracture. Sometimes a pos-

terior malleolar fracture is the only fracture accompanying a dislocation of the ankle joint.

There has been some difference of opinion as to the necessity for obtaining perfect reduction of posterior malleolar fractures. Usually displacement is upward and produces a condition of the articulating surface whereby the curved upper surface of the talus does not impinge on the displaced fragment although it comes into contact with the back edge of the main tibial fragment. The smaller the fragment the less chance there is of much weight bearing of the talus against a rough edge. Efforts should be made to manipulate the fragment into position by closed means, but, in most instances, perfect reduction cannot be accomplished. Whenever the posterior fragment is sizable and displaced downward, which is rare, it must be forced upward to its normal position. If this cannot be accomplished by the closed method, open reduction and fixation with a nail or screw are advisable. If, however, the fragment is moderately displaced upward and is judged to be no greater than a fourth of the whole articulating surface, it can be left with a fair chance of successful ankle joint function. If the fragment is

on (anteroposterior view). Note (lateral view). Because of multiaxial motion must be guarded.

Figure 107. Abduction (Pott's) fracture of ankle. Note the transverse fracture of the medial malleolus at the level of the articular surface of the tibia, outward displacement of the lateral malleolus and lateral displacement with tipping of the talus. The inferior tibiotalar ligament is intact

Abduction and Adduction Fractures. Knowledge of normal anatomy and careful study of x-ray films will assist in planning proper treatment of ankle fractures. It is self-evident that adduction fractures must be brought to normal position or slightly overcorrected and abduction fractures must be corrected in the opposite manner. Twisting and combination-type fractures require more study, but the same reversal of direction of force which caused the displacement will usually reduce the major portion of the

displacement. In adduction and abduction fractures, it should be emphasized that immobilization in markedly overcorrected positions in plaster casts should be avoided. Such treatment frequently reverses the original deformity and spreads the mortise unduly. Usually the best practice to follow in ankle fractures is to restore normal alignment or use only slight overcorrection. Molding inward over the felt-padded malleoli with moderate pressure often tightens the mortise to its original position. Care must be taken not to cause pressure areas.

Adequate x-ray studies must be made for ankle region fractures. Anteroposterior, lateral and oblique views are desirable. The position of the medial malleolus is often a question and if x-ray films show significant displacement of a large fragment of the medial malleolus after attempted closed reduction, it is wise to perform open reduction and fixation with a nail or a screw (Figs 108 and 109). This is necessary because

the mortise and often fail to unite. They are of no great consequence, but occasionally result in some pain and, if it is desired, they may be removed.

The posterior lip of the lower tibial articulating area is now termed, in common parlance, the "posterior malleolus." While not anatomically accepted as yet, the desig-

Fig 108

Figure 108 Isolated fracture of medial malleolus. Because the fracture is at the level of the articular surface of the tibia, the mortise is disrupted. Perfect reposition is desirable. Open fixation with a nail or screw is the safest method of treatment

Figure 109. Abduction fracture reduced (anteroposterior view). Medial malleolus secured in place with a screw.

flexion fractures, the posterior process or plantar flexion fractures, and body or compression fractures. Actually the posterior process and body fractures are no more common than the avulsion types from the neck or from the medial or lateral borders, and about the only warning that need be sounded is that of not mistaking the common anomaly of a congenitally ununited posterior process, or os trigonum, for a posterior process fracture. Strong plantar flexion will, in rare instances, cause the posterior process to impinge against the posterior lip of the tibia and bring about fracture. In such cases, closed reduction can usually be

obtained by dorsiflexion, and immobilization in a plaster boot for about six weeks suffices to restore continuity. Body and avulsion type fractures are also rare and require about the same type of plaster boot immobilization.

The most dangerous fracture of the talus is also the most common, namely, that of the neck of the bone. This is a dorsiflexion type of fracture in which the superior surface of the neck of the talus is driven forcibly against the anterior aspect of the tibia and, because the body is locked in the ankle mortise, fracture occurs across the neck in a vertical manner. Occasionally this fracture is associated with fractures of the an-

is across the neck of the

Figure 112 A, Fracture-dislocation of ankle, compression type (anteroposterior view). Tibia driven downward, forward and medially results in marked displacement B, Lateral view of fracture-dislocation of ankle. If reduction is delayed, permanent circulatory damage may occur

greater than a third of the whole articulating surface and does not reduce satisfactorily by closed methods, open reduction by posterior approach close to the Achilles tendon is desirable. Fixation with a nail or screw is sufficient (Fig. 110). The question of open reduction when the fragment is between one-third and one-quarter the size of the whole articulating surface remains a moot point. All ankle fractures that have much displacement before reduction are immobilized after reduction in plaster casts which extend from the toes to the upper thigh. The knee is flexed about 45 degrees. After three or four weeks, the casts are changed and knee-length casts are applied.

Compression Fractures. Compression fractures frequently cause marked comminution of the articular surfaces and guarded prognoses for painless joint function must be made (Fig. 111). Oftentimes it is necessary to resort to an ankle fusion when comminution has been so severe that good anatomic relationships could not be re-established (Fig. 112). Whenever possible, clinical trial of function should be given even though the chances of success appear minimal. Therefore, it is best to obtain everything possible

in the way of reduction of these fractures. Traction by means of a wire above the tubercle of the calcaneus or through the calcaneus is the method of choice. After a few days of traction, manual molding of the fragments may be helpful. A plaster cast is applied when union has progressed to a safe degree, this usually takes about four weeks. One should avoid trying to sort out many comminuted fragments and fix them with screws, wires or plates or other metal devices. These metal devices placed close to the ankle joint in severely comminuted fractures militate against the chances of a successful result.

FRACTURES OF THE FOOT

Fractures of the foot are considered under five divisions: the talus, the calcaneus, the navicular, cuboid and cuneiform bones, the metatarsals, and the phalanges of the toes.

Fractures of the Talus. All fractures of the talus are rare, but the most common fracture with its associated injuries is so disabling that careful attention must be paid to its diagnosis and treatment. It has been the usual practice to divide fractures of the talus into three groups: the neck or dorsi-

Figure 114. Tracings of roentgenograms of normal and fractured calcanei, showing alterations in the relationship of lines prolonging their superior surfaces. A, Normal, B, slight defect, C, moderate defect; D, very marked defect.

of early prognosis, because if we could definitely know the exact location of each fracture line and the degree of displacement present, we would then be able to foretell results with a high degree of accuracy. Whenever there is comminution into the articular surfaces of the calcaneus with displacement of fragments, a guarded prognosis is given. If the displacement is marked, operative fusion of the talocalcaneal, calcaneocuboid and talonavicular joints is indicated. This so-called triple arthrodesis is performed because if such fractures are treated by closed methods, painful arthritis practically always develops.

In general, fractures of the calcaneus can be separated into two large groups, which statistics show to be about evenly divided: those which involve a sizable portion of the articulating surfaces and those which do not involve articulating surfaces to any significant degree. In the first group, the prognosis for good recovery following the use of closed methods for reduction is poor, while in the second group the prognosis is excellent. The amount of comminution and the degree of displacement are not too significant. The important element is the degree of involvement of the articulating surfaces of the bone. The tuber-joint angle formed by a line touching the anterior and posterior articulating surfaces intersecting a line drawn along the superior border of the tuberosity normally measures about 40 degrees (Fig. 114). Decrease of this angle is caused by upward displacement of the tuberosity from fractures, but the extent of decrease of the angle does not necessarily measure the se-

verity of the injury. Badly comminuted fractures with marked displacement may not involve articulating surfaces and, while it may be difficult to effect reduction of the fractures, a good result should be expected (Fig. 115). In all these patients, efforts should be made to restore the normal length of the Achilles tendon by replacing the tuberosity. If the tuberosity has been com-

Figure 115. Markedly comminuted fractures of calcaneus with loss of tuber-joint angle (lateral view). Fractures did not significantly involve the articular surfaces and after reduction the functional result was good. Note that the tuberosity is displaced upward with the large fragment.

terior lip of the lower tibia, the medial malleolus or the calcaneus. If the dorsiflexion force continues after fracture of the neck of the talus, the rest of the foot may be driven forward in relation to the mortise and the anchored body of the talus, and dislocation of the talocalcaneal joint, with the calcaneus forward in relation to the talus, will occur (Fig. 113). In some instances the force continues even beyond this injury and forces the calcaneus further forward in relation to the body of the talus to the point where the sustentaculum tali becomes locked in front of the medial tubercle of the talus. When the dorsiflexion force is removed and the foot springs back toward a neutral position, it is found that there is complete backward dislocation of the body of the talus, which lies rotated and locked with the main portion of the body lying medially and the fractured surface pointing upward and laterally. Frequently the disruption causing this marked dislocation is so violent that the skin below and behind the medial malleolus ruptures and the fracture becomes compound.

In all fractures of the neck of the talus, injury to the blood supply of the body of the talus is to be feared. If the fracture occurs across the neck and there has been no subtalar subluxation or dislocation, the blood supply of the body of the talus will not be injured and union should occur without incident. Reduction is usually accomplished by plantar flexion and immobilization in that position for six to eight weeks is indicated.

Whenever subluxation or dislocation of the subtalar joint has occurred, the danger of aseptic necrosis of the body is present. If the dislocation is, or was, marked, injury to the blood supply of the body is usually of sufficient severity to eventuate in aseptic necrosis. Whenever dislocation of the body occurs at both the tibiotalar and subtalar joints, aseptic necrosis of the body is inevitable.

Treatment of fracture of the neck of the talus with dislocation of the subtalar joint should be accomplished by closed reduction. Plantar flexion should be maintained in a plaster cast for about eight weeks, or longer if aseptic necrosis becomes evident.

Treatment of fracture of the neck of the talus with dislocation of the body from both the tibiotalar and subtalar joints is attempted by closed reduction, first manipulating in marked dorsiflexion to try to unlock the talus from behind the sustentaculum tali and then replacing the upper articulating surface in the ankle mortise. Open reduction must fre-

quently be done in order to accomplish reduction. Position is maintained by a boot cast in plantar flexion.

Because of the inevitability of aseptic necrosis of the body of the talus in severe fracture-dislocations, many surgeons advocate immediate astragalectomy as the treatment of choice. In some clinics this treatment has produced satisfactory results, but in many other centers, the long-term results have been poor and pain has been a disabling factor. Differing from the head of the femur in aseptic necrosis, the body of the talus seems to have more favorable conditions to permit revascularization and consequently more rapid substitution of live bone for dead. It would appear that adequate replacement of bone may occur in from twelve to eighteen months. For this reason, it does not seem advisable to do astragalectomies routinely. Even though arthritis may be expected to develop in joints which have adjacent bone undergoing aseptic necrosis, better eventual results may be anticipated if ankle and subtalar fusions are brought about operatively, when necessary.

Fractures of the Calcaneus. The calcaneus is by far the most commonly fractured tarsal bone. It has been estimated that about 90 per cent of all tarsal fractures occur in this bone. In addition to its vulnerability to fracture, the calcaneus is also apt to be found fractured in association with compression fractures of the vertebral bodies. When a calcaneus fracture is occasioned by falling in an upright position so that the feet strike the ground first, or by an explosion forcing the deck of a ship or a floor suddenly upward, compression fractures of the vertebral bodies are likely to occur also. In such accidents the combination of compression fracture of the calcaneus with compression fracture of the spine is so common that it is advisable to x-ray both regions, even though the symptoms may be confined to only the heel region.

A good deal of confusion has existed for years because of the difficulty in judging which calcaneal fractures were apt to heal with little or no residual pain and which ones would be painful to the point of incapacitation for work. One difficulty lay in inability to evaluate the extent of calcaneal fractures by clinical and ordinary x-ray examination. The advent of superoinferior or axial x-ray views of the bone has helped a great deal, but it is still difficult to outline accurately the extent of many fractures. In this difficulty lies the source of our errors

region opposite the sustentaculum tali while pulling strongly downward on the heel and the forefoot and then placing the foot in a cast in plantar flexion for six weeks, followed by neutral position for six weeks. Sometimes it is necessary to use a Bohler type apparatus which employs a Steinmann pin in the upper posterior portion of the calcaneus to effect longitudinal traction and then oblique downward traction (Fig. 119). Countertraction is obtained by the use of a pin through the tibia just above the ankle. After reduction is effected, a plaster cast embracing both pins is applied and left in place for eight to twelve weeks. As one becomes more efficient with the use of molding in plantar flexion,

it will be found that fewer of the patients will require pin traction. There have been numerous serious infections around pins which are incorporated in plaster casts and, if possible, such use of pins should be curtailed.

Fractures of the Navicular, Cuboid and Cuneiform Bones. The navicular bone has somewhat the appearance and function of the keystone of an arch. It is fractured only occasionally, but severe fractures may result in long, painful disability. Among its more usual fractures, three types may be recognized: tuberosity fractures, in which the medial hooked area is fractured vertically, but is seldom displaced, and requires casting for

Figure 118 A, Fracture of the body of the calcaneus with only moderate displacement. Note that the tuber-joint angle is not greatly reduced. The fracture did not involve the articular surfaces. The prognosis is good. B, Axial view of fractured calcaneus showing spreading of bone and fracture lines extending obliquely upward through bone.

Figure 119. A, Apparatus for reducing a fracture of the calcaneus by skeletal traction (after Bohler); B, special clamp designed by Bohler to correct lateral spreading of the calcaneus.

Figure 116 Fracture of the tuberosity of the calcaneus (lateral view) This type of fracture must be treated by open reduction and fixation

pletely separated and displaced upward, open reduction and fixation with a nail or screw may be indicated (Fig 116).

In the group of fractures which extend into the articulating surfaces are two main varieties: the type that runs upward and outward into the posterior portion of the subtalar joint and causes widening of the

articulating surface by displacing the lateral fragment outward and the type that by compression drives either or both the anterior and posterior articulating surfaces downward into the body of the calcaneus (Fig 117). Some surgeons are now reporting success following open reduction of such fractures, but it seems likely that in most instances operative fusions will be required.

Of the fractures not involving articular surfaces, three principal varieties are common. tuberosity fractures, either vertical or the beak type involving the upper portion of the tubercle; fractures through the body, but not involving joint surfaces, and fractures of the sustentaculum tali. The tubercle and sustentaculum fractures can usually be treated by closed manipulation and the use of a plaster boot cast for four to six weeks. The fractures of the body frequently cause marked loss of the tuber-joint angle and require more effort to effect reduction. In all fractures where there is spreading of the calcaneus laterally (Fig. 118), pressure by hand and knees or by a clamp should be used to squeeze the bony fragments together.

Whenever there is marked loss of the tuber-joint angle, regardless of whether articulating surfaces are involved, efforts should be made to restore the bone to normal contour. This may in some cases be effected by molding the foot while in plantar flexion by forcing upward on the sole in the

ilar surfaces. Note the loss of the involvement of the articular sur-

medial dislocation of the forefoot, the navicular may lock against the collar of the talus and defy all closed efforts to release it. A small incision permitting an elevator to pry the navicular loose from the back of the head allows subsequent reduction. A well-molded cast for six to eight weeks followed by arch-support footwear is indicated.

Fractures of the Metatarsals. Fractures of the metatarsal bones are common, the fifth metatarsal being most frequently fractured and the first metatarsal the next most frequently. Care must be taken not to mistake the normal epiphysis present in children at the lateral base of the fifth metatarsal for fracture. In addition to fractures due to direct violence, a variety of fatigue fractures, seen often in untrained military recruits required to take unaccustomed long walks, are recognized. Such march fractures occur at the necks of the second, third and fourth metatarsals, do not displace appreciably, but cause considerable pain. For relief of pain

a cast may be applied for two or three weeks, but in most instances a heavy-soled, arch-support shoe and limited activity for three weeks suffice for treatment.

The important feature of metatarsal fractures is the amount of plantar angulation of the fragments. Many metatarsal fractures have no significant displacement and many others have medial or lateral angulation or displacement with no plantar angulation (Fig. 123). Such fractures, as a rule, heal without residual pain. The undisplaced fractures are treated by thick, leather-soled, arch-support footwear and limitation of activity. The angulated and displaced fractures of the second, third, fourth and fifth metatarsals with no plantar angulation (Fig. 124) should be manipulated in an effort to improve the alignment and accomplish reduction, if possible. When the best possible position has been accomplished and there is still no plantar angulation, treatment by application of a well-molded plaster boot

Figure 122. A, Midtharsal fracture-dislocation (anteroposterior view). Note the marked medial displacement of the navicular from the talonavicular joint. B, Midtharsal dislocation reduced. Note the fracture of tuberosity of the navicular bone.

Figure 120 Isolated fracture of the tuberosity of the navicular bone (anteroposterior view).

about four weeks (Fig 120), dorsal chip fractures which are caused by direct trauma and seldom require more than elastic bandage support and some limitation of activity, and compression fractures which may result from an intolerable force applied over the crest of the longitudinal arch, causing the navicular bone to be violently squeezed between the head of the talus and the cuneiform bones. The compression force may

fracture the navicular transversely or in a stellate manner. Sometimes the dorsal fragment displaces upward and backward and, in rare instances, it cannot be reduced by closed methods. If open reduction of navicular fractures is required, it is advisable to take steps to promote arthrodesis of the talonavicular-cuneiform joints, by removing the articular cartilages and packing many small bone chips or flakes all around the cartilage-denuded joints. If fusion is not promoted, painful disability from the consequences of rough joint surfaces may be expected. A boot-type plaster cast, well molded upward in the region of the longitudinal arch, should be worn for ten to twelve weeks when fusion is occurring. This should be followed by use of a firm arch-support shoe or Oxford.

The cuboid and cuneiform bones are rarely fractured and, when fractured, they are seldom displaced significantly (Fig. 121). A well-molded plaster cast supporting the longitudinal and transverse arches is indicated for comfort and support. It should be employed for about four to six weeks, following which a good arch-support shoe or Oxford should be worn.

An unusual type of fracture-dislocation involving the midtarsal area is occasionally seen (Fig. 122). The forefoot may be dislocated either laterally or medially with major displacement at the talonavicular and calcaneocuboid joints. The dislocation is almost invariably associated with fractures of some of the involved tarsal bones, although at times the fractures may be minimal. Reduction by closed manipulation is usually simple, but occasionally, in patients with

Figure 121. Chip fractures of the cuboid bone (lateral view).

immobilization is used for about six to eight weeks. In all instances, thick, leather-soled, arch-support footwear is indicated following cast removal.

Fractures of the Phalanges of the Toes. One should be careful to secure good alignment of the great toe phalanges following fracture. Fortunately, all phalangeal fractures, whether caused by stubbing the toes or having weights dropped on them, tend to remain in satisfactory alignment. They may be quite painful. In all patients, good alignment should be obtained, particular care being taken to avoid persistent plantar cocking or hammer toe deformity. Fractures of the great toe phalanges are best treated by employment of a metal splint or plaster cast. Fractures of the phalanges of all other toes can usually be treated by placing lambs' wool or cotton gauze between the adjacent toes and splinting to unbroken toes with adhesive strapping. Care must be taken not to have the strapping too tight or permit it to cut into the flesh. Sometimes a small dorsal splint is useful. Ambulation is permitted, but thick, leather-soled, arch-support footwear is advised. If swelling is excessive, the cap of the shoe may have to be cut.

INTERNAL DERANGEMENTS OF THE KNEE JOINT

Internal derangements of the knee joint are commonly considered to be due to three mechanical causes: fractures of semilunar cartilages, tears of cruciate ligaments and osteocartilaginous loose bodies. Closely akin to these agents, but separated because of anatomic position and pathologic differences, are two other major causes of knee joint disability, tears of the collateral ligaments and chondromalacia patellae.

Tears of the cruciate ligaments and fractures of the semilunar cartilages are frequently seen accompanying fractures of the knee joint region. Fractures of the plateau of the tibia are prone to cause injuries to the semilunar cartilages, the cruciate ligaments and the collateral ligaments. Dislocations of the knee joint always damage the menisci and all knee joint ligaments.

Osteocartilaginous bodies are commonly seen in the knee joint as the result of three conditions: osteoarthritis, osteochondritis dissecans and osteochondromatosis, the last being rather rare. Internal derangement is caused by the loose bodies getting between the articulating joint surfaces.

The collateral ligaments are supporting structures to the knee joint, medially and

laterally. The internal semilunar cartilage is closely attached to the medial joint capsule which blends intimately with the internal collateral ligament. The external semilunar cartilage is more loosely connected with the lateral portion of the joint capsule and the blended external collateral ligament.

Chondromalacia patellae is a condition affecting the articular surface of the patella in which the surface becomes shredded and the hyaline cartilage degenerated. It is considered by some to be the result of trauma to the cartilage caused by the patella being driven against the femur. It gives symptoms of pain in the anterior compartment of the knee joint and usually produces crepitus on motion. If the symptoms become too troublesome, surgery is performed with complete scraping off of the degenerated cartilage down to healthy bone. Some surgeons prefer to resort to patellectomy as an initial procedure.

Tears of the collateral ligaments are not really internal derangements of the knee joint, but they are more common than any internal derangement. Tear of the internal collateral ligament at or near its femoral attachment is the most frequent of all major disabilities of the knee, and tear of the external collateral ligament at or near its femoral attachment follows injuries of the internal collateral ligament in order of frequency. A few surgeons taking care of highly skilled athletes operate on fresh collateral ligament tears if a diagnosis of complete rupture is made; their results are encouraging. The majority of surgeons utilize immobilization by a splint or a plaster cast for about four weeks, supplementing the therapy with good quadriceps exercises. Collateral ligament tears are diagnosed by pressing against the side of the patient's knee when his leg is extended. If abnormal motion is present, the joint opens on the side opposite the hand pressure and rupture of the ligament on that side is presumed. Chronic laxity of collateral ligaments due to old tears produces instability of the knee joint. Surgery for the repair of poor collateral ligaments or for substitution of collateral ligaments has not been uniformly successful and therefore the majority of surgeons prescribe a routine of quadriceps exercises in an effort to make the quadriceps mechanism strong enough to stabilize the knee joint.

In addition to tears of the menisci, mucoid cysts of the semilunar cartilages may cause symptoms of locking and pain. Cysts are more common in the external semilunar car-

Figure 123 Fracture of second metatarsal with slight displacement (anteroposterior view) No manipulation was necessary. Plaster boot cast provided satisfactory treatment.

extending from the tibial tubercle to the toes, to be worn for four to six weeks, is indicated, or thick, leather-soled, arch-support footwear or an inserted rigid arch support may be used. Fractures of the first metatarsal should be reduced to anatomic position by closed manipulation when possible or by open reduction when necessary.

The only metatarsal fractures which require painstaking attention are those exhibiting significant plantar angulation. If the bones heal with marked plantar angulation, walking is often quite painful. In most of the patients, closed manipulation is successful in eliminating the plantar angulation, but if not successful, or if improved position cannot be maintained in a plaster cast, open reduction and fixation with transfixion wires or plates and screws may be indicated. Skeletal traction applied by the use of small pins through the phalanges of the broken metatarsals is a useful method of treating difficult fractures. The pins are connected by rubber bands to a banjo splint arrangement formed by a loop of heavy wire extending beyond the toes and incorporated in a plaster cast. With the banjo splint arrangement,

Figure 124. A, Frontal view. B, Lateral view of multiple metatarsal neck fractures. The plantar angulation is not marked.

notch and if it remains there, it may produce minimal symptoms; however, it is more apt to slide out and lock between the articular surfaces, occasionally causing repeated episodes of disability. In such cases, there is always at least slight limitation of extension and of flexion.

Transverse and oblique tears may occur anywhere along the free edge of the cartilage and in some rare cases along the capsular edge, although the usual capsular tear is longitudinal and at the junction of the capsule and the cartilage. Oblique tears may produce a long tongue of cartilage fastened only at one end and the free end of the tongue may get caught between the articular surfaces. Quite a variety of tears may be produced in cartilages that undergo repeated fracture and one may have multiple bucket-handle tears or Y or double oblique tears.

Initial treatment consists of making the patient comfortable and, if possible, reducing a displaced cartilage. Several methods of manipulation have been advocated for accomplishing replacement of torn cartilages which are caught in a position causing stretch on the capsule with the production of pain, but no certain manipulation is generally successful. Often, the patient is put to bed after manipulation with the knee still "locked" only to awaken the next morning with disappearance of symptoms. Perhaps it would be better to administer a sedative and let the patient spend a relaxed night in bed and if the knee is still very painfully locked the next morning, manipulation might then be considered.

With the first attack of meniscus fracture, immobilization of the knee in a splint or a cast with the knee in almost full extension is indicated. If the tear is close to the capsule, the blood supply is sufficient to heal the tear, but if the tear is in the cartilage body, it will never heal because of deficient circulation. Since one cannot accurately diagnose whether the tear is capsular, it is better to give the meniscus an opportunity to heal, if perchance the tear is favorable. The cast or splint should remain on three or four weeks and quadriceps exercises should be done several times daily. If the attacks of knee disability recur and the diagnosis is firm, operative removal of the torn meniscus is indicated.

In diagnosis, several points need to be considered: the history of initial occurrence, the number and manner of recurrences, the length and severity of attacks and the findings. Anterior and

bucket-handle tears usually show tenderness on pressure over the anterior horn of the cartilage just to the side of the patellar ligament, there is pain on rotating the tibia on the femur with the knee at right angle, there is loss of at least some degrees of extension and sometimes a "click" is evident on extension from a flexed position. X-ray studies in all patients with cartilage injuries are non-confirmatory. If the tear is lateral, there may be pain over the lateral aspect of the joint instead of anteriorly, and if the tear is posterior, there may be pain and limitation of motion on the extremes of knee flexion. Sometimes one can palpate the cartilage in different positions.

The question of the advisability of removing a torn cartilage which has caused several recurrent attacks of disability, but which has gradually become less troublesome, is pertinent. Only by seeing the inside of a joint with an old badly torn cartilage and observing the damage to the articular cartilage of the femur can one be positive in advising removal of all torn cartilages which continue to give even minimal symptoms. The damage to the articular cartilage is sure to predispose to arthritic changes, and therefore, particularly in younger patients, it is wise to remove all chronically torn menisci.

The technique of removing fractured semilunar cartilages varies somewhat between surgeons. The majority of surgeons prefer to keep the incision anterior to the collateral ligaments and vertical or oblique across the joint space. Some surgeons prefer an incision posterolaterally to remove all of the posterior horn of the meniscus. There is also difference of opinion as to whether the entire meniscus should always be removed or just the torn portion of a bucket-handle tear. While, from the standpoint of eliminating all future chances of residual tearing it is probably safer to remove the total cartilage, statistics from some excellent clinics show very little difference in long-term results. After removal of a semilunar cartilage a fibrous replacement forms that looks very much like the original meniscus.

Tears of Cruciate Ligaments. Cruciate ligament tears are frequently associated with fractures of the lower femur or upper tibia and always with dislocations of the knee joint. They may also occur in conjunction with fractures of the semilunar cartilages and are observed to happen in athletes participating in active contact sports.

Tear of the anterior cruciate ligament. The anterior cruciate ligament is fastened to

Figure 125 Types of fracture of the internal semilunar cartilage.

tilage and may cause the cartilage to protrude externally so that it can be seen and felt. Total removal of the cartilage is indicated when cysts are found.

In testing for range of motion and for stability of the knee joint, it is well to remember that great variations normally occur between individuals. The findings on the affected leg should always be compared with the findings on the other leg of the same individual.

Fractures of Semilunar Cartilages. Fractures or tears of semilunar cartilages are much more common in young men than in women and are frequently associated with forms of contact sports such as football, basketball and hockey. Tears of the medial semilunar cartilage are about ten times as common as tears of the lateral cartilage and "bucket-handle" tears are more common than transverse, oblique or capsular tears.

Fracture of the medial meniscus occurs when the tibia is fixed to the ground and externally rotated on the femur. The knee is flexed and adducted when a force moves the leg into extension and the medial meniscus is caught between the tibia and the medial condyle of the femur, causing the meniscus to tear. Fracture of the lateral meniscus occurs in a reverse position with the tibia internally rotated on the femur and the knee flexed and abducted when sudden extension is applied. A definite sensation of tearing may be noted by the patient and frequently

the knee joint becomes locked in partial flexion. In the majority of patients, the locking disappears when someone moves the leg or when the patient manipulates the leg. Occasionally the locking fails to disappear even after weeks have elapsed and only surgical removal of the cartilage gives relief.

In the average case, the limitation of motion preventing full extension and full flexion gradually becomes less and less until only by careful examination can any limitation be noted. Still, the patient may feel uncertain about the stability of his knee even though he may be able to participate in active sports. If the tear is in the cartilaginous portion of the meniscus, healing does not occur and after a while another episode of locking and disability will occur, however, often the trouble will not be as severe as the first attack. Subsequent episodes of displacement of the cartilage may cause less trouble until only minor difficulty may be experienced; however, additional tears may occur, causing increased symptoms.

Tears of the semilunar cartilages (Fig 125) may be placed in four groups: bucket-handle tears, transverse tears, oblique tears and capsular tears. The bucket-handle type of tear is the most common and is a longi-

Figure 127 Osteochondromatosis of the knee with multiple loose bodies

patella. Symptoms are vague until the body becomes entirely loose and happens to get between the articular surfaces. At first, there is a feeling of uneasiness about the knee

... may be present. . . . small defect just below the articular cartilage in a localized area. Since this trouble occurs primarily in adolescent boys and in young men, it is wise to remove the body before it gets entirely loose and causes damage to the articular cartilage elsewhere in the joint. A word of caution is in order to remind surgeons that sometimes it is quite difficult to find the exact spot of the loosening body when the cartilage-covered area is examined. It may be wise to wait until the condition has progressed to the point where final loosening seems imminent and then it is not difficult to identify the region of softened, dull cartilage and minutely shredded surface. A sharp scalpel finds the line of demarcation between good surface cartilage and poor cartilage and, as the area is cut circularly, the loose body below with its core of bone separates and is removed. If the body is discovered by x-ray examination to be free in the joint, it may be difficult to find when the joint is opened because it moves about quite freely and justifies its common name of "joint mouse."

Osteochondromatosis. The synovial membrane possesses the ability under certain benign pathologic processes to form numerous osteocartilaginous bodies which extend into the joint (Fig. 127). Many of the bodies arise from the region where the synovia is fastened to the bone and they may project inward as single bodies or in bunches like

grapes. They grow on pedicles which break and permit the bodies to become completely free in the joint. Hundreds of bodies of various sizes have been removed from a single joint, but unless synovectomy is done, just as large a crop of bodies may be found the next time x-ray examination is made. Removal of the bodies and synovectomy are indicated in younger patients, in older patients, nothing need be done unless symptoms become troublesome. Symptoms are caused by the loose bodies getting between the articular surfaces.

DISLOCATIONS OF LOWER EXTREMITY JOINTS

Lower extremity joint dislocations may be divided into five categories: dislocations of the hip joint, dislocations of the knee joint, dislocations of the patella, dislocations of the ankle joint and dislocations of the joints of the foot.

It is not unusual to have dislocations occur either directly or indirectly because of infections of joints, Charcot joints, paraplegia, cerebral spastic palsy, tumor formations and many other pathologic conditions. However, consideration will be limited to dislocations caused by injuries of violence.

Dislocations of joints are severely traumatic episodes and in every instance there is damage to the capsule, the ligaments and the periosteum. Initial dislocations are usually very painful and may cause varying degrees of shock. Frequently there is considerable bleeding and this may produce a condition of myositis ossificans. Injury to the blood supply of the bone and to the surrounding soft tissues may lead to necrosis

the anterior portion of the tibial spine and to the back of the inner surface of the lateral femoral condyle in the intercondylar region. Thus it runs obliquely backward and laterally and limits the forward excursion of the tibia on the femur. A sudden forward push of the internally rotated leg with the femur stationary causes rupture of the anterior cruciate ligament and may also cause damage to the collateral ligaments. A strong thrust backward on the femur with the tibia stationary causes the same type of tear of the anterior cruciate ligament.

Evidence of rupture of the anterior cruciate ligament is shown by the "drawer"

below the knee joint. Abnormal forward motion is indicative of injury to the anterior cruciate ligament. Rupture of this ligament is much more common than is rupture of the posterior cruciate ligament.

Tear of the posterior cruciate ligament. The posterior cruciate ligament is fastened to the posterior portion of the tibial spine and to the forward portion of the inner surface of the medial femoral condyle in the intercondylar region. Thus it runs forward and medially and limits the backward excursion of the tibia on the femur. Sudden backward thrust of the tibia with the femur fixed, or forward thrust of the femur with the tibia stationary, causes rupture of the posterior cruciate ligament.

Rupture of the posterior cruciate ligament is demonstrated by putting the patient in the same position as for testing the anterior cruciate ligament and pushing backward on the tibia instead of pulling forward. If abnormal backward motion is found, it may be presumed that the posterior cruciate ligament is injured.

In some instances both anterior and posterior cruciate ligaments are found to be ruptured.

Treatment of cruciate ligament tears. The marked instability of the knee joint when both cruciate ligaments are ruptured produces a sensation of uncertainty on weight bearing. If only the anterior cruciate is ruptured and the patient has relatively strong muscles, there is not much disability. Rupture of the posterior cruciate ligament causes an increased feeling of insecurity, but strong musculature may overcome this difficulty.

If the patient is seen shortly after injury, it is well to apply a long leg plaster cast

with the knee flexed about 30 degrees and pushed backward if the anterior cruciate ligament is torn and forward if the injury was to the posterior cruciate ligament. The cast should remain in place for eight to twelve weeks. It is of extreme importance to build up strong quadriceps power so that extra strength in that mechanism may substitute for injured ligaments.

Surgical repair of cruciate ligament tears is seldom of permanent value, although numerous ingenious operations have been devised to assist this condition. Substitution operations are likewise disappointing. Development of strong muscle power about the knee joint is the best treatment at present.

Osteocartilaginous Loose Bodies. Loose bodies in the knee joint produce symptoms by irritating the synovial lining and by getting between the articular surfaces of the femur and the tibia. In some instances they closely simulate the symptoms of tear of the semilunar cartilages and only x-ray examination gives definite differentiation.

Osteoarthritis. Osteophytes arising from the margins of the tibia, the femur and the patella may break off from their stems and become loose bodies in the knee joint. As long as the osteophytes remain attached and have a synovial covering, they are rough, but when they break off from their pedicles and wander about the joint, they become smooth and round. Any number may break off and become loose bodies and it is not unusual to see four or five such bodies in a knee joint. They produce symptoms by getting between the joint surfaces and if the symptoms are too troublesome, surgical removal is indicated. One must evaluate these cases, however, because the condition is more apt to occur in late middle age and old age when the arthritis present in the knees may be the major cause of symptoms. Only when firmly convinced that removal of the loose arthritic bodies will give relief should surgery be undertaken.

Osteochondritis dissecans. Loose bodies from osteochondritis dissecans may appear in the knee joint from the femur or from the patella. It is thought in some quarters that the condition of osteochondritis dissecans results from trauma and the local manifestation is that of avascular or aseptic necrosis of a small piece of bone and cartilage.

Most of the bodies arise from the inner portion of the medial femoral condyle (Fig. 126), but they may come from any part of the cartilage-covered femur in the knee joint. More rarely, they may separate from the

As strong upward lift is exerted, a gentle rocking motion is used to permit the head of the femur to find the tear in the capsule and return through the tear into the joint. Commonly a "pop" is elicited as the head snaps into the socket. The leg is then gently straightened.

The method of Bigelow (Fig. 131) uses

circumduction and requires the head to sweep around the outer rim of the acetabulum until it reaches the posteroinferior part of the joint where the rim is the lowest and then reduction is effected. The wide arc of travel of the head increases the danger of injuring adjacent tissues and also presents the hazard of the head continuing its upward

Figure 130. Grip used in reduction of a dislocated hip.

Bigelow method of reduction of a posterior dislocation of the hip (Cotton) a, The thigh is flexed and gently lifted in adduction with the leg in flexion, b, the thigh is rotated inward (foot outward); c, the thigh is abducted and rotated upward, d, the thigh is abducted, e, the thigh is rotated outward (foot inward), f, the leg is extended. This is done with a sweeping circular motion without force. In the diagram the heavy arrow indicates the sequence of positions

and permanent disability and the longer the dislocation is permitted to remain unreduced, the greater the hazard of irreversible damage. Violent manipulative attempts at reduction may cause additional trauma and unnecessary complications.

Dislocations are often associated with fractures and it is not unusual to have unrecognized fractures because the massive displacement inherent in dislocations covers fractures which would otherwise be visualized on x-ray films. Occasionally, fracture fragments are displaced into joints and prevent reduction of dislocations. Nerves are not infrequently damaged by dislocations and such damage may constitute the major residual disability following injury.

In recent years there has been a steady increase in the proportion of dislocations in bone and joint injuries. This is due to the increased violence which occurs in accidents of high-speed vehicles and also because the injuries happen when seated persons are hurled into projecting ledges and cramped corners.

Dislocations of the Hip Joint. Two principal types of hip joint dislocations occur: posterior dislocations (Fig. 128) and anterior dislocations. Posterior dislocations are subdivided into two types: upper or iliac dislocations and lower or sciatic dislocations. Anterior dislocations are subdivided into two types: upper or pubic dislocations and lower or obturator dislocations. The subdivisions are descriptive of the regions occupied by the dislocated head of the femur, iliac being on the ilium, sciatic at the sciatic notch, pubic near the os pubis, and obturator near the obturator foramen. Both anterior and posterior dislocations may be displaced even beyond the areas above noted, but such displacements are rare.

There is also a so-called central dislocation, but this can only occur in conjunction with fracture of the acetabulum.

Posterior dislocation of the hip is by far the most common. This usually occurs in automobile accidents and is brought about by the sudden forward thrust of a seated person striking the knee against the instrument panel or a seat. If the knees are crossed at the time, the dislocation occurs more easily. If the hip is markedly flexed at the time, the head of the femur is driven backward and downward toward the sciatic notch. If the hip is only moderately flexed, the femoral head is driven almost straight backward toward the ilium. Fracture of the posterior portion of the acetabulum may occur. The

Figure 128 Posterior and upward dislocation of the left hip.

Figure 129. a, Posterior dislocation of the hip; b, anterior dislocation of the hip

lower extremity on the affected side remains in a position of adduction, moderate hip and knee flexion and internal rotation (Fig. 129a). Pain and shock may be severe.

Treatment of posterior dislocation of the hip consists of gentle manipulative reduction with the patient under general anesthesia. Three methods are in common use: the method of Allis, the method of Bigelow and the method of Stimson.

The method of Allis is probably the one most commonly used. The patient is placed on his back on the floor or on a low table and anesthetized. The pelvis is fastened down by a swath, or held down by an assistant, while the surgeon performs the manipulation. The hip and knee are flexed to right angles with the thigh adducted and slightly internally rotated. The surgeon then places his forearm up to the elbow under the bent knee and lifts upward (Fig. 130).

nology of knee joint dislocations is based on consideration of the femur as a fixed object and the tibia as the movable part. There are four types of dislocations of the knee joint: anterior dislocation (Fig. 132), posterior dislocation, lateral dislocation and medial dislocation.

In all dislocations of the knee joint the capsule is torn, the cruciate ligaments are ruptured, the collateral ligaments are torn and the gastrocnemius and popliteus muscles are damaged. Other muscles may also be injured according to the type of dislocation. In posterior dislocations, the arteries and veins in the popliteal space may be injured, and in medial dislocations, the peroneal nerve is frequently damaged, causing peroneal nerve paralysis.

Dislocations of the knee joint are not common, but, like other disabilities due to severe trauma, they are undergoing a relative increase in occurrence.

The majority of knee joint dislocations are readily reducible by manipulation. Pulling down on the leg produces traction, and firm pressure over the protruding dislocated upper tibia pushes the bone back into place. In some dislocations, reduction is more easily accomplished by traction with the knee flexed to 90 degrees. Lateral dislocations may displace the semimembranosus, semitendinosus, sartorius and gracilis tendons into the intercondylar notch and in such patients it is impossible to reduce the dislo-

cation with the knee in extension. Flexion of the knee to 90 degrees or more relaxes these tendons and permits them to slide behind the condyle as reduction is accomplished.

Because of the instability of the knee joint resulting from any dislocation, it is necessary to immobilize the joint in a plaster cast for a period of six to twelve weeks. It is most important to institute quadriceps exercises as soon as the cast is applied and these exercises should be pursued diligently. After removal of the cast, exercises should be continued. The inevitable multiple tearing of ligaments accompanying every knee joint dislocation produces a weak, unstable condition in a joint that largely depends upon ligaments for its stability. Only by attaining strong power in the quadriceps can good stability with fair function be expected.

Dislocations of the Patella. Dislocation of the patella is much more common than any type of knee dislocation. Invariably the dislocation is to the lateral side of the knee (Fig. 133). The patella may lock against the outer rim of the lateral condyle and stay with its anterior surface pointing forward or, more frequently, it may dislocate laterally and then rotate 90 degrees so that the articular surface lies against the lateral side of the lateral condyle. Spontaneous reduction is the rule rather than the exception and, for this reason, differential diagnosis is often difficult. Dislocation may only be momentary

Figure 132. A, Anteroposterior view of anterior dislocation of knee with some medial displacement of tibia. B, Lateral view of anterior dislocation of knee.

sweep and converting a posterior dislocation into an anterior one. With the hip and knee flexed, the thigh is brought into increased adduction and internal rotation. While strong upward lift is exerted, the knee is moved toward the umbilicus, then outward, downward and inward. The maneuver brings the thigh from marked internal rotation to marked external rotation. The final position after reduction is extension of the hip and knee.

The method of Stimson uses the force of gravity to aid in reduction. The patient is placed face down on an operating table with the pelvis at the lower break of the table. The lower table hinge is then released and an assistant holds the unaffected leg out straight to keep the patient from slipping. The thigh on the affected side is permitted to drop to a right angle to the body, and then, with the knee kept in a bent position by holding the ankle downward, force is applied to the back of the calf just below the knee. This manipulation is frequently successful in reducing dislocation and actually is the same maneuver as the Allis method, but performed with the patient in a reversed position.

After reduction the patient is placed in bed on his back with his legs extended. The legs are kept in abducted positions by sandbags. Bed rest is enforced for three weeks, then crutch walking with little weight bearing on the affected side is advised for another three weeks.

Anterior dislocations of the hip occur as the lower extremities are forced into wide abduction and external rotation, as in the position commonly known as "the split." Anterior dislocation causes the extremity to assume a position of moderate flexion of the knee and the hip with the extremity externally rotated and abducted (Fig. 129b). This type of dislocation is not as common as is posterior dislocation but it may present more difficulty in reduction. The degree of disability and shock is similar to that occurring in posterior dislocation and the dangers, while somewhat different, are no less.

Reduction of anterior dislocations is accomplished by one of two methods: the method of Allis or the method of Bigelow. The method of Allis is less traumatic and is in more common use. The method of Bigelow frequently results in converting an anterior dislocation into a posterior dislocation and, while in some patients such conversion seems necessary in order to accomplish reduction from the posterior position, the wide

excursion of the head of the femur around the outer rim of the acetabulum is not without danger of damage to important soft tissue structures.

In reducing anterior dislocations by the method of Allis, the patient is laid on his back and the pelvis is secured by a swath. The surgeon gently increases the abduction of the thigh to about 90 degrees, with the hip flexed and the knee flexed to 90 degrees. Upward lift is constantly exerted by the surgeon while an assistant pushes firmly with his hands against the upper, inner portion of the thigh in an effort to shove the head of the femur laterally. As the surgeon gently rocks the extremity, the head finds the rent in the capsule and goes to the rim of the acetabulum. The extremity is then gently rotated inward and adducted while still being lifted. The head then goes over the rim of the acetabulum and reduction is completed as the extremity is straightened.

In the Bigelow method of reduction of anterior dislocations, the thigh and knee are flexed at 90 degrees and, as strong upward lift is exerted, the thigh is further abducted, further flexed and then adducted, internally rotated and finally straightened into extension.

Treatment after reduction consists of bed rest in the supine position with the legs tied together with a bandage so as to maintain an adducted position. After three weeks in bed, the patient is kept on crutches for another three weeks.

Muscles and capsule are always torn in dislocations of the hip, but the two most serious frequent complications are injury to the sciatic nerve and injury to the blood supply of the head of the femur, resulting in subsequent aseptic necrosis of the head. In posterior dislocations, the sciatic nerve may become stretched across the neck of the femur or may be injured by direct pressure of the head of the femur. If reduction is prompt, and not unnecessarily rough, the chances of complete recovery of sciatic nerve function are good but slow, sometimes requiring six to twelve months.

The incidence of aseptic necrosis of the head of the femur following hip dislocations is unfortunately quite high, being estimated at close to 25 per cent. Frequently, x-ray and clinical evidences of necrosis fail to be confirmatory for almost a year.

Hip dislocations usually occur in vigorous young adults and prolonged disabilities from complications are of serious import.

Dislocations of the Knee Joint. Termi-

considered true dislocation and is better classified under injuries of ligaments.

The closely fitted mortise of the ankle joint with its posterior narrowing, and its lateral and medial malleoli projecting downward as cleats, makes true dislocation without fracture a rare occurrence. It is surprising that such pure dislocations ever occur because they necessitate very extensive rupture of ankle joint ligaments and, in the case of posterior dislocations, some spreading apart of the tibia and fibula. Yet a few true dislocations occur posteriorly and, extremely rarely, anteriorly.

In posterior dislocation, the foot is pushed backward while the tibia and fibula are pushed forward. The astragalus locks behind the tibia and moves somewhat laterally. The dislocation occurs with the foot in plantar flexion, with the Achilles tendon in a shortened position.

In anterior dislocation, the heel is driven forward with the foot in dorsiflexion while the tibia and fibula are pushed backward. The strong Achilles tendon resists this displacement and is one reason for its rarity.

Nerves and blood vessels may be seriously damaged in such massive displacement.

Reduction of ankle dislocations is usually not difficult. With the patient anesthetized, the knee is flexed and traction exerted downward on the foot. With posterior dislocations, the foot is put in plantar flexion during traction and then pressure is exerted backward on the lower tibia and forward on the foot. With anterior dislocations, traction is made downward with the foot in dorsiflexion and then the foot is pushed backward while the tibia is pressed forward.

The extensive ligamentous damage necessitates cast immobilization for six to ten weeks, but after a few weeks a walking heel may be applied to the cast. The foot is placed in a neutral position during immobilization.

Dislocations of the Joints of the Foot. Dislocations of the joints of the foot may be divided into five types: dislocation of the talus, subtaloid dislocation, midtarsal dislocation, tarsometatarsal dislocation and metatarsophalangeal dislocation.

Dislocation of the talus. Complete dislocation of the talus without fracture is very unusual. Dislocation with fracture is discussed in the text concerned with fractures of the talus. Subluxations of the talus without fracture are concerned primarily with ligamentous injuries and are not true dislocations.

The talus may completely dislocate either forward and outward or inward and backward. Frequently the injury is compound and always there is marked circulatory damage. Reduction should be accomplished promptly in an effort to keep the soft tissue damage minimal and to release the pressure on the nerves and vessels. If manipulation with hand alone is not sufficient to pull the heel down and slip the talus back into its socket, a pin should be put through the calcaneus and strong skeletal traction exerted while manipulation of the protruding bone is carried out. Even though aseptic necrosis of the talus may result, it is better to go on to a pantalooid fusion later than to do a primary talectomy, however, if the area is compound and dirty, talectomy is the treatment of necessity.

After reduction, a plaster cast is applied with the foot in a neutral position and is left on for eight to ten weeks.

Subtaloid dislocation. On rare occasions, the talus may remain in its normal position while the foot below dislocates at the talocalcaneal and talonavicular joints (Fig. 134). Displacement may be forward, backward, lateral or medial. Disability is marked and circulatory impairment may be hazardous. Immediate reduction should be performed and ordinarily is not difficult. Traction downward on the foot to release the bones, then manipulation to bring them back to their normal positions, ordinarily give prompt results. Plaster cast immobilization for four to eight weeks is indicated.

Midtarsal dislocation. Midtarsal dislocation is usually associated with one or more fractures. Rarely, such a dislocation may occur without fracture and the position of displacement may be in any direction. Reduction should be prompt, but may be difficult. The anterior portion of the foot should be pulled forward, the displaced bones manipulated and attempts made to push them into place. The joints concerned are the talonavicular and the calcaneocuboid. If reduction cannot be accomplished by the closed method, open reduction should be performed.

Tarsometatarsal dislocation. Tarsometatarsal dislocation is the most common dislocation affecting the tarsal bones. The metatarsals may be displaced in almost any direction in relation to the tarsal bones and the dislocation may be single or multiple. The first and the fifth tarsometatarsal joints are most frequently dislocated.

Reduction is imperative if a painless foot is to be expected. Strong pull on the toes

Figure 133. A, Anteroposterior view of lateral dislocation of patella. B, Lateral view of lateral dislocation of patella.

because extension of the knee usually causes reduction and the patient may never see the region of dislocation. Pain along the medial side of the patella and over the lower fibers of the vastus medialis may be confused with symptoms of a torn medial meniscus, and unusual mobility of the patella cannot always be evaluated because of the reaction of apprehension of the patient when the patella is pushed laterally.

Dislocation of the patella occurs when the foot is fixed on the ground with the tibia externally rotated and a sudden force pushes the knee inward. This brings the quadriceps tendon and the tibial tubercle on a line outside the lateral condyle and sudden contraction of the quadriceps causes tearing of the lower fibers of the vastus medialis and permits dislocation of the patella. A sudden force applied directly to the medial border of the patella when the quadriceps is relaxed may also cause dislocation of the patella.

Dislocations occur in adolescents and adults and should be distinguished from congenital dislocating patellae, in which the patellae dislocate almost every time the knees are flexed. It is considered that knock-knees with their valgus positions are more liable to dislocations of the patella than are normal knees and it is further considered that congenital flattening of the anterior portion

of the lateral condyle permits dislocations to occur more readily than in normal states. The majority of dislocations occur in women.

Reduction of dislocation is simple. With the knee extended, the hip is flexed and the patella pushed upward and medially with the fingers.

Because of the marked tendency for recurrent dislocations, it is wise to immobilize the extremity in a plaster cast in almost full extension for eight weeks. Quadriceps exercises should be instituted as soon as the cast is applied and should be continued after removal of the cast.

If dislocations become recurrent, surgery is indicated. Provided the patient is old enough for the epiphyses to have closed, the most successful operation is transplantation medially of the tibial tubercle with its patellar ligament attachment. This brings the pull of the quadriceps more in line with the middle of the knee joint and prevents the patella from moving laterally.

Dislocations of the Ankle. Dislocations of the ankle are generally considered in five categories: posterior dislocation, anterior dislocation, medial dislocation, lateral dislocation and upward dislocation. Actually, it is virtually impossible to produce medial, lateral or upward dislocations without fractures. Extensive rupture of ligaments, permitting subluxation of the ankle joint, is not

Figure 134 A, Anteroposterior view of ankle showing lateral subtaloid dislocation B, Oblique view of lateral subtaloid dislocation. C, Lateral view after reduction of lateral subtaloid dislocation

while the dislocation area is being manipulated usually accomplishes reduction if done early enough, but, if done late, it may fail to put the bones in place. Open reduction should be done if attempts at closed reduction are unsuccessful.

A plaster cast for four to six weeks is indicated following reduction

Metatarsophalangeal dislocation. Dislocations at the metatarsophalangeal joints are rare but occur occasionally. The first metatarsophalangeal joint is the most frequently affected and displacement is with the phalanx lying on top of the head of the metatarsal. Strong pull on the toe, while rocking it in dorsiflexion and sideways, usually accomplishes reduction. Immobilization for two or three weeks is recommended.

Muscles, Ligaments and Bursae

By JAMES K. STACK, M.D.

JAMES KEANE STACK is a graduate of Notre Dame and Northwestern Universities to which he came from Duluth, Minnesota. He has had a wide experience in traumatic injuries of the skeletal system as surgeon for a large railroad system. He is an Associate Professor of Orthopedic Surgery at Northwestern University.

The muscles, ligaments and bones, with accompanying joints and bursae, make up, with their nerve and blood supply, the motor-skeletal system. These structures are responsible for our ability to maintain an upright posture and to move agilely, accurately and freely from place to place. Most of the structures in the motor-skeletal system differ from the other physical systems in that they are accessible to the sight and touch. The male of the species is especially attentive to his muscular development and the muscular system constitutes a substantial percentage of him. Ingrained in all persons is a pride of physique and this concept is so well established that compensation awards may be granted for its disturbance. For centuries the demonstrations of feats of strength, speed and agility have played an important role in our civilization. These demonstrations of the prowess of the motor-skeletal system are perhaps more frequent and accepted than those demonstrations concerning other vital but more concealed systems, such as digestive and respiratory.

Locomotive freedom is occasionally challenged by injury, bacterial invasion, neoplastic change or other disease and, for the surgeon to meet this challenge, certain established fundamentals must be available to him.

MUSCLES

MUSCLES

In surgery involving muscle tissue, the primary concern is with skeletal or striated muscle. The muscles of the skeletal system are derived from the mesoderm. We are inclined to think of them as having a single function, a fist. However, we simultaneously and synergistic action of myriads of muscle cells, each

equipped with the ability to contract, relax and to interchange with the capillary circulation those substances necessary for the function and survival of the cell. These cells are bound together in ever-enlarging systems until the point of the obvious and palpable muscle mass is reached. The power of contractility enhanced by the cooperative effort of the smaller muscle bundles is transmitted to bone by tendon or by a direct fibrous union. The cooperative, or team effort, concept of muscle action can be taken a step farther. Each joint has antagonistic muscle groups moving it one way or the other and each group usually has protagonists to help. Seldom, however, is the struggle an even one, as most joints are more effectively used one way than another. Gravity also enters the game and by aiding one group or another may promote the production of contractures and deformities, especially for the unwary surgeon.

The principles which govern the action of skeletal muscle have been established by those working in the fields of anatomy, neurology, physiology, chemistry, physics and mechanics and can be summed up briefly.

Each muscle cell, like all other living tissues, must have an arterial, a venous, lymphatic and nerve supply. The mass of cells making up the individual muscle bundles must have attachments called origins and insertions in order to function according to the laws of leverage. Some of the muscle, bone and joint arrangements in the body are very efficient levers, while others leave something to be desired. The muscles consist of plasma, proteins, carbohydrates and acid and they give off measurable electrical potentials and measurable amounts of heat. The muscles have the property of, or are held in a state

of, tone, which is responsible for our ability to maintain an erect posture without conscious effort. It is this same state of tone which holds the voluntary muscles in a state of readiness to act according to conscious impulse. This property of tone and thus ability to respond are dependent, among other things, upon the intact nervous system. Studies in muscle kinetics tell us of the mechanics of muscle function and the relationships between them and the bone, joints and ligaments. They also explain the deformities and the functional disturbances which can be produced by paralysis, contractures and shortenings and faulty weight-bearing alignment caused by habitually bad postures and attitudes.

Muscle tissue, like other highly specialized tissues in the body, such as the brain and liver, is not capable of regenerative repair. Any gross defect in a skeletal muscle, such as is created by a rupture, incision or perforating wound, will heal by fibrous tissue invading the hematoma which is formed at the time of the insult. The basic muscle cell, with its highly integrated neurochemical contractile properties, will not heal by regeneration. However, after any but the greatest loss, the fibrous tissue scar will unite the remaining muscle fibers and thus produce a functional result that may not greatly impair the use of the associated joints. In other words, an anatomic defect in voluntary muscle tissue need not create a significant functional defect. Voluntary muscle will atrophy when deprived of its nerve supply by direct nerve section or by disease, such as anterior poliomyelitis. It will also atrophy by being subjected to unfavorable reflex stimuli. Perhaps the most common form of atrophy is that of disuse, when the muscle is deprived of the opportunity to carry out its normal function. An example is the shrinkage occurring after fracture and subsequent immobilization.

Voluntary muscle is also capable of hypertrophy and by progressive resistance exercises can be developed to even greater than normal size. Thus, when one muscle is paralyzed, as for instance by poliomyelitis, protagonists can be strengthened and taught to compensate for this loss. Thus, the loss or impairment of a single muscle group does not mean necessarily the loss of all of the particular action in which that muscle group participates.

Skeletal muscle is heir to the ills which befall most other tissues. They run the gamut of life from congenital absence and anomalous origins and insertions to the lesions of

attrition that result in the fraying and ruptures of senescence and senility. In the years between, it is subjected to injury, infection, the vague inflammatory diseases that affect the collagen tissues, parasitic infestation and tumors that arise either in the muscle fibers proper or in the fibrous tissues that bind them. Peculiar to skeletal muscle are other conditions, such as myasthenia gravis and the various dystrophies of which the basic causes are as yet unknown.

It is seldom that congenital absence of a skeletal muscle actually produces deformity or dysfunction enough to warrant transplantation of others to overcome contracture or to improve action. Usually the congenital absence is an academic curiosity and the attention of the patient is called to it because it involves gross defects which are unilateral. The muscle which is most commonly absent is the pectoralis major. This defect does not seem to affect the power of either adduction or internal rotation, as its protagonists seem to serve well.

Trauma to skeletal muscle tissue can be open or closed, e.g., the tissue can be punctured or lacerated, as by a gunshot or knife. It may be ruptured by nonpenetrating blows applied violently over, for instance, the calf, the anterior surface of the thigh and the anterior surface of the upper arm. The muscles of the abdominal wall may be ruptured, usually incompletely by hard coughing. The rather common fractures of the transverse processes of the lumbar vertebrae are due basically to muscle action and are associated with muscle tearing at the point of insertion. It is likely that some of the low-back complaints following lifting and torsion strains are due to incomplete tearing of muscles within the substance or at the point of attachment to the ilium, sacrum or the lumbar vertebrae. Muscles may also be ruptured by longitudinal stresses which are beyond the tolerance of the elasticity of the fibers. The so-called Charley-horse of the athlete is an incomplete muscular rupture caused by this particular violence and likely to occur in the early period of strenuous endeavor before the muscles have become accustomed to and are ready for the strains which will be put upon them. These incomplete ruptures are followed, of course, by hemorrhage of varying degrees and the insult sets up a local spasm which accounts for the symptoms.

When it can be demonstrated that the rupture of a skeletal muscle is incomplete, rest in a position of relaxation is the treatment of choice. This may be followed by heat and

massage and the gradual resumption of activity. If it is demonstrated that the rupture of the muscle is complete and there is no protagonist which can take over its duties to the point where there will be no functional disability, an open repair is indicated. As stated before, skeletal muscle tissue is not capable of regenerative repair and therefore the torn muscle ends should be anastomosed as accurately as possible so as to minimize the amount of scar and to prevent the healing of the muscle tissue in an elongated manner. In those instances in which the muscle has been parted by an open wound, the repair should be preceded by a thorough cleansing and a wide and complete investigation to determine the viability of the muscle and the extent of its soiling. It is especially important to note its color and its response to delicate pinching. Lacerated or contused muscle tissue makes the ideal culture medium for those anaerobic pyogens and gas-forming bacilli which threaten first the muscle group and, later, the entire limb or even the life of the patient.

Primary hematogenous infection of skeletal muscle is rare, because it has a copious blood supply which is principally anastomotic and devoid of the end-arteries that make certain other tissues particularly vulnerable to this method of infection. Muscle will, of course, be involved secondarily in those suppurative infections that arise in the contiguous tissues, as in osteomyelitis, suppurative arthritis, infected open fractures and those abscesses which develop as the result of infected deep perforating wounds.

Skeletal muscle, and particularly the fibrous elements which form its interstitial parts, can be the site of nonbacterial inflammation. This condition is known as fibrositis, myositis, or muscular rheumatism. It may be temporarily acute and disabling and frequently is chronically uncomfortable, but it is not deforming or crippling. It is thought to be a mild variant of the group of collagen diseases, the more severe of which are rheumatoid arthritis, lupus erythematosus and periarteritis nodosa. The diagnosis of fibrositis or myositis should be made only after potentially serious, underlying lesions which produce lumbago, coccydynia, torticollis and pleurodynia have been ruled out. In other words, this diagnosis should not be a "working diagnosis," but rather should be one that is made by exclusion. Fortunately, this type of muscular inflammation responds to simple home measures, such as aspirin, heat, massage and exercise, though many people are

plagued with intermittent symptoms for discouragingly long periods.

Invasion of skeletal muscle by the *Trichinella spiralis* which enters the body by the ingestion of insufficiently cooked pork is occasionally seen. The inflammatory change developing around the encapsulated parasite will produce considerable local pain and tenderness during the acute phase and may, in the chronic phase, weaken muscle tissue and predispose it to rupture. Infections by the *Cysticercus* or by the *Echinococcus granulosus* are much rarer and, in this era, almost surgical curiosities.

Myositis ossificans is another of the inflammations of muscle and is characterized by the laying down of new bone in the site of the hematoma following muscle rupture. In this instance, the rupture may be due to a single major violence or to repeated minimal tears which are said to be occupational in origin, as in the adductor muscles of horsemen. This new bone is the end result of the metaplasia of the connective tissue which invades the hematoma. The process develops in the same basic manner that results in bone deposition between and around the ends of a fracture. The early phase of this condition is characterized by pain and dysfunction in the involved muscle group and, early in the development of the lesion, x-ray examination reveals no abnormality. There follows, in most instances rather rapidly, the development of a spotty or granular appearance in the affected muscle. This goes on to give the typical appearance of solidarity that makes the diagnosis possible on x-ray examination. If superficial, the bony mass may be palpable, but, if deep, its presence may not be suspected on clinical examination and will be seen only on x-ray films. In the x-ray study of such a lesion, it is important that additional tangential views be taken with the usual anteroposterior and lateral ones. This is necessary in order to establish the fact that the bony mass is not connected with the long bone in the affected limb. It is most rare for the ossified area to connect itself with the shaft of the bone, but, if it does so, it then gives the appearance of a benign osteoma. It is not to be confused with those tumors arising in or invading muscle which are capable of laying down new bone.

Excision of an area of myositis ossificans is necessary only when it is of sufficient size to interfere with function, if it is excessively tender or if it jeopardizes major blood vessels and nerves in the area. It is important that the excision be carried out only after interval

x-ray studies show it to be mature. If excision is attempted in the immature phase of the development of this lesion, a recurrence from the operative interference may follow. In the nonoperative management of myositis ossificans, the instillation of hydrocortone or hyaluronidase is an adjunct which may be of value in deterring the formation of bone in the hematoma or of hastening its absorption.

Tumors of skeletal muscle are relatively rare when compared with those arising from the glandular, osseous, nervous and lymphatic tissues of the body. However, there are some, both benign and malignant, which bear mention.

Lipomas arise in the fatty areolar tissue lying between the muscle bundles. Attention is usually called to them by changes in the circumference or contour of the affected limb rather than by any interference with function or by pressure on nerves or important vessels. The x-ray examination discloses a typical density which makes the diagnosis possible. Fat does not absorb the x-rays as they pass through the affected limb and, therefore, the lipoma gives the typical dark circumscribed appearance. It may appear globular if it is small and free or it may be elongated if compressed within fascial planes. In either case, its periphery is sharply demarcated and there is no suggestion of the invasion of contiguous parts.

Fibromas arising in the fibrous tissue between the muscle bundles are not as common as those arising in the subcutaneous fibrous tissue or in the fibrous tissue surrounding glandular structures, for instance, the breast. Here again, attention is called to the lesion because of the alteration in contour. It is usually not painful or tender and generally does not develop sufficiently in size to interfere with function.

Hemangiomas, developing from congenitally abnormal arteriovenous communications, are also found within skeletal muscle. These can be identified by the change in size on elevation and depression in the limb, by the compressibility on palpation if the tumor is superficial enough, by the appearance of calcified flecks within the suspected area on x-ray films and by venography or arteriography.

The acutely painful glomus tumor (myoneuroarterial glomus) has a muscle component but, as a rule, does not arise from skeletal muscle or from its fibrous interstices. Rhabdomyomas, which are the only true tumor-derivative of the muscle cell, are extremely rare and the diagnosis can be made only by microscopic study.

All malignant tumors of muscle and the fibrous and fatty tissue within them are sarcomatous in nature and are accurately identified only by biopsy.

Metastatic tumors are rare, because no tumor has a predilection for skeletal muscle in its vascular or lymphatic spread. However, tumors arising from the elements of bone or those from synovia will invariably invade or compress skeletal muscle in the course of their growth.

Herniation of muscle fibers through the containing fibrous sheath is occasionally seen in the anterior tibial, hamstring and lateral thigh areas. These are seldom capable of producing disability and rarely require surgical repair.

Lesions of attrition involving skeletal muscle and its associated tendon constitute a very important segment of the surgery of the skeletal system; first, because they are so common and, secondly, the nature of these lesions is frequently misunderstood. Normal muscle and tendon tissue will rupture only when subjected to substantial violence and this violence must be a specific stretching force applied longitudinally and with sufficient intensity to be beyond the limits of elasticity of the muscle or the tendon. These structures, because of their mobility and compressibility, can withstand all but the most powerful of direct and lateral forces. This is brought out by the rarity of muscle and tendon ruptures in instances of massive violence, as in falls from heights or head-on collisions, in which the osseous system and the abdominal, thoracic and cranial organs sustain severe damage. The history of most muscle and tendon ruptures suggests relatively trivial trauma, and some degenerative change, either fibrous, fatty or xanthomatous, will be found to exist on microscopic study of the sections taken at the time of repair.

When a powerful young athlete ruptures his plantaris muscle on reaching for a shot in handball, or tears away the rectus femoris origin in starting a dash, or pulls apart his heel cord in making a turn in a downhill ski race, he is not at all appreciative of the diagnosis of rupture secondary to degenerative change. He cannot understand how such would happen in doing something he had done thousands of times before. The answer lies in the disturbing fact that we begin to show signs of wear and tear in our motor skeletal system, as well as in other body systems, much earlier in life than we may think. It has been said that our tissues in general will never be better than ^{at the age} of ten years.

Figure 135. Partial rupture at proximal musculotendinous junction of the long head of the right biceps due to direct trauma. Note the characteristic bulging of the muscle belly

The bicipital tendon in its humeral groove is frequently frayed and will rupture with the slightest provocation. It will also part less frequently at its musculotendinous juncture and, still less frequently, it will be torn, usually by substantial violence, from its insertion on the bicipital tubercle of the radius. The proximal ruptures through the bicipital tendon and through the musculotendinous juncture will in a surprising number of instances cause no great disability and the patient's question will concern the change in contour of the biceps area as compared with the opposite side (Fig. 135). If excessive pain or disability is present, however, satisfactory power can be restored by transplanting the tendon to the coracoid process of the scapula, thus having both heads of the biceps come from the same origin. Or, in instances of lower tears, the muscle belly can be sutured to the humerus at the base of the bicipital groove. The rupture at the point of insertion in the bicipital tubercle of the radius has a much more disabling potential and should be replaced accurately by open surgical methods. Ruptures of the quadriceps muscle or tendon, which usually occur at the musculotendinous juncture or at the tendinosus insertion onto the patella, require open repair and sufficient healing time in the position of relaxation. The Achilles tendon likewise lends itself to end-to-end anastomosis and the results are uniformly good by permitting healing with the foot held in the position characteristic of equinus, thereby relaxing the gastrocnemius group of muscles.

The plantaris muscle and tendon, because it plays a relatively minor role in the action of the calf muscle group, need not be openly repaired and, following the initial pain and disability, it will heal well by keeping the foot in an equinus position, usually by simply having the patient wear an elevated heel.

Those tendons which make up the rotator

cuff of the shoulder and join together the actions of the supraspinatus, infraspinatus, teres minor and subscapularis muscles are frequently the site of lesions of attrition. The tendon cuff and the bursa that lie immediately above them are impinged between the acromion process and the greater tuberosity of the humerus whenever the arm is elevated over 90 degrees. This wear and tear and the danger of subsequent rupture is the price we pay for brachiation. The deposition of calcium salts in the frayed fibers of these tendons is a common occurrence and is one of the common causes of shoulder pain (Fig. 136). When this calcium deposit reaches a size which permits it to irritate the floor of the bursa, acute shoulder disability follows. A complete rupture of this tendon cuff makes it impossible for the patient to initiate abduction of the humerus because the mechanism has been disrupted which ordinarily would stabilize the humeral head against the gle-

Figure 136. Calcification within the tendons of the rotator cuff of the shoulder, producing secondary bursitis in the subacromial bursa.

noid. In the absence of this stability, the deltoid cannot get sufficient purchase to abduct the arm through the first 15 degrees. Open repair of the tendon cuff is necessary when these circumstances exist, but in the relatively minor tears which are one of the common causes of the painful shoulder, operation is not indicated if abduction of the humerus can be initiated.

LIGAMENTS

Ligaments are basically of fibrous tissue structure, modified and strengthened to bind together and support all joints. They yield within the limits of their tolerance as the muscles move the joints or as the joints are moved passively by varying forms and degrees of violence and gravity. Many joints, especially the larger ones, have ligaments which are well defined, can be isolated and identified in the dissecting and the operating rooms and have specific names. Other joints, especially the smaller ones, are supported by blended reinforcement and expansions of the heavy fibrous layer of the capsule and these ligaments cannot, from a practical operative standpoint, be individualized. An example of the former would be the knee with its large and well-defined collateral and cruciate ligaments. An example of the latter would be the many reinforcements present throughout the multiple joints which make up the carpus. Some ligaments are relatively fragile and do not have the support of numbers. They are easily compromised and an example of this group is the fibulotalar ligament of the ankle. Others are heavy and numerous to the point where they will permit no functional motion and an example of this is the sacroiliac.

Ligaments are highly innervated by fibers concerned with proprioception and pain and, because of the latter group, are capable of producing a degree of discomfort and disability beyond what one might expect on the basis of purely local findings on clinical examination. Because of their close relationship with the joints they support, they are endowed with a good blood supply which promotes prompt and efficient healing if the principles of rest and relaxation of the injured structures are adhered to. The ligamentous structure, being basically a fibrous tissue, enables ligaments to reproduce a like tissue in the healing process and, if not permitted to heal in an elongated manner, the healed ligament will function as before.

Because ligaments are so intimately associated with joint structure and function, they have to be involved by association in dis-

eases, infections and neoplasms involving joints. Some injuries, however, may be selective enough to be confined to the ligaments alone, particularly when the ligament is not so intimately associated with the joint capsule, as in the case of the fibular collateral ligament of the knee and the nuchal ligament of the neck. The ligaments supporting a joint will be edematous in acute inflammatory diseases of that joint and thickened in the chronic conditions which affect it. The ligaments will be invaded and destroyed by tumors originating in the contiguous synovial membrane, periosteum or bone. They will be infiltrated, frayed and weakened by the sodium urate crystals deposited in gout, but seldom will the surgeon be dealing with serious conditions arising primarily in and involving solely a ligament.

The surgeon's principal contact with ligaments will be in the field of the surgery of trauma. Two terms used by the profession and the laity now enter this subject and, if used interchangeably, they may be confusing. These are "strain" and "sprain." We should think of a strain as a stretching of a ligament within the tolerance of its tissue. There is no tissue in the body, with the possible exception of adult cortical bone, that does not have some elasticity and yield. But if a persistent effort is made to strain a joint, for instance, to hyperextend the metacarpophalangeal joint forcefully and for several minutes, it will stretch and produce a very painful hand. Yet, on release, comfort will follow and no demonstrable tissue change will have taken place. As another example of strain, let us use the bamboo pole of the vaulter, it may bend to a frightening angle as he ascends to the crossbar, but it shows no gross change when the vault has been completed. It is then used again and again.

A sprain, on the other hand, represents a definite rupture of ligamentous tissue, complete or incomplete. It may or may not permit the joint to dislocate. A sprain is caused by forces of violence which are beyond the limits of the tolerance of the tissue. A gross dislocation of the shoulder, for instance, caused by substantial violence is permitted because the antero-inferior supporting ligaments and the capsule have given way, either in their substance or at the attachment to the glenoid rim or humerus. This exemplifies an extreme form of sprain, permitting actual joint disruption.

Other sprains involving major ligaments may not be so obvious and may be missed unless thought about. ulotalar liga-

ment on the anterolateral surface of the ankle, when it is torn by inversion or adduction violence, will permit the talus to tilt on the distal articular surface of the tibia when the ankle is forced into inversion. This can be demonstrated by x-ray study after local infiltration with Novocain or with the patient under a light general anesthesia. When it is present, it is known as an occult dislocation of the ankle (Fig. 137). Normally, one is unable to change the relatively parallel relationship between the articular surfaces of the tibia and the talus by forced inversion. If such a sprain is not immobilized for from four to six weeks to permit solid healing, ankle instability may result and the patient may then become one who recurrently "sprains" his ankle. Plaster immobilization in a neutral position usually suffices and open repair of this ligament is seldom necessary.

On the opposite or medial side of the ankle is another important ligament, the complete and unrecognized sprain of which can also produce recurring disability. This is the deltoid ligament, so named because of its roughly triangular shape. This ligament is sprained by eversion or abduction violence, the same mechanism that produces the common Pott's fracture. The talus is forced laterally and by pressure against the fibula breaks it, usually an inch or two above the articular surface. If the force is continued, the talus

moves farther laterally and the medial malleolus of the tibia is then pulled off, thus producing the typical bimalleolar fracture. If, on the other hand, the medial malleolus remains intact, then the deltoid ligament will tear, completely or incompletely. Whether the tear is complete or incomplete will be determined by the amount of lateral displacement of the talus, by the condition of the medial malleolus and by the amount of local reaction about the medial side of the ankle. If this tear is thought to be complete, an open exploration and repair should be executed. If this is not done under such circumstances, ankle instability will result and the stage will be set for future development of traumatic arthritis.

A third joint, the ligaments of which are subject to serious sprain, is the knee. The medial collateral or tibial collateral ligament is commonly sprained in twisting injuries and by forces tending to push the knee into a valgus or knock-knee position. Because of its attachment to the medial meniscus, it is likely to be involved, at least in some manner, when this meniscus is torn. However, this ligament can also be completely torn either in its substance at the level of the joint or from its femoral or tibial attachments. When torn completely, the resultant instability of the knee can be demonstrated by an anteroposterior x-ray exposure. If the knee can be

Figure 137. The talus can be tilted on the articular surface of the tibia by forceful manipulation with the patient under general or local anesthesia, indicating a rupture of the fibulotalar ligament. The shadows above and below are the lead gloves protecting the hands of the demonstrator.

forced into a knock-knee deformity of 15 degrees or more, then open repair of this ligament is indicated.

The cruciate ligaments lying within the knee joint are also subject to sprain and strain, particularly the anterior cruciate. It is the function of the anterior cruciate ligament to prevent the anterior displacement of the tibia on the femur and this ligament is taut when the knee is in extension or in mildly flexed positions. For this reason, it is more likely to be damaged than the posterior cruciate ligament which prevents posterior displacement of the tibia on the femur and is taut when the knee is completely flexed, as in the squatting position. The posterior cruciate ligament is seldom torn alone but gives way in complete disruptions of the knee. The anterior cruciate ligament, on the other hand, is not uncommonly torn without other damage to the joint and is frequently associated with tears of the medial meniscus with or without accompanying disruption of the medial collateral ligament. Fortunately, an open repair of the anterior cruciate ligament is not, as a rule, necessary because the quadriceps muscle can be developed by progressive resistance exercises to stabilize the knee and effectively take over the function of the anterior cruciate ligament.

There are dangers inherent in the diagnosis of sprain in certain joints. When applied to the knee, one must be sure there is no underlying internal derangement, such as a torn meniscus, or no disease, such as osteochondritis dissecans. One also must be sure that the patella did not dislocate and return to its normal position spontaneously. When applied to the lower back it must be determined that there is no congenital structural weakness or neurologic evidence of nerve root involvement or early manifestations of rheumatoid spondylitis. The diagnosis of a sprained wrist should not be made until all possibility of a fracture of the navicular bone has been ruled out by x-ray films exposed in oblique positions with the wrist held in ulnar deviation. Such x-ray study should be repeated ten to fourteen days after the injury, as the hairline fracture through the wrist or the proximal pole of the bone may not be seen until sufficient absorption has taken place at the fracture line to widen it. The "sprained neck" can be a unilateral subluxation and the "sprained elbow" can mask an impacted fracture of the radial head. The "sprained hip" can be an impacted fracture of the femoral neck which may come apart after absorption and attempted use.

The diagnosis of "sprain" is used loosely by laymen and doctors alike and the failure to recognize underlying lesions which are part of the sprain picture, or independent of it, will lead to serious diagnostic errors.

BURSAE

"Bursa" is a Latin term meaning purse or pouch. Its plural form is "bursae." Bursae are most important in the musculoskeletal system and there are literally dozens of them. They are sacs containing a small amount of lubricating fluid which physically and chemically is the same as joint fluid. It is the same because the bursa is lined with a secretory membrane which, for all practical purposes, is the same as synovial membrane. The outer wall of a bursa is of fibrous tissue inseparably attached to the inner serous surface. Most bursae have but a single cavity, i.e., they are monolocular or unicameral, but the demands of function or the residuum of disease or injury may cause the development of membranes which will divide them into two or more compartments. It is pointless to number the bursae and useless to name them, except for those that are of practical surgical interest.

It has been suggested that we are born without bursae because, in infancy, the physical pressures and frictions of this rather passive phase of our existence are not great enough to warrant lubrication other than that provided by the joints. Certainly, babies in the crawling stage do not develop prepatellar bursitis or housemaid's knee, presumably because there is no prepatellar bursa at this stage in life. At any rate, the bursae either are formed or develop from a basic potential structure in response to the demands which are put upon the involved areas. During the course of human growth, bursae develop at all points where any appreciable friction or motion exists. They are found where muscles and tendons must work around corners, where muscles cross to work in opposite directions and at those points between the skin and the underlying bone where frequent pressures and frictions are exerted. They are actually only potential cavities and under normal conditions are collapsed so that the serous surfaces are in contact. They are usually attached above and below and the gliding mechanism is achieved much like moving the palms of the hands back and forth with a collapsed lubricated balloon interposed. The rubber surfaces move on each other while the palms are adherent to the outer surfaces. In order to glide, there

must be a certain amount of redundancy in the bursa so that in some positions one surface will be taut and the other in folds. We know that in certain areas of the body adventitious bursae develop and are well known for the lesions they produce. They develop in response to structural change or to the need for additional protection to a part. Perhaps the best known of the adventitious bursae is that occurring on the medial side of the first metatarsophalangeal joint in association with a bunion deformity. The pressure and friction of the shoe are responsible. An ill-fitting slipper may cause a bursa at the back of the heel and a bursa may form over any arthritic outgrowth on the dorsum of the foot where the tongue and the lacing of the shoe constantly press against it.

Bursae can be the site of local infection or injury and they can be involved in systemic disorders. The superficial bursae are most likely to be injured by direct violence, either by a single substantial blow or by repeated minor traumas. Examples of this are the chronic swelling of the prepatellar bursa in front of the knee—housemaid's knee; that over the tip of the olecranon process—miner's elbow, and that over the ischial tuberosities—tailor's bottom. The superficial bursae are also the most likely to be involved in puncture wounds and, if infection intervenes, a true suppurative bursitis will result.

The deeper bursae are inaccessible to the usual direct violence and are more likely to become inflamed from chronic strain or a wearing and fraying process in the tendon tissues contiguous to them. This, for instance, is the most common cause of pain arising from the subacromial bursa in the shoulder and the trochanteric and iliopectineal bursae about the hip. The irritation produces hyperemia and causes the development of an effusion within the closed sac and it is this tension which can be so excruciatingly painful.

The diagnosis and treatment of bursal conditions is based upon the same orderly concept as that of any other tissue. We may list the various types of involvement, such as congenital, infectious, neoplastic, metabolic, traumatic and atrophic.

The congenital category is not an important one because there is a possibility that bursae are either absent or only potentially developed during the period of infancy. From a surgical point of view this may be helpful in a negative way because the possibility of a primary bursal lesion can be ruled out during the adult and infantile periods.

Bursae can be infected by perforation and contamination and subsequently involved in cellulitic processes, abscess formation and local gangrene, as can any other soft tissue. The bursae may be invaded by the spread of infection from a contiguous tissue and, in theory at least, they can be involved by hematogenous infection. Primary tuberculosis or tuberculous involvement of a bursa by any means is not common, but a bursa may be involved in tuberculous infection if it lies adjacent to an involved bone, joint or tendon sheath. The nonbacterial inflammations, such as rheumatoid disease, frequently involve bursae because they have a predilection for synovial surfaces. Hypertrophic villous bursitis of unknown cause does occur and this may result in the formation of rice bodies and, later, in the osteochondral foreign bodies which are also seen in joints (Fig. 138).

Tumor formation is not common in bursal tissue in the primary phase and there is no tumor that has any special affinity for bursal metastases. Like all fibrous tissue, the outer wall of the bursa can undergo sarcomatous change and a fibrosarcoma can originate there. Also, the highly malignant synoviomas can have their origin from the serous lining of a bursal sac just as readily as from the serous lining of a synovial surface.

The outstanding metabolic disease with a predilection for bursal involvement is gout. Gout causes the deposition of crystals of so-

Figure 138 Osteochondral foreign body in the bursal sac. The foreign body was present throughout the lining.

dium urate in the synovial lining of joints, bursae and tendon sheaths. The amount of this urate may be so great as to destroy the structure by pressure, followed by rupture and invasion of the contiguous soft tissues. It is not uncommon for a superficial bursa, such as the olecranon or prepatellar, to be filled with solid crystals, and occasionally it will rupture and drain and become secondarily infected.

The management of bursal disease will be dictated by the nature of the involvement and the location and will range from simple advice as to home remedies to amputation of the limb of which the bursa is a part. The milder forms of superficial bursitis have a strong tendency toward spontaneous recovery with or without the help of rest, protection and moist heat. Usually the olecranon and the prepatellar types will regress with one or more aspirations and the application of a pressure dressing. The instillation of 1 cc. of hydrocortone within the sac after aspiration is also an established method of treatment because of the local anti-inflammatory properties of this drug. In the chronic stage of bursitis, however, in which the hypertrophic villus formation has taken place, pain will be present on pressure and a crepitant sensation will be obtained on palpation of the involved bursa. Such a bursa should be excised. Most patients will ask about the function of the extremity without the bursa and they should be told that a new one will form in response to the demand. Excision is also the treatment of choice in those bursae containing chondral or osseous foreign bodies or a gouty mass which threatens to rupture and become secondarily infected.

Substantial enlargements of the anserine bursa on the medial side of the upper tibia between the collateral ligament of the knee and the gracilis and semitendinosus insertions will have to be excised because of pain and interference with knee function. In the milder forms of this type of bursitis, multiple needle punctures, using 1 per cent Novocain and 1 cc. of hydrocortone, will decompress the bursa and bring relief. When the bursa is small it is difficult to actually aspirate material from it, but the excess fluid can be dispersed into the surrounding tissues by the needle punctures and it will ultimately be absorbed. Affections of the greater trochanteric bursa at the insertion of the gluteus maximus muscle and the lesser trochanteric bursa at the insertion of the iliopsoic muscle can be treated in a similar way.

The bursal lesion which will receive the most attention, however, will be the subdel-

toid, or subacromial. This is located immediately superficial to the rotator tendon cuff of the shoulder and it usually extends from an area just distal to the tuberosities to a point about 1 inch under the acromion process of the scapula. It lies on the tendon cuff and is covered distally by the deltoid muscle and proximally by the coracoacromial ligament which forms the roof of the humeral-scapular joint. Because of the proximity of the long tendon of the biceps muscle and its sheath within the bicipital groove, lesions of this structure must be kept in mind in the differential diagnosis of bursitis of the shoulder. The inflammatory process involving this bursa is usually not primary, but is secondary to a fraying or a lesion of attrition of the tendon cuff beneath it. Depositions of calcium salts in this cuff are common, whereas deposition in the bursa is rare and occurs only when the mass of calcium is large enough to rupture out of the tendon and through the floor of the bursa. The inflammatory process binds the bursa and the cuff together and thus makes such a change in the position of the calcium possible. Further adherence between the bone, tendon, bursa and deltoid muscle leads to a gradually developing restriction resulting in the so-called frozen shoulder.

Open surgery is occasionally indicated to remove large calcific deposits after the usual conservative measures have failed. However, the needling procedure and instillation of hydrocortone usually decompress the "chemical boil" and relieve the intense pain. The lower grade forms of bursitis in the shoulder will respond to heat, analgesics and stretching exercises designed to overcome the limited motion. X-ray therapy has its enthusiasts when bursitis is in the acute stage, but most agree that in the chronic state, with an associated fraying in the tendon cuff, this type of treatment will not be effective. This is particularly true if night pain and restricted motion are featured.

In dealing with the painful shoulder, it should be remembered that the mere presence of calcium in the rotator tendons does not necessarily mean that bursitis is present. Such calcium deposits are commonly seen in the routine chest films of patients without symptoms and so long as they remain deeply embedded, not involving the gliding surface of the tendon or bursa, they will be clinically silent.

No examination of the shoulder is complete without attention to the cervical spine. Tests to disclose the presence of reflex, motor, sensory or tro-

terations in the color, temperature, pulse and perspiration phenomena in the upper extremities, should always be performed. The shoulder pain, instead of being primarily about the joint, may be referred from the cervical spine. Degenerative arthritic change, protrusions of intervertebral disk material, tumors, tuberculosis and congenital anomalies are conditions which may simulate shoulder inflammations.

Acute and Chronic Infections of the Bones and Joints

By FRANCIS M. McKEEVER, M.D., JOHN C. WILSON, JR., M.D., and FRANCIS E. WEST, M.D.

FRANCIS MICHAEL McKEEVER is a native Californian and received his education at the University of California. He was Chief of Orthopedic Surgery at the Army's large Percy Jones General Hospital during World War II. He serves as a senior orthopedic surgeon at the Children's and Los Angeles County Hospitals and teaches at the University of Southern California where he is Professor of Orthopedic Surgery.

JOHN CREE WILSON, JR., has followed in his father's surgical specialty. Also a native Californian, he was educated at Stanford University and Harvard Medical School. He is associated with Doctor McKeever in the Department of Orthopedic Surgery at the University of Southern California.

FRANCIS EDWIN WEST is a native California who impartially claims both the University of California and the University of Southern California as his alma mater. After a short sojourn at the University of Michigan, he returned to San Francisco to further his orthopedic surgical training. Following World War II, in which he carried on his work as an orthopedic surgeon, he returned to San Diego where he practices his surgical specialty and has charge of the orthopedic section of a hospital for tuberculous patients.

Suppurative bacterial infection in bone is called osteomyelitis. Osteomyelitis in its strict interpretation signifies an inflammation of the marrow cavity only, but by general usage

through the years this term has come to signify an inflammatory reaction in any or all parts of bone tissue. The term *periostitis* is used to designate specifically a pathologic

process which manifests itself by the production of increased bone immediately beneath the covering membrane and does not involve cancellous bone. It may be noninflammatory and is often the manifestation of neoplastic disease or a blood dyscrasia. It also results from a granulomatous infection such as syphilis.

Infection in bone occurs in two ways. The pathogenic organisms may be brought to the bone through the blood stream. When this is the method of infection, the bone disease is known as *acute hematogenous osteomyelitis*. Organisms may be introduced directly into a portion of the bone by a disruption of the soft tissues covering a part of the skeleton. This occurs with a compound fracture or perforating wound, when exposed bone becomes directly contaminated with bacteria. This type of bone infection is called *exogenous osteomyelitis*. A more descriptive designation is *osteomyelitis due to direct contamination*. Hematogenous osteomyelitis and osteomyelitis due to direct contamination have a different pathogenesis and are diseases with different manifestations, different prognosis and involve different surgical principles in their management.

Acute hematogenous osteomyelitis, promptly diagnosed and properly managed, has changed over the past twenty years from a malignant disease to a relatively benign illness. Since the advent of chemotherapy and antibiotics, the clinical course, sequelae and prognosis of bone infection from bacteremia have been greatly altered. Prior to 1937, acute hematogenous osteomyelitis was a disease with a high mortality and prolonged invalidism, often resulting in severe crippling and grotesque deformity. Since the development of powerful agents for bacteriostasis and a better understanding of fluid balance, the prognosis of blood-borne osteomyelitis has been markedly improved. Antibacterial drugs, together with better appreciation of basic surgical principles, have also reduced the invalidism and loss of extremities from osteomyelitis due to direct contamination.

ACUTE HEMATOGENOUS OSTEOMYELITIS

Acute hematogenous osteomyelitis is predominantly a disease of infancy and childhood. The highest incidence is in children between the ages of one and ten years. It is seen less often in the first years of life but may occur even in the newborn. Acute hematogenous osteomyelitis is rare in the adult af-

ter closure of the epiphyses and the completion of growth.

Acute hematogenous osteomyelitis is a local manifestation in bone of bacteremia. The infecting organism most commonly recovered from acute hematogenous osteomyelitis is *Staphylococcus aureus* (*Micrococcus pyogenes* var. *aureus*). Next in frequency is *Staph. albus* (*M. pyogenes* var. *albus*) and then streptococcus, either alpha, beta or gamma. However, any pathogenic bacteria may be the causative organism of osteomyelitis. Pneumococci, salmonellae, typhoid bacilli, enterococci and *Pseudomonas aeruginosa* have all been recovered from foci of osteomyelitis. The infecting organism is carried in the blood stream to the bone. The initial focus of infection very often cannot be found, as it is only a minute break in the skin or mucous membrane. At other times there is direct evidence of a portal of entry, which may be a furuncle, an infected crusted abrasion, impetigo, omphalitis in a newborn infant or an abscessed tooth. On some occasions the onset of osteomyelitis is concurrent with or occurs during convalescence from acute tonsillitis, upper respiratory infection, pyelitis, or exanthematous disease such as scarlet fever.

The structure of the normal bone (Fig. 139) explains why hematogenous osteomyelitis is a disease of infancy and childhood. Although bacteremia to some degree is probably present as often in adults as in children, in adults organisms do not localize in bones early, therefore, natural body defenses have an opportunity to bring about the death of the bacteria in the blood stream before localization results. During infancy and childhood, which are periods of rapid growth, the epiphysal-metaphysal junction, where cartilage is being converted to bone, requires a rich blood supply. The arrangement of the blood vessels in the metaphysal area of growing bone is such that it predisposes to the focalization of any bacteria which may be free in the blood stream.

At the line of ossification in the bones of children there is a continuous proliferation of capillaries. The anastomoses between the vessels of the metaphysis and epiphysis result in many arterioles with a blind end. The sum total of this anatomic arrangement is a very slow movement of a very large supply of blood, which almost becomes pooled. This situation presents an ideal condition for bacteria to take tenancy and multiply.

With the lodgment of pathogenic bacteria in bone, there is a cellular response with ex-

ulation and the formation of an abscess. If the immunologic reaction is strong or when bacteriostatic agents are brought promptly to the site of infection, the bacteria may be rendered ineffectual and the abscess will be promptly localized. However, if the bacteria multiply because of weak bodily defenses or late diagnosis and the withholding of antibiotics, the abscesses which form may coalesce and extend, causing destruction and absorption of bone structures. The many microscopic canals in the haversian system are enlarged and eroded, and the products of inflammation extend through them beneath the periosteum. Periosteum in the bones of children is loosely attached to the cortex. The loosely attached periosteum is stripped from the cortex to an extent which is dependent on the pressure of exudate. When the abscess is permitted to persist and extend, the periosteum finally ruptures and the pus decompresses itself into the soft tissues covering the bone. Exudate in the cancellous bone of the metaphysis also forces its way to the epiphyseal junction and at this point soon extends beneath the periosteum. The bone destruction in the haversian canals and the elevation of periosteum deprive the denuded cortical bone of its blood supply so that metabolic processes cease in that portion of bone, which becomes inert, calcified tissue, or dead bone. The dead bone which thus results is termed "sequestrum." Various gradations of this process may result, from a promptly attenuated

microscopic abscess, which may never be demonstrable by any x-ray change, to massive death and complete sequestration of the entire shaft of the bone. The outcome of the initial infection in bone depends on the virulence of the invading bacteria and on the resistance of the individual. The patient's resistance can be immeasurably improved and the virulence of the infection greatly diminished by early diagnosis and prompt institution of intelligent treatment.

The symptoms and signs of acute hematogenous osteomyelitis in infants under one year of age are different from those in children from one year of age to adolescence. Similarly in adults, after epiphyseal closure and completion of bone growth, the symptoms show another pattern. These varying manifestations result from the anatomic differences in bone and the physiologic variations in individuals at progressive ages.

In the newborn, full-term infant, the central nervous system is far from completely developed. Sensibility, though present, is not very acute. Deep muscle and joint sensibility is not highly developed until from eight to ten months after birth, when the infant first tries to stand. In the early months of life, systemic reaction to infection may be sluggish. At birth and for several months following, there is some persistence in the extremities of the intrauterine position of flexion of the trunk with fixed flexion contractures of the hips. In addition, in the bones of infants

Diagram of Localization and Spread of Pyogenic Abscess in Bone

Figure 139 A, Diagrammatic sketch of structure of normal bone. B, Diagrammatic illustration of pathologic changes which ensue in acute hematogenous osteomyelitis.

there is massive pooling of blood in blind infection. At the bone is the periosteum is very loosely attached. Out the metaphysis, an anatomic arrangement which permits the early escape of exudate at the metaphysal-epiphysal junction. These facts make it evident that in an infant it is easy to fail in making an early diagnosis of acute osteomyelitis. The first sign is usually elevation of temperature, which may be marked to 39 or 40° C. or need not be very pronounced. Very shortly after this there appears a swelling of the soft tissues over the part involved which is rapidly followed by a refusal on the part of the infant to move an extremity. Thus loss of function develops. Examination often reveals a flexion contracture of the joint adjacent to the infected bone. This deformity may be hard to determine definitely at the hip because of the persistence of the intrauterine position. Restriction of normal passive motion in the joint is also present and can be determined by comparison with the normal extremity. The evaluation of restricted joint motion in an infant is difficult because of a certain normal amount of rigidity and mass reflex action. The leukocyte count is generally elevated, strikingly so at times, at others only mildly. Roentgen ray examination in the first forty-eight to seventy-two hours of the disease gives little information. From five to seven days after onset of the illness in an infant, x-ray study often shows evidence of bone involvement, but this is very late in the disease and by the time x-ray examination reveals the lesion, the abscess has ruptured into soft tissues. The disease being usually juxtaepiphysal, the epiphysis has already been badly damaged and a

by the time . . . The most frequent localization of osteomyelitis in infants is the upper end of the femur, next most frequent is the lower end and upper end of the tibia, where the hip and knee joints are in jeopardy. The upper extremities, though less frequently involved, are not spared and any bone may be infected. Multiple foci are more common in infancy than at any other time of life.

In children from one year of age to adolescence, bodily reactions are more stabilized, and the central nervous system has reached physiologic maturity. The epiphysal-metaphysal junction has become more resistant to the escape of exudate and the periosteum

more rigidly attached to the cortex in the progress to adulthood. The commonest sites of osteomyelitis in the child up to adolescence are the lower end of the femur, the upper end of the tibia and the upper end of the femur. The earliest symptoms of acute hematogenous osteomyelitis in the child over one year of age are those of infection, which, of course, will vary with the virulence of the infecting organism and the patient's resistance. Although the initial temperature rise may be slight, the disease may at other times be ushered in with a chill and a very sharp febrile rise, which is probably the manifestation of the bacteremia. Vomiting with concomitant dehydration and alteration of fluid and electrolyte balance often occurs. Pain is an early symptom. It is usually constant, severe and aggravated by any motion or jar. The cause of this is the expanding exudate in the bone. When the periosteum ruptures and intrasosseous tension is released, the patient is more comfortable. Examination sometimes reveals an obvious portal of entry for bacteria, such as a furuncle, crusted abrasion or large succulent tonsils. There may be a history of proximate infectious disease, an upper respiratory infection or even an exanthem. Early swelling over the painful area is absent. However, there is an area of definite tenderness to pressure or percussion, which is more easily detected in a superficial bone like the tibia or ulna than in bones covered by bulky muscles. Careful examination will detect it even in the femur. If the focus is juxta-articular, there may be spasm of the muscles about the joint, accompanied by limitation of motion, the adjacent joint being held in a position of comfort by this protective muscle spasm. The knee will be held flexed and the hip in a position of flexion and abduction. The joint even though not invaded by bacteria, is held in a position of discomfort. The knee is in the lower end of the femur.

The white blood cell count is generally markedly elevated, the count possibly ranging from 25,000 to 40,000 cells per cu. mm. of blood. The presence of polymorphonuclear leukocytes is characteristic of pyogenic infection.

Patients with hematogenous osteomyelitis because the bacteremia is most often transient, no organisms will be grown at the time the blood is taken for culture. In the early course of the disease, roentgenograms are of no value except to rule out trauma. The earliest roentgen ray change is an area of vague de-

mineralization in the metaphysis or a punched-out defect at the epiphysal junction. This change is rarely present at seven days and usually not until from ten to fourteen days after the onset of the infection. *For therapy to be effective, the diagnosis must be established long before roentgen ray changes are evident.*

Acute hematogenous osteomyelitis in the adult after completion of growth is a rare occurrence. In such patients the symptom complex has no established pattern. It does not have the same proclivity for localization in the metaphysal area as in the child. Not infrequently the infection is located quite a distance from the ends of the long bones. The disease is rarely fulminating, as in the infant or child. The infection may be ushered in by a sharp rise in temperature with general malaise, but more often the onset is subacute with intermittent bouts of mild fever and a feeling of fatigue and exhaustion. Pain may not be pronounced early but generally becomes established and asserts its character in from ten to fourteen days. It is dull and boring in nature, and often worse at night. Much less distressing than in a child, it may be relieved by simple anodynes. It does not manifest itself strongly until the periosteal covering, which is tightly applied to the cortex, becomes irritated.

Examination most commonly reveals an area of tenderness to pressure or percussion, which can be detected even in those bones well covered by soft tissue. Late in the disease, after an abscess has emptied into the soft tissues, fluctuation may be palpable. However, because of the great resistance of the mature calcified cortex, this may never occur and the abscess may be entirely confined within the bone, which shows enlargement with a very marked thickening of the periosteum. When periosteal reaction is pronounced, it is accompanied by muscular atrophy and the bone enlargement due to periosteal proliferation can be palpated. If the focus of osteomyelitis is juxta-articular there may be a contracture of the adjacent joint due to protective muscle spasm. This contracture is aggravated by activity and relieved by rest.

The number of white blood cells may be increased but usually to only a slight degree. The sedimentation rate is generally elevated. Early roentgen ray examination is unrevealing, it may show nothing even as late as the third week of illness. The earliest roentgen ray change is an area of radiolucency, accompanied by slight periosteal thickening.

Even though changes are far advanced after the disease has been existent several weeks, there is often nothing pathognomonic about the roentgenograms. Roentgen ray changes resulting from infection in adult bone are frequently indistinguishable from those produced by malignant disease or blood dyscrasias. The finding most characteristic of infection is the presence of a definite sequestrum which is only seen very late in the course of the illness. Usually not until after changes are evident in the roentgenogram is acute hematogenous osteomyelitis in the adult diagnosed with certainty. By this time the disease has passed into the subacute or chronic stage. Biopsy of the bone will often be necessary to differentiate the process from neoplastic disease.

Although hematogenous osteomyelitis of the vertebral column and its appendages is rare, its symptomatology is sufficiently different to warrant special mention. The initial signs of infection may be severe; however, the signs localizing it to the vertebral column are so obscure that the first definite evidence of localization may be neurologic. If exudate drains into the epidural space, causing pressure, the neurologic signs will vary with its location in the spinal canal. When the epidural abscess originates from an osteomyelitic focus below the second lumbar vertebra, where the cauda equina and not the spinal cord occupies the canal, there will be nerve root signs and signs of meningeal irritation, but without paralysis. The earliest physical finding is a positive Lasègue sign or spasm of the hamstring muscles, which restricts the range of flexion of the hip with the knee extended. If the abscess originates above the second lumbar vertebra and occupies the neural canal in the area of the spinal cord itself, there may be rapidly progressive transverse myelitis with a sensory level and paralysis. Prompt and early decompression of the spinal canal by laminectomy and drainage is indicated if irreparable cord damage is to be avoided.

The general physical examination of a patient suffering from acute hematogenous osteomyelitis should be thorough and complete. A careful search of the skin may reveal infected cuts or abrasions, crusted papules or follicular infections, which may be the source of entry for the causative organisms. Mucous membranes must be carefully inspected with particular attention being given to the tonsils. Both middle ears should be examined for the presence of infection. The existence of an upper respiratory infection or the prodromal

phase of an exanthematous disease can often be detected by careful scrutiny of the mucous membranes. Auscultation and percussion of the lung fields and a careful evaluation of the heart are important. Abnormal murmurs may suggest endocarditis; the osteomyelitis may be secondary to the embolic seeding. Abdominal distention from alteration in fluid balance or from toxemia will give additional information as to the patient's general condition. An enlarged spleen or liver may indicate a blood dyscrasia, tenderness in the costovertebral angle, kidney infection. Stiffness of the spine may point to perinephric, spinal or meningococcal infection. In an adult, a history of typhoid fever may be suggestive, since, in these patients, bone infection may occur many years following the initial systemic disease, as a result of liberation of typhoid bacilli in the blood stream from a chronic focus.

Local examination of the suspected site of infection should include observation for the presence or absence of swelling. The maintenance of an extremity in an abnormal posture from protective muscle spasm of an adjacent joint often helps to localize the site of infection. The range of motion present in the joints above and below the suspected site of infection and its departure from normal should be determined. Restriction of motion is especially difficult to determine accurately in infants, but if the motion in the suspected joint is compared with that of the normal side, errors will be few. Palpation for sites of tenderness which are present early is very important. Percussion over a site of tenderness will help to verify its location. This part of the examination should be done last in the child, as it is very often so distressing that if done early the remainder of the examination is rendered difficult. The clinical examination yields the most information. Laboratory tests help in verifying clinical findings and in the estimate of the patient's total reaction to infection.

The patient should have an initial red blood cell count, white blood cell count, hemoglobin test and a differential count of the white blood cells. From this information the necessity for transfusion can be appraised and with repeated blood counts the course of the infection can be followed carefully. A blood culture should be made as soon as possible, although the blood may be sterile, as the bacteremia is often transitory. Blood for the culture should be taken when the temperature is elevated and it is best to take two or three samples at different times rather than

only one. The initial sample should be obtained before antibiotic therapy is instituted. Organisms obtained in the blood culture should be tested for sensitivity to antibiotics. Moreover, a culture should be made from

cultures should be obtained. A microscopic examination of the urine sediment indicates findings suggestive of an infection, stool cultures, if enteritis is suspected.

The urine should be analyzed at the initial examination and at least weekly during the acute illness. Acetone in the initial urine may indicate severe dehydration and acidosis. Occasional

indications. The appearance of casts in subsequent urine specimens may forewarn of developing nephritis. Serologic studies on the blood should be made routinely during the initial laboratory survey. These latter findings are of more importance in the adult than in the child.

The roentgenogram records only change in density in bone. In acute osteomyelitis, time is required for the bony structure to be altered by decalcification to the extent that the x-ray film will record these changes. As the bone becomes more mature, a longer time is required for these changes to take place. Consequently, in the initial stages of hematogenous osteomyelitis, the roentgenogram shows no abnormality as far as bony contour and structure are concerned, however, soft tissue swelling and alterations in the soft tissue planes are sometimes of help in localizing the infection, if compared with roentgenograms of the normal side. In the child over one year of age, x-ray study seldom shows bone changes prior to from ten to fourteen days. In an adult, longer periods are required for alterations in bony density. However, it is of great importance to obtain an early x-ray picture of the suspected area to compare with

roentgenograms should be taken at right angles above and below the suspected area should be visualized. A roentgenogram showing no abnormality does not exclude the possibility of acute hematogenous osteomyelitis, if clinical findings warrant the diagnosis.

Any pain in an infant or child, accompanied by tenderness in the region of a bony metaphysis with concomitant signs of infection, should be regarded as due to acute hematog-

eous osteomyelitis until proved otherwise. However, pathologic conditions in the infant or young child which may be confused with acute hematogenous osteomyelitis are many. Scurvy may manifest itself by bone tenderness. Complete examination will usually reveal corroborating evidence, such as ecchymosis or petechiae or both. Bleeding gums are not seen before teeth have erupted, but there may be stomatitis. X-ray examination will show characteristic changes. The plasma ascorbic acid level will be low. Before the age of six months and after the age of eighteen months, scurvy rarely occurs.

Infantile cortical hyperostosis should offer very little difficulty in differential diagnosis, being recognizable by its mild systemic manifestation, the frequent involvement of the mandible and the pronounced soft tissue thickening covering the involved bones. It most often involves the clavicle, scapula and humerus.

Hypervitaminosis A can be differentiated by systemic symptoms that precede it: anorexia, itching and fretfulness of weeks' duration. There is always a history of more than adequate vitamin A intake and the systemic reaction is mild.

Cellulitis may be confused with acute osteomyelitis in an infant or child. At the onset of cellulitis, the signs of infection, pain and tenderness of the skin may be misleading. However, osteomyelitis in its early stages is rarely accompanied by reddening or induration of the skin, which after forty-eight hours is usually pronounced in cellulitis.

Pyogenic infection of a joint may be secondary to osteomyelitis in the adjacent metaphysis. Joint infection, however, is most often primary. Swelling from intra-articular effusion is readily detectable in superficial joints, such as the knee, wrist and ankle. Deep-seated joints, such as the hip, manifest acute infection by marked restriction of motion, extreme pain on motion and pain on palpation, as well as the associated signs of infection. Aspiration of the joint with examination of the synovial fluid will determine whether it is infected.

Rheumatic fever should not offer great trouble in differential diagnosis. The manifestations of this disease are in the joint and not juxta-articular. Usually one or more joints are involved simultaneously or in rapid sequence. Moreover, rheumatic fever is rare in children under four years of age.

Leukemia in an infant or child may manifest itself with acute bone pain and tenderness. The general physical examination will

probably reveal enlargement of the lymph glands or the spleen. The differential blood count should also give helpful information. The crisis of sickle cell anemia may cause acute bone pain and tenderness with subperiosteal hemorrhages, and in a Negro patient it is to be considered as a possible cause of these symptoms. Careful blood study will reveal the abnormal erythrocytes and establish the diagnosis.

In the adult with complete growth and closure of all epiphyses, it is often impossible to differentiate the roentgen ray findings of hematogenous osteomyelitis from those of a malignant bone tumor. The roentgenographic changes in the former so closely mimic those which result from malignant neoplastic disease that exploration and biopsy are the only methods of establishing a definite diagnosis.

The treatment of acute hematogenous osteomyelitis is twofold: prophylactic, or measures taken to prevent the disease, and therapeutic, or treatment of an already established case.

From the prophylactic viewpoint, a certain number of instances of blood-borne osteomyelitis will be prevented if attention is given to superficial cutaneous infections and furuncles. Abrasions should be properly dressed so that they do not become crusted over and retain infected secretions. Furuncles should be drained when localized and not traumatized by squeezing. In the stage of diffuse cellulitis, they should be treated by warm applications and antibiotics, if indicated. Persistent and recurrent acne should be properly treated and eliminated. Tonsillitis and upper respiratory infections should be respected and the child so afflicted made to avoid fatigue and receive proper therapy. Infected and decaying teeth with abscesses in the gums should be removed. Any other persistent haven of pyogenic bacteria, such as persistent pyelitis or an ingrowing toenail, should receive proper care. By elimination of the portal of entry for bacteria, bacteremia may be avoided.

The treatment of acute hematogenous osteomyelitis is both medical and surgical. With early diagnosis and promptly instituted medical treatment, many patients with acute hematogenous osteomyelitis will recover without surgical drainage of bone. *However, medical treatment should not be persisted in to the exclusion of surgical treatment, when there is evidence of pus under pressure in the bone or soft tissues.* These two types of treatment are not antagonistic; they are complementary and the appropriate application of each with

proper timing will produce the best results. The medical phase of the treatment consists of the following procedures: proper attention to the general condition of the patient, with restoration of fluid and electrolyte balance, maintenance of adequate caloric intake, prompt institution of high blood concentration of multiple antibiotics with the broadest possible antibacterial spectrum and maintenance of this concentration until it is possible to determine the specific antibiotic for the infecting organism, at which time this single antibiotic may be substituted, the use of antipyretic measures if fever is inordinately high in infants and children, drainage of any obvious purulent focus, such as a furuncle or crusted abrasion, which is not draining.

Many infants and children, following the onset of osteomyelitis, will be dehydrated and have acidosis. They may have severe anemia, with a low hemoglobin level and red cell count, as a result of destructive activity of the bacteremia on the blood cells. If severe anemia is present, transfusions may be indicated. To combat and rectify dehydration and also supply part of the caloric requirement, glucose in amounts suitable to the patient's weight should be administered intravenously. Potassium, as indicated, may be added to the intravenous fluid. If the child cannot take medication by mouth, vitamin B and ascorbic acid in appropriate dosage may be added to the intravenous fluid. As improvement occurs and the patient resumes oral intake, the intravenous administration of fluids may be decreased or discontinued. An adequate caloric intake with sufficient protein content should be striven for. Protein concentrates may be necessary to accomplish this.

Antibiotics must be administered promptly and continuously if a high blood concentration is to be maintained. Because the invading organism is usually not obtainable for typing as sensitivity, multi-antibiotic therapy should be started as soon as possible to eliminate the possibility that resistant strains of bacteria may thrive. Even though the infecting organism may not be available for culture and typing, the probabilities are 95 to 98 per cent that the invading organism is either *Staphylococcus aureus* or a streptococcus. Unless there is clinical evidence such as enteritis, which might implicate salmonella, or some other clinical fact pointing suspiciously toward an unusual organism as the causative factor, the antibiotics used should be those which are effective against staphylococci and streptococci.

In the light of the present effectiveness of antibiotics, an excellent combination for broad-spectrum coverage against the staphylococcus and streptococcus is erythromycin, oleandomycin or tetracycline with chloramphenicol. Penicillin is no longer the drug of choice because many strains of staphylococci are insensitive to it and allergic reactions to it may occur. Erythromycin should be given in amounts of 30 to 40 mg. per kg. of body weight for twenty-four hours, oleandomycin in amounts of 75 to 100 mg. per kg. of body weight; tetracycline in amounts of 100 mg. per kg. of body weight. The dose of chloramphenicol is 75 to 100 mg. per kg. of body weight. If there is a history of previous therapy with chloramphenicol, this drug should not be used unless there is a failure of clinical response to a combination of the other antibiotics. In the infant and young child, whose cooperation is questionable, and even in the older severely ill child, antibiotics are best given in a continuous intravenous drip.

This intensive multi-antibiotic therapy should be continued until there is definite general improvement and a drop in fever, which will usually result after three or four days of treatment (Fig 140). If the initial blood culture is positive, and an antibiotic

in adequate dosage. When the patient takes medication by mouth, intravenous therapy should be continued for at least three weeks after the patient's temperature is normal to insure bacteriostasis in the bony focus.

If roentgenograms show any bone lesion, antibiotic therapy should be continued for a period of six weeks after the temperature has become normal. While membranous colitis is not a common complication of antibiotic therapy in children, if it becomes necessary to administer antibiotics for weeks, it is well to administer an antifungal drug, either separately or in combination with the antibiotic, to avoid moniliasis.

When marked hyperpyrexia is a feature of the illness, alcohol sponges and an antipyretic drug, such as acetylsalicylic acid in adequate doses, should be used.

Surgical treatment of a possible primary focus of infection has already been mentioned. Any such focus should be insured prompt and adequate drainage. If during the course of the medical treatment of acute osteomyelitis it is reasonably certain that there

is a collection of frank pus either subperiosteally or in the medullary canal of the bone, drainage should be promptly instituted. Surgical drainage should be done with the patient under appropriate anesthesia and, when possible, with a tourniquet on the extremity so that a clear bloodless field may be obtained. The operation must furnish adequate drainage and the incision should be packed with petrolatum gauze to keep it open so that it can granulate from the depths to the surface. When surgical drainage is performed in acute hematogenous osteomyelitis, the incision should not be closed. At the time of surgery, the periosteum should be lifted from the cortex of the bone only to the degree that is necessary to permit removal of enough cortex to produce adequate drainage. The operative procedure should be planned so that there is not wanton stripping of periosteum and so that no unnecessary cortex is removed. Splinting of the joint above and below the operative site will give added comfort in the postoperative period. This can be accomplished by means of molded splints, cast or traction. The stress of anesthesia and surgery should never be placed on a patient who is dehydrated, who has acidosis or who has severe anemia. These conditions can always

be rectified before the patient is subjected to surgery. At the time of the initial surgical drainage in the acute stage of the illness, it is impossible to determine whether sequestration is going to result and, if it does, to what extent. For these reasons, only enough bony cortex for adequate drainage should be removed. Even though pus is found in the soft tissue or immediately beneath the periosteum, a window should always be made through the cortex for drainage from the medullary canal.

The intelligent application of both medical and surgical treatment and the proper timing of well-planned surgery, based on daily complete examinations of the patient, will result in the quickest recovery from acute hematogenous osteomyelitis. Recurrence of the infection and unfavorable sequelae (Fig. 141) will be reduced to a minimum by this program.

A discussion of the prognosis of disease due to bacterial infection should take into account that what is true today may be at variance with the past and may well not hold in the future. The era of chemotherapy and antibiotic therapy in which we now live has rather effectively combated the many pathogenic bacteria which were so devastating to

TEMPERATURE CHART

AGE - 20 mos

Figure 140 Clinical chart to illustrate the medical treatment of acute hematogenous osteomyelitis, with a prompt response when adequate treatment is instituted early. This patient recovered without surgical drainage; roentgenograms three months after illness revealed only minor bone changes.

Figure 141 Drawing of roentgenogram of acute hematogenous osteomyelitis in the fibula of a two-year-old child. Prompt adequate medical treatment was instituted. However, an obvious abscess was not drained surgically. Note the extensive destruction of bone, sequestration and pathologic fracture which might have been avoided by properly timed surgical drainage.

human tissues in the past. With the passage of years, the balance of power between therapeutic agents and the invasiveness and toxicity of pathogens may shift. When this results, the prognosis in acute hematogenous osteomyelitis may be altered.

Today the prognosis in acute hematogenous osteomyelitis varies with several factors: the age of the patient at the time of onset of the disease, the promptness of diagnosis and the adequacy of treatment. In infants under one year of age, acute hematogenous osteomyelitis has some mortality. The death rate is about 5 per cent. In those who survive there is a high incidence of crippling as a result of growth disturbances, resulting from rapidity with which the epiphyses are destroyed by infection. Discrepancies in extremity length and aberrations in directional growth, such as genu valgum, genu varum and radial deviation of the hand, are common. Disruption of the hip joint, with pathologic dislocation, is also a relatively common condition resulting from osteomyelitis in infancy.

agnosis in the infant is often very late in being established. In one well-studied series of twenty-five patients, only seven escaped deformity from epiphyseal damage. In most of those free of deformity, diagnosis was made in the first seventy-two hours of their illness. The mortality rate in children over one year of age and in the adult is extraordinarily low. Death results in not more than 1 or 2 per cent of the patients. When the diagnosis is established in the first forty-eight hours of bone infection and treatment with antibiotics is adequate and continued long enough, 40 per cent of the patients can be expected to experience resolution of the inflammation and recover without surgical drainage of bone, with very little residual change from the normal bone demonstrable in subsequent roentgenograms. An additional group, perhaps 5 to 10 per cent, will recover, but at a later date—from three to six months—and will present a small sequestrum, which will require surgical removal. Complete recovery is usually prompt after sequestrectomy. About 50 per cent of children will have an abscess which requires surgical drainage, even though diagnosis has been early and treatment adequate. A greater number of this group will require a second operation for sequestrectomy.

Although marked epiphyseal disturbance with aberration of growth is less frequent in patients above the age of one year than in those younger, it will occur in approximately 10 per cent of patients. Dislocation of the hip joint does not occur unless the child is deprived of medical observation and treatment is delayed. Massive sequestration of the entire shaft of a bone practically never occurs in patients of the younger age group when diagnosis is prompt and treatment intelligent and adequate. Multiple bone foci are uncommon also when treatment is prompt.

In the adult, after completion of growth and epiphyseal closure, hematogenous osteomyelitis is a rarity, consequently statistics regarding mortality are not available, but death is probably infrequent. Deaths which occur are largely in the group of patients having rare cases of primary fulminating osteomyelitis of the spine, or of a bone of the skull, such as the mastoid process of the temporal bone. Death then results because of a spill of septic material into inaccessible areas. Growth disturbances do not occur in adults and joint destruction is not common, since the localization of osteomyelitis in the adult does not have the same predilection for the ends of bones as in the child.

CHRONIC HEMATOGENOUS OSTEOMYELITIS

Acute hematogenous osteomyelitis occurs in varying degrees of severity dependent on the relationship between virulence of the infection and host resistance. Today, although most patients with acute hematogenous osteomyelitis rarely enter the chronic stage when diagnosis is early and treatment adequate, nevertheless there are a few who, despite adequate early treatment, do not recover promptly but suffer a chronic phase of the disease, characterized by persistent sequestration of bone and continuous drainage from sinuses.

In the acute stage of hematogenous osteomyelitis, the purulent exudate of inflammation extends through the haversian system and out the epiphyseal junction beneath the periosteum to form an abscess and strip the periosteum from the bone. This is accompanied by thrombosis of blood vessels, which causes a loss of blood supply to the calcified cortex and trabecular bone of the metaphysis and death of that portion of the bone deprived of blood. As the acuteness of the process subsides and the patient gains dominance over the invading bacteria, granulation tissue forms beneath the periosteum and in the medullary canal about the devitalized area of bone. This granulation tissue has many osteoclasts, or cells, which remove bone. When given enough time, this osteoclastic granulation tissue demarcates the dead bone from the live bone and at the junction of live and dead bone cuts a ridge. After a sufficient period, the dead bone is actually separated and cut off from the live bone and is completely surrounded by granulation tissue, or sequestered from the living bone. Hence, the separated dead bone is called a sequestrum. The presence of a fragment of dead bone surrounded by granulation tissue in a cavity with rigid walls is conducive to continuous growth of bacteria and results in persistent drainage. A minute sequestrum may ultimately totally dissolve in the exudate or may extrude itself, with cessation of drainage and spontaneous closure of a sinus. If the sequestrum is of appreciable size, its dissolution or extrusion can take place only after years of drainage or it may never occur.

After sequestration has occurred, the elevated periosteum, because of its osteogenetic function, starts a reparative process (Fig 142). On the undersurface of the periosteum over and around the devitalized cortex, new bone is formed which has a blood supply and can survive. This new bone is formed to

replace that which has been lost by sequestration. It is separated from the sequestered bone by granulation tissue and is usually perforated with sinuses, called cloacae, to permit the escape of pus. The new bone formed over the dead bone is called involucrum. The involucrum may and often does form so that it enmeshes the sequestrum or entraps it. Removal of a sequestrum may require sacrifice of a portion of the involucrum. This sequence of sequestration-involucrum formation naturally leads to cavities with rigid bony walls, which cannot collapse even after the escape or removal of a sequestrum. Non-collapsible cavities are a fertile ground for bacterial growth and of themselves are a cause of persistent drainage, even though not housing a sequestrum.

The symptoms of the chronic phase of os-

Figure 142 Drawing of roentgenogram of chronic stage of osteomyelitis of shaft of humerus, with chronic sinuses, large involucrum and multiple sequestra.

teomyelitis are few, provided drainage is constant and adequate, that is, provided the sinuses are open and permit exudate to escape. When a sinus closes so that exudate is retained, pain will result and all the signs of inflammation, consisting of swelling, local heat and elevation of temperature, may follow. Leukocytosis and anemia may occur if retained infection is not relieved.

A patient who has very extensive sequestration involving all or most of the shaft of a long bone, with drainage which is adequate to prevent an acute reaction but inadequate to drain the involved area completely, may show signs of chronic infection. The large focus of infection may produce elevation of temperature, sweats, loss of weight, weakness

rate. Unrelieved chronic infection of this type leads to cloudy swelling of parenchymatous viscera and, if allowed to persist indefinitely, may result in amyloid disease. The cloudy swelling of the parenchyma of the kidney may give rise to albumin and casts in the urine.

The patient presenting chronic draining sinuses following hematogenous osteomyelitis should be subjected to a general physical examination to determine his physical condition and to ascertain whether there is evidence of infection elsewhere. This individual, being a patient who at some time or other has had bacteremia, may have other sites in which there have been metastatic foci. He may have an infected genitourinary tract or an encapsulated pleural effusion. The initial source of bacteremia, such as an alveolar abscess or badly infected tonsil, may still be present. The condition of the genitourinary tract, the cardiovascular system and the lungs should be evaluated. Chronic infection may produce severe depletion of the red cells, the hemoglobin and the plasma protein, which would interfere with wound healing under the most favorable circumstances.

Complete and thorough x-ray study of the involved bone should be made. X-ray films should be exposed in at least two planes at right angles to each other. Oblique projections may be indicated when conventional anteroposterior and lateral views do not give the desired information. If there is very dense, extensive involucrum, it may be desirable to take films with an increased degree of exposure to penetrate the involucrum and identify sequestra.

Examination of the sinus by insertion of a

flexible steel probe or catheter may give valuable information. A small sequestrum which the x-ray study will not disclose may often be discovered by this means. Small sequestra of this type can be felt with a probe and occasionally extracted from the sinus. Such an examination also determines the direction in which a cavity or sequestrum may extend in relation to the mouth of the sinus. Roentgenograms made after the injection of a radiopaque material, such as Lipiodol, inserted into the sinus through a catheter, will give information about the architecture of the problem which is not evident in conventional x-ray films.

The object of treatment of the chronic stage of hematogenous osteomyelitis is to terminate drainage from sinuses by restoring the bone to as nearly a normal state as possible. This is accomplished by the following procedures: removal of sequestra, preservation of the involucrum, obliteration of all non-collapsible cavities with rigid walls in the bone in order that they may fill from the bottom with healthy tissue, and obtaining good soft tissue coverage for the involved bone. Antibiotics have their place in accomplishing this end, but no antibiotics can remove sequestra or obliterate noncollapsible cavities. To use them to accomplish this not only wastes good drugs, but unnecessarily depletes the patient's resources and wastes his time. Antibiotics are nevertheless a valuable adjunct in the treatment of this stage of the disease. Their function is to work in conjunction with intelligent well-planned surgery. They should be used preoperatively for a short time to protect the patient against dissemination of bacteria incident to the surgery; they should be used in the postoperative period to hold in check any increase in virulence the bacteria may gain at that time. After the operative site presents no evidence of infection and the patient shows no systemic signs of it, these drugs have served their purpose.

Operation in the chronic phase of hematogenous osteomyelitis should be deferred until a reasonable estimate of the amount of bone that may sequestrate can be made. Operation does not need to be deferred until sequestration is complete, as this may lead to undue invalidism. Good roentgenograms, properly interpreted, will outline the extent of devitalized bone long before the sequestrum is completely separated. At this time, when the bone is exposed, a definite demarcation will be seen. The dead bone appears ivory-like and the live bone pink and is etched

line or groove between the two areas. At the time of surgery, as little attached periosteum as is required to accomplish the proper exposure should be lifted. Unnecessary stripping of periosteum from the cortex may lead to further devitalization of bone and progressive sequestration. Involucrum may have to be sacrificed to free a sequestrum which is incarcerated in its meshes. This should be done with as little sacrifice of the new bone as possible. After the removal of all sequestra, any cavity with rigid walls and undercut

shelving or roofing edges should be obliterated so that there is a gentle slope from the superficial edge of the bone into the bottom of the cavity. A well-sculptured cavity can be completely filled from the bottom by blood clot, which gradually turns to fibrous tissue, thus obliterating dead space. Cavities in bones which are well covered by muscle can be filled by pulling vascular muscle flaps directly into them. When the infected bone presents multiple-roofed cavities rather than a single cavity, the removal of bone should

Figure 143. Drawing of femur showing entire bone, multiple cavities, and soft tissue.

be planned so that all or several small cavities are converted into the fewest possible large exenterated areas.

After removal of sequestra and creation of a bony cavity which has no overhanging roofing edges or noncollapsible tunnels, the decision must be made whether to close the soft tissues over the bone or to place a petrolatum pack in the wide-open wound and permit the cavity to granulate from the bottom to the surface. This is a decision which requires experience and judgment. By and large, it is safer to leave the cavity open for drainage. However, in certain selected cases more rapid convalescence may be effected by immediate closure of the wound. Certain principles to follow in making this decision may be suggested. An area extremely contaminated by much gross pus is safer when left open. The soft tissues must be adequate, well vascularized, flexible and must fall easily into the cavity. It is futile to obliterate a cavity with inflexible avascular scar. Consequently, immediate closure should be restricted to those bones well covered by good muscle. It is rarely applicable to the subcutaneous area of the tibia, where chronic osteomyelitis so frequently occurs.

After completion of the operation, the extremity should be immobilized in a splint or cast to insure physiologic rest. When the incision has been closed primarily, this immobilization should be continued until it is soundly healed. When it has been left open, the use of the cast should be continued until healthy granulations approach the surface of the wound. The dressings and casts may be changed at intervals so that odors from drainage do not become offensive.

The prognosis for the termination of drainage and the restoration of good function depends on the extent of the pathologic process present and on the degree to which the involved bone has become sclerotic and avascular (Fig 143). Generally the prognosis is good and most cases of chronic osteomyelitis can be terminated with cessation of drainage and restoration of a good extremity. When much ivory-like avascular bone is present and large segments of soft tissue have been replaced by avascular scar, closure is sometimes impossible because of the diminished ability of the bone to resist bacterial invasion. At other times the architectural

tual operations foredoomed to failure. However, amputation should not be resorted to until at least one attempt has been made to terminate drainage by surgery, which will give an accurate knowledge of the status of the bone. With prompt, adequate and intelligent treatment of the acute phase of hematogenous osteomyelitis, amputation is becoming less frequent than it was formerly.

OSTEOMYELITIS DUE TO DIRECT CONTAMINATION

Osteomyelitis due to direct contamination is a suppurative infection which results from the direct introduction of pathogenic bacteria into a localized area of bone. Its development necessitates a break in the soft tissues covering the bone. Unlike hematogenous osteomyelitis, the bacteria are not brought to the bone through the blood stream and lodged in areas of sluggish circulation. True, bacteremia may result, but when this does occur, the bacteria gain access to the circulation and are fed to it from the localized osteomyelitis or concomitant infection of soft tissue enveloping the area of bone infection. The patient suffering from osteomyelitis due to direct contamination may and often does show the systemic signs of infection.

The commonest cause of osteomyelitis due to direct contamination is a compound fracture, in which the broken bone emerges through the skin or the soft tissue covering the fracture is perforated or crushed. There are other causes such as contamination at surgical operations, infection from metallic appliances used for skeletal traction and internal fixation, such as Kirschner wire, Steinmann pin, bone plates, screws and metallic rods for intramedullary fixation of bones, and perforating wounds. A perforating wound seldom results in osteomyelitis unless the periosteum or the cortex of the bone or both are disrupted. Intact bone, covered by periosteum, has great resistance to pathogenic bacteria, a normal bone may even be bathed in a large active soft tissue abscess for a long time without being invaded by bacteria. Bone surrounded by an abscess may become demineralized and lose radiographic density as a result of the inactivity of the patient and local increase in circulation. This radiographic change should not be misinterpreted as due to osteomyelitis. The exception to this occurs in the distal phalanges of the fingers. In the pulp of the finger, there exists an anatomic arrangement found nowhere else in the body. A small fragment of bone is encased in

such circumstances, amputation of an extremity is indicated as being preferable to multiple ineffec-

an unyielding closed space. The blood supply to the area is vulnerable to pressure so that swelling and edema will produce ischemia and necrosis of the bony phalanx. Subsequent to necrosis, the phalanx is easily invaded by bacteria. This is the sequence of events in a felon of the distal closed space of the finger when drainage is delayed.

The pathologic anatomy of osteomyelitis due to direct contamination is different from that of hematogenous osteomyelitis. The pathology of the former varies with both the causative factor of the infection and with the bone in which it is located. The principal differences are, first, that the bacteria are not being fed to the infected area from the circulation, second, there is not an expanding area of infection within a rigid structure which must burrow its way to drainage by destruction of bone and elevation and rupture of the periosteum, since the exudate, because of the pathogenesis of the disease, has easier access to exterior drainage through the channel by which the infection was introduced, third, there is not the same tendency to extensive thrombosis of blood vessels and devitalization of bone.

The pathologic anatomy varies in degree and extent with the factors and condition leading up to the implantation of the bacteria. In osteomyelitis due to direct contamination which results from a compound fracture, the most common cause, conditions may vary widely from a small perforation of the soft tissues to extensive laceration and bruising of the overlying muscles and skin. The bone may be broken into only two major fragments with little stripping of periosteum or it may be extensively comminuted into many fragments. The periosteum may be widely stripped and lacerated. In the latter circumstance, some bone may be deprived entirely of its vascular supply. More bone, although not totally deprived of blood, may have its vascular supply compromised. Bacteria introduced into such a locus may be brought to a state of submission if bodily resistance and therapeutic help (antibiotics) are promptly brought to the infected site. Or the bacteria may multiply and suppuration result, dependent to a greater or lesser degree on the relation of bodily defenses and virulence. Fortunately exudate travels along lines of least resistance. It can find its way out through the same channels by which the bacteria were introduced if wounds have not been closed too tightly. Even though drainage is promptly established and the exudate permitted to escape, devitalized bone with a

deficient blood supply cannot entirely rid itself of bacteria and in itself acts as a foreign body to perpetuate exudation. In the presence of devitalized bone, even after the virulence of invading bacteria has been neutralized, drainage tends to continue as granulation tissue carries on its efforts to dissolve dead bone. Consequently chronic draining sinuses result. New bone may form around the dead bone and union of the fracture may result or reparative osteogenesis may be interrupted and only fibrous union or even non-union of the fracture may occur.

When osteomyelitis results from the entrance of bacteria with wires or pins used for transfixing the skeleton, the sequence of events is the same, but because there is little or no devitalized bone, the manifestations are milder. Pins for traction are placed through an area of cancellous or trabecular bone such as the lower end of the femur, upper tibia or os calcis (Fig. 144). The organisms multiply in the cancellous bone and produce necrosis of the trabecular bone to varying degrees, with or without the formation of a sequestrum. Fortunately, spontaneous drainage results easily and early along the pin tract and is facilitated by removal of the pin. No great intraosseous pressure is established and thrombosis of vessels is not extensive. Little bone is destroyed. The end result is often a small noncollapsible cavity with rigid walls which houses granulation tissue and a small sequestrum. The small opening through the rigid cortex provides inadequate drainage for the abscess and a chronic sinus results. The abscess is analogous mechanically to a compression chamber. At other times, a small ring-shaped piece of bony cortex will sequestrate about the pin where it perforates and grips the cortex. The ring sequestrum acts as a foreign body and drainage continues until it is removed.

When infection complicates the insertion of a large metallic rod into the medullary canal of a long bone, the indication for the intramedullary rod is practically always to immobilize a fracture. The area immediately adjacent to the fracture site is the most traumatized and, because of this, the most deficient in circulation. At this site, the least resistance is offered to the multiplication of bacteria. Fortunately this is the site at which exudate can most easily escape into the soft tissues. The inflammatory process generally localizes itself at the site of fracture. However, the abscess or granuloma often extends a considerable distance up and down from the fracture site in the medullary canal and

Figure 144 Drawing of roentgenogram of osteomyelitis of femur, with large sequestrum, involucrum and infected screw channels resulting from direct contamination. This followed open reduction and internal fixation of a closed fracture.

infection may spread through the entire medullary canal. After the systemic aspect of the infection has subsided, the presence of the metallic foreign body tends to call forth an inflammatory reaction in the medullary canal with the formation of a granuloma and foculated abscess. Sequestration is ordinarily confined to the area in proximity to the fracture. Drainage from sinuses continues until the metallic foreign body is removed. The same is true of metallic screws and plates. A granuloma will form about them and inflammation will not subside as long as the metallic objects remain in the tissues.

Treatment of osteomyelitis due to direct contamination involves two phases: prophylactic measures and treatment of established disease. The greatest opportunity to prevent infection of bone presents itself in the management of compound fractures. Such a fracture is an emergency of the highest degree and definitive treatment should be rendered as soon as a patient's general condition will permit the use of anesthesia. Débridement must be painstaking and thorough and internal fixation should be avoided if possible. Great judgment must be used in making the decision to convert a compound fracture to a simple fracture by primary closure at the time of initial débridement. Closure should not be done if there is any lack of good soft tissues which would be put under tension by suture. If the locale and extent of injury point to a high probability of infection, the fracture should be drained through the open wound and a delayed secondary closure should be substituted for primary closure. Broad-spectrum antibiotics should be administered promptly in adequate dosage.

In elective clean surgery, the skin in the area of incision and in the line of lymphatic drainage must be absolutely free of any semblance of infection. Tissues must be handled with gentleness during operation to prevent unnecessary trauma. Good hemostasis should be effected and the soft tissues must never be approximated under any tension.

To avoid bacterial contamination of bone in the use of pins and appliances for skeletal transfixion, the same requirements for skin perfection are necessary as in clean elective surgery. Pins for skeletal fixation and traction which extend out of the skin should be so applied and the dressing so secured that in carrying out their function they are not permitted to slide back and forth through the bone. Dressings should be applied in the operating room, should be sealed and should not be changed until the pins are removed. Constant change of dressings results in contamination. The use of antibiotics should not be necessary for skeletal transfixion in closed fractures.

Most instances of established osteomyelitis due to direct contamination result from compound fractures. If a compound fracture has been closed primarily, both the patient and the wound must be observed assiduously for any evidence of developing infection. At the first sign of infection, stitches should be removed to permit drainage of exudate. This simple procedure will often prevent the bacteria from gaining a foothold. The drainage

must be promptly cultured and the sensitivity of organisms to drugs determined so that the most effective antibiotics can be used. Once there is definite evidence of bone infection, adequate drainage must be maintained so that there is no retention of exudate. If the condition becomes chronic and a draining sinus continues, certain principles should be followed.

Adequate time should elapse between the infection and any definitive surgery so that the extent of bone involvement can be determined and, when a fracture is present, to permit the formation of sufficient involucrum or callus to give some stability to the fracture site. As a rule, this requires ninety to 120 days and can be demonstrated in good x-ray pictures. Clinical examination will determine the solidity of the fracture.

Appropriate systemic therapy should be instituted so that humoral conditions are conducive to wound healing. Transfusions and high protein intake may be indicated prior to definitive surgery so that the wound healing will be at a high potential.

Appropriate antibiotic therapy should be instituted twenty-four hours prior to definitive surgery and continued as long postoperatively as is indicated by the condition of the patient and wound.

At the time of surgery, all sequestered or potentially sequestering bone should be removed, leaving no shelving or roofing edges to trap infection.

Any and all foreign metal which may be in the draining area should be removed.

If the cavity thus created can be closed, it should be.

flexible vascular soft tissue is not available but only rigid ischemic scar tissue is available, the bone cavity should be left open, packed with petrolatum gauze and permitted to granulate from the depths to the surface.

Physiologic rest of the wound should be carried out for an adequate time postoperatively by immobilizing the joint above and below the wound in a cast or splint.

In many instances, the drainage from osteomyelitis by direct contamination will terminate spontaneously in a reasonable time if adequate drainage is maintained and the invading organism is sensitive to an antibiotic or chemotherapeutic agent. This, of course, does not hold when there are conditions of sequestration, noncollapsible cavities with rigid walls or deficiency in soft tissue coverage. Even when the above deleterious situa-

tions are present, the drainage resulting from osteomyelitis due to direct contamination can be terminated if sound surgical principles are followed. It may at times be necessary to have prepared a good pedicle skin graft for use in the final closure to accomplish a satisfactory end result.

When osteomyelitis is associated with a compound fracture, the fracture may fail to unite. Infection is the commonest cause of nonunion and bone defects. In patients with large bone defects and nonunion, bone grafting may be required to produce union. Bone grafting procedures in a previously infected operative field are many times complicated by recurrence of the infection and failure of the bone graft. This is especially true if there has been extensive scarring so that bone grafts cannot be surrounded by well-vascularized muscle and covered with soft flexible skin. Because of the failure of union of the bone with a large hiatus after osteomyelitis due to direct contamination, some extremities will require amputation, despite the fact that the drainage from the initial osteomyelitis can be terminated.

PYOGENIC INFECTION OF JOINTS

The term "pyogenic infection of a joint" means the invasion of a joint by pathogenic bacteria which induce a suppurative reaction in the tissues of a joint. Suppuration in a joint is also termed "pyarthrosis" and is sometimes referred to as empyema of a joint. Most joint diseases are the result of nonspecific nonbacterial insults rather than bacterial invasion. However, the effect of suppuration in a joint is so rapidly destructive to the tissues comprising the mechanism of the joint that it is imperative to recognize promptly and treat adequately a pyogenic joint if function is to be preserved. Treatment of most of the nonbacterial joint affections is not specific and the destruction of tissues is less precipitous than it is in a suppurative joint. Consequently the necessity for prompt and efficacious treatment is not so demanding.

Acute pyogenic infection of a joint is uncommon. Such infections represent less than 2 per cent of all joint disease. The condition is more frequent in infants and children than in adults. It is also more frequent in males than in females. The hip and knee are the joints most frequently involved. Bacterial invasion of joints may occur by three routes: hematogenous infection, direct extension and direct contamination.

The infection may be hematogenous, in which case the bacteria are carried to the

joint and implanted in the joint tissues by the blood stream from a site of infection elsewhere in the body. This mode of infection necessitates bacteremia.

In direct extension of infection, a suppurative focus immediately adjacent to the joint ruptures into the joint cavity, implanting pathogenic bacteria which activate an inflammatory reaction in the joint tissues. This cause of joint infection is most often seen as a complication of osteomyelitis. In certain locations, particularly in the upper femur, the initial focus of osteomyelitis may be within the capsule of the joint. Consequently, when the bone abscess escapes the confines of the cortex and periosteum, it empties bacteria directly into the joint.

A joint may become infected by direct contamination. This may result from an accidental wound with direct implantation of pathogenic organisms or foreign material into a joint cavity. An infection may also be caused by diagnostic or therapeutic paracentesis of a joint. With the increasing use of intra-articular injection of therapeutic agents in the treatment of nonspecific joint disease, this may more often be a cause of direct contamination of a joint. Strict asepsis must be observed in joint aspirations or injections to avoid contamination.

The bacteria most frequently found in a suppurative infection of a joint are the staphylococcus and streptococcus. Some type of these two organisms is the cause of 95 per cent of pyogenic joint infections. *Gonococcus*, *pneumococcus*, *meningococcus*, *Escherichia coli* or *Shigella dysenteriae* is found occasionally to be the etiologic organism in an infected joint.

A joint is made up of two or more bones, bound together at their cartilage-covered ends by a sheath of dense connective tissue. This sheath of dense connective tissue is attached to the bones and constructed in such a way that it produces stability of the opposed cartilage-covered ends of the bones and yet permits mobility. The inner surface of the intra-articular portion of the connective tissue capsule is lined by a specialized tissue termed "synovial membrane," creating a closed cavity (Fig. 145). The synovial membrane is connective tissue which is modified in structure and function. Through the synovial membrane, a fluid dialyzes and enters the joint to lubricate the articular cartilage on the ends of the bones. The specialized synovial membrane produces mucin, which is added to the dialyzed synovial fluid. This increases the viscosity of the synovial

Diagram of Structure of Joint

Figure 145 Diagram of joint, illustrating relationship of articular cartilage, which is avascular, and highly vascular synovial membrane

fluid within the joint. The synovial fluid, except for the addition of mucin, is a dialysate of plasma. The mucin is a product of the specialized function of the synovial membrane. The connective tissue capsule and its inner surface, the synovial membrane, are richly supplied with capillaries and blood and have extensive powers of regeneration. The articular cartilage, however, is a tissue which is scanty in cells and has a very poor blood supply. As a consequence, articular cartilage has little or no power of regeneration. Articular cartilage, which is damaged or destroyed by any insult, is not regenerated, but is replaced by scar tissue. Since synovial fluid is a dialysate of plasma, substances in the blood may enter a joint by crossing the synovial membrane in the synovial fluid. Bacteria, antibodies, chemicals and drugs all do this but are found in synovial fluid in a slightly lower concentration than in the plasma.

The synovial membrane is especially susceptible to the lodgment of organisms when bacteremia is present. When pathogenic bacteria are deposited in a synovial membrane, the outcome, as in any infection, is dependent on the balance between the virulence and number of organisms and the local resistance of the tissue as well as the general reaction of the host. Vague joint pains of mild degree are common with many infections. These arthralgic pains are not

and by ob-

servable clinical changes in the painful joints, but it is probable that they represent the lodgment of a small number of bacteria in the synovial membrane which are quickly rendered innocuous by host resistance. When the pathogenic organisms gain ascendancy, hyperemia and swelling of the synovial membrane are rapidly produced. Polymorphonuclear leukocytes congest the area of inflammation. The synovial lining thickens and becomes covered with exudate. There is increased production of synovial fluid, which accumulates in the space which encloses the articular cartilage on the bone ends. In the normal joint, only enough synovial fluid is present to produce a film of viscose fluid for the smooth sliding of bone ends. Normal synovial fluid has few nucleated cells and the percentage of leukocytes is extremely low, being from 5 to 8 per cent of the total cells. The mucin content of normal synovial fluid is high. With the abnormal conditions which result from inflammation of the synovial membrane, there is a marked outpouring of leukocytes and of bacteria into the synovial fluid. The increased intra-articular pressure and swelling of the synovial membrane decrease the normal resorption of synovial fluid. As a result of these changes, considerable pressure may be built up in the joint cavity by the exudate. In advanced inflammation, the entire surface of the synovial membrane may be covered by a thick fibropurulent exudate and clots of fibrin may form in the accumulated fluid, which, because of its high concentration of leukocytes, may appear frankly purulent. The cell count of normal synovial fluid is below 100 cells per cc., of which from about 5 to 8 per cent are leukocytes, but in a pyogenic joint the abnormal synovial fluid may contain over 100,000 cells per cc. and 90 per cent of these cells may be polymorphonuclear leukocytes.

The articular cartilage, which is a tissue with few cells and with a sparse blood supply, undergoes pathologic changes as a result of the increase in abnormal joint fluid. As leukocytes in the pathologic fluid disintegrate, they liberate a proteolytic enzyme which digests the articular cartilage. The sites of greatest digestion of articular cartilage occur at areas of contact. If the inflammatory process subsides quickly, the destruction of articular cartilage may be superficial and recovery may occur with negligible impairment of joint function. However, if an exudate high in leukocyte content continues to occupy the joint space, the articular cartilage may be digested through to the underly-

ing bone and undermined so that pieces of varying size flake off.

As the virulence of the invading organism is overcome by the resistance of the host, the accumulation of the high leukocytic synovial fluid decreases and the fluid is absorbed. Granulation tissue, which is formed in the areas of damaged and destroyed synovial membrane and articular cartilage, is gradually transformed to fibrous tissue. The granulation tissue formed in a joint after damage to its normal tissues is called pannus. The degree of recovery of a joint depends on how severe the initial infection has been and how long the products of exudation have been permitted to act in the joint cavity. When only a small portion of the synovial membrane has been necrotized, the joint may return almost to normal. If there has been extensive lysis of an articular cartilage, fibrous bands may grow between contacting surfaces, form adhesions and markedly limit function of the joint. If articular cartilage is digested through to underlying bone, an osseous bridge may unite the bone ends making up the joint and produce bony ankylosis.

The symptoms associated with a pyogenic joint infection are the general symptoms of infection and the local symptoms in the joint involved. When a pyogenic joint is the prime manifestation of the bacteremia, the onset will vary with the virulence of the invading bacteria. Malaise is a general rule. The onset may be initiated with a mild febrile rise of from 1 to 2° C or it may be marked by severe hyperpyrexia and a chill, the temperature rising as high as 40 or 41° C. There may be concomitant dehydration and acidosis accompanied by vomiting. This is more common in the child than in the adult and persists until fluid and electrolyte requirements are satisfied. The infected joint itself causes pain which, in the first few hours or the first day, may be mild and aggravated only by motion but soon becomes so severe that the patient does everything possible to maintain the joint immobile and resents the slightest jar of the bed. When a joint becomes infected during the course of a systemic disease associated with bacteremia, such as pneumonia, meningitis, meningococcemia or bacillary dysentery, the general symptoms of the original illness may predominate. The only additional symptom will be pain in the involved joint. However, if the joint becomes involved after improvement in the initial disease has occurred, there may be a sharp rise of a falling temperature and a recurrence of general malaise.

The earliest signs of a joint infection are, first, tenderness to palpation in the joint line and, second, restriction of the normal range of motion. Tenderness to pressure in the joint lines where they are palpable will often be present very early, even before there is any evidence of an effusion or swelling about the joint. Restriction in the normal range of motion, particularly a loss of the last few degrees of extension of a joint, is also an early

accompanied by involuntary muscle spasm, which is a protective mechanism to splint the joint in the most comfortable position. With an infection of the ankle joint, the foot will be held by muscle spasm in a position of plantar flexion, the knee when infected will be held in a position of flexion. Muscle spasm about the hip in acute infections leads to a position of flexion, abduction and external rotation. In the upper extremity, a finger will be held flexed, the wrist will be held in palmar flexion, the elbow will be flexed; and with an acutely infected shoulder, the arm will be held adducted against the thorax by muscle spasm. Any attempt to alter these positions of protective muscle spasm abruptly evokes increased muscle spasm and produces severe pain. Effusion and increase in synovial fluid, with distention and swelling of the joint, occur relatively early in pyogenic infections of joints. The effusion may be small in quantity if resistance to the invading organism is good. In superficial joints, which are not covered by bulky muscles, the effusion can be seen and palpated. However, in the hip, shoulder, and joints of the spine, which are heavily covered by large muscles, this is not possible. Local heat also accompanies the effusion into the joint, but may not be im-

and signs of an acute suppurative infection of a joint may occur in an infant prior to the age of one year. Generally, however, the symptoms and signs are less pronounced, as the infant's incompletely developed nervous system modifies pain and decreases muscle spasm.

With recent advances in the therapy of rheumatoid arthritis, there has developed another group of patients in whom the signs and symptoms of a pyogenic joint may be masked. Patients with multiple joints involved by rheumatoid disease who are receiving sys-

temically the antiphlogistic hormone, ACTH or cortisone, or any of the modifications, over a long period, are in a nonreactive condition as far as the manifestations of an acutely infected joint are concerned. Because of the already well-established rheumatoid disease, any aggravations of symptoms in a joint or any increased swelling about a joint is likely to be dismissed casually by the patient and the doctor. Long-sustained hormone therapy abolishes or delays the systemic reaction to infection insofar as pain is concerned. In these patients the febrile response is diminished and leukocyte response to infection is altered. In addition, the ability to localize infection is abrogated and the additional stress of a superimposed infection is not tolerated. For these reasons, any unnecessary insertion of a needle into a joint of a patient who is receiving cortisone systemically should be avoided. The ever-present minimal contamination, which occurs in any surgical procedure under the most aseptic technique, is readily rendered innocuous by a patient not receiving antiphlogistic hormones, but with the loss of defense against infection which results from prolonged cortisone therapy, empyema of a joint may result from the slightest contamination. Infections in closed cavities attain great virulence in patients in this state before systemic symptoms are manifested and a very large amount of exudate may accumulate in a joint under these circumstances before its significance is appreciated.

In the initial evaluation of the patient suspected of suffering from a pyogenic infection of a joint, detailed questioning should be carried out to determine whether there has been any recent illness, such as an upper respiratory infection, tonsillitis, urethritis or gastrointestinal disturbance. The possibility of a recent exanthematous disease should be inquired about if the patient is a child. All cutaneous surfaces and mucous membranes should be observed for a possible focus of bacteria. The throat and tonsils should be carefully inspected and in children the ears should be examined to determine the state of the middle ear. The condition of the lungs should be ascertained. If physical examination leaves any doubt, roentgenograms of the chest should be obtained. Pneumococcus is an organism which occasionally causes a pyogenic joint. Examination of the heart may give information suggesting rheumatic fever. Palpation of the abdomen is important, especially when the hip is the joint in question. Any irritation along the scale in its

retroperitoneal portion may cause the hip joint to be splinted in flexion. Examination of the abdomen may bring to light a tender appendix or enlarged retroperitoneal lymph glands. Enlargement of the spleen or liver may direct attention to a pathologic condition of importance. The presence or absence of abdominal distention is indicative of the extent of toxemia or disturbance in fluid balance or electrolyte metabolism. Urethral or vaginal discharge may point to a recent gonorrheal infection.

In the examination of the joint or joints involved, the condition of the skin and soft tissues overlying, surrounding and adjacent to the joint should be noted. Swelling, edema and redness of the skin, with an obvious contiguous purulent area, may indicate that the infection is superficial rather than intra-articular. In the superficial joints, which are covered only by skin and subcutaneous tissue, distention of the joint itself may be obvious. Distention is not easy to be certain of in the shoulder and is impossible to detect in the hip and joints of the spine. The position in which the patient maintains the joint and the protection which he extends to it will give information about involuntary muscle spasm. Palpation of the joint lines may reveal tenderness before an effusion is present. The musculature above and below the suspected joint should be palpated for areas of tenderness, fluctuation or thickening. A juxta-articular inflammation, such as osteomyelitis, may give joint signs when the joint itself is not involved. The presence or absence and the degree of effusion within the joint can be verified by palpation. Examination of the range of motion present in the joint should be carried out and compared with that of a similar uninvolved joint. Motion must be tested gently, since rough or forceful handling of an infected joint will cause severe pain. In the examination of the hip and shoulder joints which are deeply buried under muscle, the range of motion is the most important fact to be determined. The presence or absence of muscle spasm and its degree can also be verified at this time. Measurements of the circumference of the joint and of the musculature above and below should be made at the initial examination and recorded, as they may be of value for comparison later in the course of the disease.

In the initial appraisal of the patient's condition, the hemoglobin value, red blood cell count and differential white blood cell count should be obtained. These examinations will shed light on the general condition of the pa-

tient and his reaction to infection. They may also bring to light an unsuspected hematologic condition of importance or present an indication for blood transfusion. Additional blood counts and hemoglobin determinations should be carried out through the course of the disease as needed, to obtain information concerning the condition of the patient and the efficacy of treatment. Initial laboratory studies should include urinalysis, which may give evidence of a primary infection in the urinary tract or indicate severe parenchymatous damage and nephritis, complicating the infection. The presence or absence of diabetes or acidosis due to dehydration may also be determined from urinalysis. Urinalysis should be repeated at least twice weekly during the febrile course and during the treatment. The initial laboratory investigation should include a blood culture. The blood culture should be made before antibiotic therapy is instituted and the blood sample is best taken when the fever is elevated. Organisms obtained by blood culture should be typed against antibiotics for sensitivity. Since bacteremia is often transitory, the blood cultures may be negative. Special circumstances may indicate additional bacteriologic studies. An obvious purulent exudate from a focus of infection in the skin or mucous membranes or urine heavily loaded with pus cells should be cultured for organisms, any organisms found should be typed for sensitivity to antibiotics. A recent history of diarrhea or enteritis may be an indication for a stool culture. Serologic examination of the blood should be included in the initial laboratory survey.

Roentgenographic examination of the involved joint or joints should be made. This should include the bones and the joints above and below the suspected joint. X-ray examination is of value to exclude the possibility of a focus of osteomyelitis or an incomplete fracture. When the joint infection results from external contamination, a roentgenogram may disclose a foreign body in the joint or adjacent to it. Early in the course of pyogenic infection of a joint, in the absence of an osteomyelitic focus, the only roentgen ray

will become evident. In those joints which progress unfavorably, destruction of articular surfaces may be evident in a roentgenogram made late in the course of the disease. Small cartilaginous sequestra, which may cause continuous drainage, will not show in roentgenograms, as cartilage is radiolucent. X-ray

examinations are of more aid later in the course of a pyogenic joint when they may then help to assess the degree of damage to the joint. They should be obtained as needed for the management of the patient.

Aspiration and study of the synovial fluid make up the most valuable procedure in the examination of a joint suspected of being infected with bacteria. Aspiration is a simple procedure, which can be done with the patient under sedation and local infiltration anesthesia. It must be carried out with strict aseptic precautions, with adequate preparation of the skin and with sufficient sterile draping. Superficial joints, such as the knee and elbow, are very easy to aspirate. The shoulder and hip are more difficult, but still quite accessible to aspiration, and this is particularly true when these deep joints are abnormally distended with synovial fluid.

From the normal joint it is usually impossible to aspirate any fluid. At the most, not more than from 1 to 2 cc may be obtained. Normal synovial fluid is clear, pale yellow, viscous and does not clot. It contains only a few nucleated cells. Generally there are less than 50 and rarely more than 150 nucleated cells per cu. mm. of normal synovial fluid. The polymorphonuclear leukocytes in normal synovial fluid comprise from 7 to 8 per cent of the nucleated cells present. Lymphocytes in the normal fluid comprise 25 per cent. The remaining nucleated cells are monocytes, clasmatocytes and unclassified phagocytes. The normal fluid is also sterile.

Synovial fluid is present in increased amount in a joint invaded by pathogenic bacteria and by aspiration it is usually easy to obtain it through a needle of adequate size. The fluid aspirated from a pyogenic joint is changed in appearance. It is turbid rather than clear. The degree of turbidity may vary from slight opacity to the consistency of frank pus, depending on the severity and duration of the joint infection. The fluid is decreased in viscosity and forms clots soon after withdrawal from the joint cavity. The total cell count of the synovial fluid from a pyogenic joint is increased astoundingly. Often from 60,000 to 120,000 cells per cu. mm. are present and if the fluid is frank pus, the cells may be too numerous to count. The polymorphonuclear leukocytes may be increased to as high as from 80 to 90 per cent of the total nucleated cells. Gram stain of a smear of the synovial fluid may indicate the presence of bacteria. Culture of the synovial fluid will often produce the organism which is the cause of the infection. The incidence

of positive cultures from synovial fluid is lower when gonococcus is the infecting organism than when a streptococcus or staphylococcus is responsible. Positive cultures are still less frequent in meningococcus infections. Thus, with the valuable information to be obtained by joint aspiration, it is obvious that in any suspected pyogenic infection of a joint, aspiration and study of the synovial fluid are mandatory at the initial examination.

Because of the multiplicity of joint affections and of general systemic conditions causing acute reaction in joints, delay in the accurate diagnosis of acute pyogenic arthritis is likely to result unless its possibility is kept in mind. *Any acute pain, accompanied by signs of infection, occurring in a joint or developing during or proximate to an acute infectious disease, should call to mind the possibility of acute suppuration in the joint.*

Acute pyogenic arthritis may be extremely difficult to differentiate from acute hematogenous osteomyelitis. When the osteomyelitic focus is in the neck of the femur, the differentiation is impossible, as all the local manifestations are joint manifestations because of the fact that the area of bone inflammation is actually within the capsule of the hip joint. However, in other sites and about the knee, which is the most frequent localization of osteomyelitis, the area of bone tenderness is juxtaepiphyseal and not in the joint line. In

there is an extensive focus of osteomyelitis in the upper tibia or lower femur, the knee joint, even though not infected, may present an effusion, the result of contiguous inflammation. When there is an obvious increase of fluid in the joint, the issue can be quickly settled by aspiration and study of the synovial fluid. Pyogenic infection of the hip joint itself is common with osteomyelitis localized to the neck of the femur, as a result of direct rupture of the bone abscess into the joint cavity. Other joints, because of different anatomic relationships, become contaminated from a juxtaepiphyseal bone abscess only after the osteomyelitis has existed for a long time or been inadequately treated. Extensive burrowing of exudate and necrosis of soft tissue barriers must occur before the adjacent joint becomes contaminated.

Cellulitis of the soft tissues adjacent to or surrounding a joint may lead to pain on motion and protection of the joint by the patient. However, the redness, swelling and in-

uration of the skin should give a clue to the diagnosis. In the acute suppurative joint, the skin itself about the joint is seldom altered in appearance.

Rheumatic fever may be difficult to differentiate from an acute joint infection. The joint manifestations of this disease, although frequently presenting an effusion into the joint, as a rule show a greater periarticular reaction than is found with a pyogenic joint infection. Frequently, multiple joints are involved and joint manifestations are likely to be transitory and migratory rather than steadily progressive in the same joint. Other indications of rheumatic fever may be evident from the general examination.

Rheumatoid arthritis is seldom abrupt in onset. There is usually a history of protracted mild discomfort in one or more joints prior to the acute swelling of a single one. The superimposition of a pyogenic infection in an already established rheumatoid joint may occur spontaneously or in the course of some infectious disease, such as pneumonia or scarlet fever. In the rare instances when this happens, the diagnosis of acute sepsis is difficult to make but can be arrived at definitely by aspiration and study of the joint fluid. The undue, abrupt swelling of a rheumatoid joint, particularly with an elevation of temperature, calls for examination of the joint fluid. This is particularly indicated if the patient is receiving systemic hormone therapy.

Gout in its initial attack may suggest a purulent joint infection. The abruptness of onset and the severity of pain may appear to indicate a severe infection. This metabolic disorder usually involves a joint in the foot and has a predilection for the metatarsophalangeal joint of the great toe. It may, however, involve one of the larger joints or even one of the upper extremity. In gout, the swelling is predominantly periarticular, joint effusion, if present at all, is usually small in amount. There is often redness of the tissues, but the systemic signs of infection are absent. A febrile rise of more than 1° C. is uncommon. Determination of the serum uric acid level, which is always elevated in an acute attack of gout, will differentiate it from purulent arthritis.

Hemophilia with acute hemorrhage into a joint may be accompanied by great distress and elevation of temperature, the result of blood in the joint, and may simulate an acute pyogenic infection. A history of previous episodes of bleeding is often obtainable and ecchymotic sites elsewhere in the soft tissues

may suggest abnormal bleeding. Determination of the bleeding and clotting time will establish the diagnosis. Aspiration of synovial fluid will reveal frank blood rather than cloudy fluid. It is imperative that incision and drainage of a hemophilic joint be avoided, as an unnecessary incision may jeopardize the patient's life.

Scurvy can produce a joint effusion from intra-articular hemorrhage. When this occurs, there will be other clinical evidence and roentgen ray findings to substantiate the diagnosis.

Bursae which become infected with pyogenic organisms should be easily differentiated from intra-articular infections. Those most commonly involved are the olecranon, prepatellar and pretibial bursae. Careful inspection and palpation will reveal the distended sac to be superficial to the joint, even though it is in proximity.

Tuberculous infections of joints are not sudden in onset. Pain is insignificant in the early stage of joint tuberculosis and the systemic manifestations of acute infection are absent. Aspiration and examination of synovial fluid will differentiate this type of infection from the acute purulent infection.

Erythema nodosum may be accompanied by joint effusion, but history and inspection should bring to light the skin lesion and thus differentiate this condition from acute infection.

Traumatic effusion into a joint follows close on the injury; therefore a definite history of some proximate trauma can be elicited. Systemic signs of infection are either mild or absent with traumatic joint effusions. Aspiration usually yields a blood-tinged fluid.

The hip joint deserves special consideration in the problem of differential diagnosis. It is motivated by the psoas muscle, which extends in the retroperitoneal space from the second lumbar vertebra to the lesser trochanter of the femur (Fig. 146), and this muscle is a strong flexor of the hip joint. Any pathologic condition which irritates the psoas muscle may cause involuntary spasm and produce a flexion contracture of the hip joint. The commonest condition to cause this is retroperitoneal lymphadenitis. Retroperitoneal lymphadenitis is usually accompanied by systemic signs of infection. The enlarged glands may resolve spontaneously, but they can suppurate and require surgical drainage. An inflamed retrocecal appendix or pelvic inflammation may lead to a flexion contracture of the hip joint by irritation of the psoas muscle.

Physical examination of the range of joint

Relation of Psoas Muscle to Hip Joint

Figure 146 Diagram of psoas muscle and its relationship to the hip joint to illustrate how extra-articular disease may produce abnormal signs in the hip joint

motions will identify these conditions as being extra-articular and not in the hip joint itself. No motion other than an attempt at extension of the joint against the flexion contracture, which puts stretch on the irritated psoas muscle, will cause pain. There is no loss of flexion or rotation of the hip joint. The patient will walk on the involved extremity with little discomfort but with a marked limp. In a thin child, the enlarged lymph glands may sometimes be palpated through the abdominal wall.

The treatment of a pyogenic infection of a joint requires the general treatment of the patient and the local treatment of the infected joint. General treatment of the patient strives to muster all body defenses against infection. Local treatment of the joint strives to minimize damage to the cartilaginous gliding surfaces, so that as nearly normal motion as possible will be preserved and deformities prevented. The patient affected with a pyogenic infection of a joint, because of the sepsis preceding or associated with its onset, may be severely dehydrated and in negative nitrogen balance. These conditions must be recti-

A high blood concentration of multiple antibiotics, with the broadest possible antibacterial spectrum, should be effected promptly after the diagnosis is made. In infants and children or in adults who will not take adequate oral dosage, these antibiotics may be added to intravenous fluid and administered as a continuous drip. This is the method of choice when the patient is profoundly toxic. Since the most probable organisms to infect a joint are the staphylococcus, streptococcus and gonococcus, the antibiotics administered should be effective against them. The broad coverage desired against the staphylococcus, streptococcus and gonococcus can be effected by a combination of erythromycin, oleandomycin or tetracycline with chloramphenicol. When there is a history of previous therapy with chloramphenicol, this drug should be used with the greatest reluctance and not unless the invading organism cannot be checked by any other antibiotic.

When there is clinical evidence or suspicion of an organism which may be insensitive to these drugs, other antibiotics or chemotherapeutic agents which seem appropriate should be added and administered in appropriate dosage. As soon as the invading organism has been identified, either from synovial fluid or blood culture, and its sensitivity to antibacterial drugs determined, a single specific antibiotic may be substituted for the multiple-drug therapy. Under no condition should antibiotic therapy be delayed to determine the specific antibiotic, as this is a waste of valuable time. When the febrile reaction is severe, antipyretic drugs and alcohol sponges may be indicated. These are especially indicated in infants and children, as convulsions may result from inordinately high fever. Any obvious focus of infection, such as a crusted abrasion, a furuncle or infected middle ear, which might feed bacteria into the blood stream should have adequate drainage.

Local treatment of the infected joint strives to rid the joint of all accumulation of pathologic synovial fluid with a high leukocyte count. The disintegration of polymorphonuclear leukocytes liberates a proteolytic enzyme which digests articular cartilage. The method chosen to prevent destruction of articular cartilage by leukocytic digestion will be influenced by two factors: the character of the synovial fluid obtained by aspiration and the individual joint infected. Certain joints, such as the knee, elbow and ankle joint, because of their superficial location and noncompartmented cavities readily evac-

ated by aspiration. On the other hand, the hip and shoulder, because of their deep location, and the wrist, because of its compartmentation, are difficult to aspirate. Thin synovial fluid with a cell count of 100,000 cells per c.c. will come through a needle easily. Frank pus with clots and cells too numerous to count is difficult to aspirate and because of its high content of leukocytes is rapidly destructive to articular cartilage. Any joint which on initial aspiration yields frank thick pus should be drained by arthrotomy, and drainage should be maintained until the patient's systemic reaction has subsided and the synovial fluid has returned to a serous state. When this eventuates, the incision may be permitted to close. The hip joint and shoulder joint, which are buried under bulky muscles, are difficult to repeatedly aspirate thoroughly; even though the synovial fluid in these joints is not frank thick pus but is definitely purulent, they are best evacuated by surgical arthrotomy. The arthrotomy of each joint should be planned to give dependent drainage and not to damage supporting ligamentous structures. In superficial joints, such as the knee, elbow and ankle, which are easy to aspirate, if the initial fluid is not frankly purulent and the systemic response to therapy is prompt and effective, repeated aspiration of purulent fluid may be adequate to prevent destruction in the joint. If this treatment steadily decreases the effusion and the leukocyte count of the fluid drops, repeated aspiration is adequate. Transarticular lavage

of saline through trocars has been advocated for thick purulent synovial fluids. This method requires anesthesia and is not to be relied upon. When the synovial effusion is so thick that it will not come through a large needle, open arthrotomy is the better course. An aqueous solution of antibiotics may be instilled directly into the joint cavity at the time of aspiration, but if the blood concentration of antibiotics is kept at a high level, all antibiotics and chemotherapeutic agents cross the synovial membrane and are present in synovial exudate in concentrations only slightly below the blood concentration. In densely purulent exudate, the effectiveness of even high concentrations of antibiotics is inhibited. Consequently, a joint filled with frank pus should have the benefit of open drainage.

Local measures to relieve the pain of muscle spasm are indicated. Continuous skin traction to the extremity in infections of the shoulder, hip and knee affords great comfort to the patient and prevents the development of contractures in positions of deformity, which may develop very rapidly if muscle spasms go on unchecked. The elbow, wrist, ankle and foot should be splinted in the position of comfort and function. Immobilization and rest of themselves are therapeutic measures of value in treating infection.

When the course of the disease indicates that damage of articular cartilage will probably result with some loss of normal motion, every effort should be made to have the re-

Arc of Motion of Best Function in Knee Joint

Figure 147. Diagram to illustrate the most useful arc of motion in the knee joint, which should be preserved when a loss of motion is anticipated

Functional Positions for Ankylosis

Figure 148 Diagram of functional position for bony ankylosis of joints A, Elbow-90 degrees of flexion If ankylosis of radiohumeral joint occurs, the forearm should be neutral in pronation and supination B, Shoulder-humerus at 70 degrees of flexion C, Wrist-10 degrees of flexion D, Knee-10 degrees of flexion E, Ankle-10 degrees of flexion F, Leg-Female, 10 to 35 degrees of flexion, neutral in abduction-adduction, and 5 to 10 degrees external rotation

maintaining motion in the arc of greatest usefulness (Fig. 147) This can be accomplished by the use of traction and proper splints For example, if as a result of purulent infection of the knee, 50 per cent or about 70 degrees of the normal arc of motion is permanently lost, the extremity will still be very useful when the preserved 70 degrees of motion is possible from a position of complete extension If the knee recovers with a severe flexion deformity and the remaining 50 per cent of motion is present only through the last half of the arc of normal motion, the individual will be severely handicapped and will require reconstructive surgery. When loss of motion is anticipated in the elbow joint, it is to be remembered that the completely extended elbow is useless. The forearm and hand function best

in the upper half of the normal arc of flexion The extended stiff elbow cannot reach the head, face, shirt or belt, and is serviceable only to scratch the knee or foot. Each joint has its own angle of greatest usefulness when ankylosed and its arc of motion which is of greatest functional value. Preserved motion must be in the most useful arc and ankylosis must be in the position of greatest function (Fig. 148).

Infections of joints due to trauma, fortunately, are rare but do occur occasionally from puncture of a joint by a sharp object or from lacerations extending into a joint. Any joint which has been punctured by a foreign body, such as glass, a needle, nail or piece of steel, from the moment of puncture must be considered potentially infected It is impera-

tive to determine whether or not any portion of the object which punctured the joint has remained within the joint cavity. When there is certainty that a piece of foreign material is within the joint, it should be promptly removed by surgical arthrotomy. A metallic foreign body or leaded glass will show in roentgenograms. A foreign body which is radiolucent will not be visible on x-ray film and its presence in the joint must be deduced from the patient's history or from that portion of the foreign body which has been recovered. Radiolucent objects which cause great trouble in joints are palm thorns and cactus thorns. Even though the joint is not infected, a fragment of such organic material in a joint causes a chemical irritation which will lead to disabling synovitis unless it is removed. The joint which has been punctured by a foreign body without deposit of foreign material in the joint cavity should be treated by rest and immediate administration of multiple broad-spectrum antibiotics to provide a high concentration in the blood. This treatment should be continued until it is evident from the systemic response and the local condition of the joint that any contamination produced by the puncture has been rendered innocuous. If fulminating infection with a purulent synovial fluid ensues, arthrotomy may be indicated.

A joint which has been opened traumatically to the outside should be treated as a compound fracture. As soon as possible, with the patient under general anesthesia, careful débridement, with removal of all foreign material and devitalized tissue, should be done. This should be accompanied by copious lavage with many thousand cubic centimeters of warm saline solution. When possible, the joint should be closed primarily, provided the lapse of time since the injury and the circumstances of the injury are not contraindications. It is often impossible to close synovial membrane or joint capsule, but a covering of fascia or even skin will suffice for primary closure. If closure is contraindicated because of contamination, petrolatum gauze is placed in the soft tissues covering the joint and the open wound is allowed to granulate to the surface. Drains should not be inserted between the articular ends of bones.

Treatment of the joint which has become infected from the extension of an adjacent focus of osteomyelitis requires intelligent treatment of the osteomyelitic focus. A joint cannot be expected to recover without severe damage when an osteomyelitic focus continues to drain through it. The area of osteomy-

elitis must be diverted and given adequate extra-articular drainage. When this is done in the initial treatment of osteomyelitis, joint destruction is rare except in the hip joint.

Pyogenic infection of a joint which occurs in a patient who is receiving protracted systemic treatment with the antiphlogistic hormones, cortisone and ACTH, occupies a special category. Such infection occurs in a joint which is already the site of rheumatoid disease and for that reason is difficult to recognize. The individual receiving prolonged cortisone therapy is unable to localize infection. Because of this lowered resistance to pathogenic organisms, drainage by arthrotomy should be promptly instituted. Any attempt at therapeutic relief by aspiration will be ineffective. Prompt open drainage helps to relieve the additional stress of the infection and does away with the closed focus, which may be responsible for bacteremia and further metastatic abscesses. The hormone should not be withdrawn or decreased during the stress of infection; its dosage may need to be increased, especially prior to being subjected to an anesthetic or surgical procedure. It may be advisable after the infection has come under control to decrease or withdraw hormone therapy in order that the arthrotomized joint may close. While a patient receives constant high-level antiphlogistic hormone therapy, drainage may go on indefinitely from an open joint. When the patient's general condition has improved and drainage from the arthrotomy incision has decreased in quantity and changed in character to a serous type, the antiphlogistic hormones can be slowly withdrawn and terminated. Their withdrawal is often associated with a great increase in discomfort from the rheumatoid disease, weakness and psychic depression and the patient may be difficult to manage.

The outcome of a pyogenic infection of a joint varies with the age of incidence, the mode of infection, the joint involved and the promptness of adequate treatment. In infants and very young children, in whom the infection most often follows bacteremia or complicates an infectious disease, mortality is highest. In older children and adults, death is rare.

The knee, shoulder, elbow and hip joints tolerate infection better than do the wrist, ankle and smaller joints of the foot and hand. In metastatic bacterial infections of the knee, shoulder, elbow and hip, with prompt diagnosis and adequate intelligent treatment, it can be anticipated that a good range of mo-

tion will be salvaged. In the wrist, ankle and smaller joints of the hands and feet, even though treatment is prompt and intelligent and the infection mild, there is usually a great loss of normal motion.

In infants and young children who have not completed growth, because of the fact that the epiphyses are juxta-articular or even intra-articular, as in the hip joint, growth disturbances may follow a joint infection. The aberrations of growth may manifest themselves as discrepancies in length or as directional deformities, for example, knock-knee, bowleg or increase of the carrying angle at the elbow, the outcome depending on the portion of the epiphysal line which is disturbed. Immediately following a joint infection, there may be an acceleration of growth, with length gain in an extremity of as much as 2.5 cm. This may occur during the first year, but it is often followed by deceleration of growth so that, as adult life is approached and growth terminates, the extremity is shorter than normal.

Infection of the hip joint may be complicated by spontaneous pathologic dislocation of the femoral head. This can be prevented by the use of traction with the leg abducted. Dislocation of the femoral head, if recognized early, can usually be easily repositioned by simple traction. Sequestration of the capital femoral epiphyses occurs in infants and children. This is a serious complication and is followed by profound growth disturbance and severe deformity.

An infected joint which is secondary to adjacent osteomyelitis has a poorer prognosis for loss of motion, growth disturbance and deformity than the joint which becomes infected from bacteremia.

Fibrous or bony ankyloses will inevitably result in some infected joints. When ankylosis is in the proper functional position for the individual joint, the disability which results from the loss of motion is minimized and the necessity for subsequent corrective surgery obviated. With proper care, neither ankylosis of a joint in a nonfunctional position nor the loss of remaining motion in a useful arc should occur.

TUBERCULOSIS OF THE BONES AND JOINTS

Tuberculosis is one of the oldest diseases

cle bacillus in 1882.

Tuberculosis of bones and joints is the

most common of the osseous infections. The spine is most frequently involved in osseous tuberculosis and the weight-bearing joints of the lower extremities are more commonly affected than the joints of the upper extremities.

The infection occurs most often in childhood during the period of rapid bone growth, the greatest incidence falling between the first and sixth years of life.

There are variations in racial susceptibility to the tuberculous organism. The Negro, Mexican and Indian peoples show the lowest resistance, the Mongolian slightly more, while the Caucasian has the least susceptibility.

There are three types of tuberculosis bacilli which may produce the disease—the human, bovine and avian. In the United States the human type is the most common organism found, but in areas where cattle inspection and milk pasteurization are neglected, the bovine type of infection in bone is most often seen. The avian type rarely infects human beings.

The involvement of the bone or joint is secondary to tuberculous infection elsewhere in the body. It suggests the presence of pulmonary, glandular or gastrointestinal foci. The most common route for bone infection from these foci is the blood stream. Minute bacterial emboli of tuberculous organisms circulate in the blood stream and lodge in the small end-arteries of the bones adjacent to the epiphysal cartilage. The bacteria multiply and tubercles form which enlarge into small local abscesses. This process is typically without secondary bone reaction.

This local bone infection by gradual extension may erode through the articular cartilage into the joint or may progress along the epiphysal cartilage extending into the adjacent capsule and synovium to involve secondarily the joint. In other instances, more commonly seen in adults than in children, the infection may start primarily in the synovial lining of the joint, producing primary synovial tuberculosis.

Characteristically, tuberculous infection in bone is primarily a lytic process with very little tendency toward new bone formation.

When the infection enters a joint a fibrinous exudate covers the articular cartilage which gradually becomes organized into granulation tissue. At times the articular cartilage may sequester because of subchondral abscesses in the bone. The tuberculous pus which is formed may dissect into the adjacent tissues of the joint.

planes of least resistance, develop abscesses in areas removed from the site of the immediate infection.

Tuberculous infection differs from acute pyogenic infection by the absence of local heat and redness. The abscess formation in the soft tissues is spoken of as the cold abscess or tumor albus. These cold abscesses may, in the process of healing, go on to complete calcification. Occasionally the cold abscess may become secondarily infected following aspiration or drainage and then may behave the same as an acute pyogenic infection.

Tuberculosis of bone may occur as three distinct clinical types: chronic, acute and subacute. The chronic type has an insidious onset, with slow progress without tendency to form abscess. This is frequently spoken of as caries sicca. The acute type runs a rapid course, with high fever, more severe pain than in the chronic type and frequent abscess

formation. The subacute type of osseous infection, follows a more moderate course characterized by low-grade fever, subacute pain and progressive deformity. Frequently, soft tissue abscess formation occurs.

The symptoms of bone and joint infection vary widely with the type of infection and rarely are the symptoms diagnostic. The general complaints of malaise, loss of appetite, low-grade fever and night sweats are frequently present. The local symptoms consist of pain, and muscle spasm in an attempt to protect the affected joint, producing a gradual progressive deformity. Boggly swelling of the joint is common with very little increase in local heat. Tuberculous joint disease is usually monoarticular. In children "night cries" are not unusual.

The diagnosis is usually demonstrated by smear or culture from joint aspiration, positive identification of the tubercle bacillus in biopsy specimens of infected tissue and the production of active tuberculosis in guinea pigs inoculated with infected material.

A tuberculin skin test is of greatest value in a negative manner. It is rare to obtain a negative reaction to a tuberculin skin test in a patient with active tuberculosis. A positive reaction to the skin test is suggestive, but not conclusive, evidence of the disease in the young patient.

The roentgenogram in bone tuberculosis characteristically shows atrophy and destruction of bone with loss of joint space without

new bone formation. Because of frequent subchondral abscess formation, the x-ray film may reveal a scalloped appearance along the joint line which is peculiar to tuberculosis. There are frequent soft tissue abscesses which may be recognized on the roentgenogram.

The presence of pulmonary tuberculous lesions may be an aid in reaching the diagnosis of osseous tuberculosis.

Tuberculosis of the bone or joint must be considered as a local manifestation of a systemic disease and, as such, the treatment should be divided into two aspects: those measures which are directed to the control of the general systemic disease and the local measures which are employed in the management of the specific joint.

Until recent years, there had been no specific treatment for tuberculosis.

At the present time, there are increasing favorable reports of the usefulness of streptomycin in combination with para-aminosalicylic acid for the control of tuberculous infection.

More recently the isonicotinic acid preparations have been used and seen to be of great value, especially in the treatment of severe chronic tuberculosis of the bones and joints with multiple chronic draining sinuses.

While it is still early to speak with complete assurance concerning the control of tuberculosis by the use of these medications, all indications have suggested that they are contributing a great deal in the control of the disease process and these drugs should be employed in the treatment of osseous and synovial tuberculosis. In addition to the specific medications, it has for years been recognized that wholesome hygienic living conditions, fresh air and a well-balanced diet are of great value. Bed rest is of extreme importance during the acute phase of the disease. Adequate control of the anemia and hypoproteinemia is necessary. In osseous lesions, heliotherapy, as popularized by Rollier, is indicated as an aid to local treatment but should be given in controlled dosage and its use not abused.

Local treatment of joint disease consists of proper immobilization of the involved joint in the functional position by continuous traction, casts or bracing.

When tuberculous disease has resulted in damage of the articular cartilage, especially in weight-bearing joints, return to activity may result in reactivation of the disease. As a result, operative fusion is frequently used to avoid recurrence.

Surgical treatment is employed when the

disease process is under control, both from the systemic and local standpoint. The disease is considered under control when there is relief of the pain and spasm, the absence of fever, a normal sedimentation rate and no progress in abscess formation.

Operative fusion may be intra-articular or extra-articular, or a combination of both methods.

Abscesses. The cold abscess of tuberculosis is treated by aspiration or incision only with impending rupture or severe discomfort. The potential of secondary infection in these abscesses is always present and aspiration, when undertaken, is usually accomplished by introducing the needle through normal tissue to enter the abscess, rather than piercing the skin immediately over the infected tissue.

In rare instances when the abscess is completely isolated, total surgical excision of the abscess may be undertaken. When there are multiple draining sinuses, great benefit has been observed with the use of chemotherapeutic agents such as streptomycin, para-aminosalicylic acid and isonicotinic acid. When these drugs are used, care must be taken in careful observation of the patient in order to avoid undesirable side reactions.

Tuberculosis of the Spine (Pott's Disease). Tuberculosis of the spine is commonly spoken of as Pott's disease, as this condition was first described by Sir Percivall Pott in 1779 and was considered then to be of tuberculous origin.

In tuberculosis of the bones, the spine is the most frequently involved structure. Although the highest incidence of Pott's disease is in children, 50 per cent of the cases occurring in children between three and five years of age, the disease does occur frequently in adults. The area of the spine most commonly affected is that portion of greatest mobility, the tenth dorsal to the first lumbar segments. The disease may occur in any portion of the cervical, dorsal or lumbar spine.

The anterior part of the vertebral body is the most commonly involved, but the disease may attack the posterior process, lamina or the transverse processes (Fig. 149). Often the intervertebral disk is the earliest site of the infection and narrowing of this space may be the first x-ray evidence of the disease. Several areas of involvement are not uncommon. With bony destruction of the vertebral body, a progressive collapse and posterior angulation of the spine develops, resulting in the kyphosis which is frequently seen in Pott's disease.

Abscesses form along the anterior margin

Figure 149 Early tuberculosis of the spine.

Figure 150 Psoas abscess (bilateral)

of the vertebral bodies and, in the dorsal area, the abscess remains in the paravertebral space and is usually globular in shape. The abscess may readily be recognized in the anteroposterior roentgenogram as a paravertebral shadow adjacent to the area of the bony involvement. Abscesses arising in the lower dorsal and lumbar region may extend along one or both psoas sheaths into the pelvis (psoas abscess, Fig. 150). These at times may present themselves in either the femoral or inguinal area under Poupart's ligament. Less often, the abscess may point posteriorly in Petit's triangle and, on rare occasions, may point in the gluteal region.

The general symptoms of tuberculous infection are frequently present. The local symptoms of spine involvement depend on the area involved. Pain and weakness in the

back associated with stiffness and muscle spasm are common. Local tenderness to percussion may be present.

Night cries are frequent in children during the early stage. A change in gait may be noticed due to protective mechanisms to avoid jarring.

In the cervical lesions, motions of the head and neck are limited and the head may be supported by the hands.

Dorsal lesions are more silent and give less evidence of limited mobility because of the natural rigidity of this portion of the back.

Lumbar spine involvement shows a loss of flexion and extension with marked protective splinting of the muscles. Any of the signs and symptoms of chronic low-back conditions may be present.

With irritation of the spinal nerve roots, there may be radicular pain and, in the lower lumbar region, symptoms simulating ruptured intervertebral disk syndrome are not unusual.

With irritation of the psoas muscle, hip flexion contractures may develop suggesting hip disease.

Occasionally the first sign of Pott's disease may be a bulging in the inguinal or femoral region from a psoas abscess which may be mistaken for a hernia.

The kyphosis of Pott's disease is a late finding resulting from vertebral body collapse and posterior angulation (Fig. 151).

Involvement of the spinal cord is not uncommon with tuberculosis of the vertebral bodies and the associated abscess formation.

It may appear in about 10 per cent of the cases.

The area most frequently involved is the upper and mid-dorsal region. The spinal cord involvement is usually secondary to extension of the granulomatous tissue with encroachment on the spinal cord rather than collapse and angulation of the spine. The lesion may progress to complete paraplegia. If regression of the symptoms is not rapidly obtained with rest, medication and splinting, drainage of the tuberculous abscess by costotransversectomy is indicated. Laminectomy is usually not advisable.

In tuberculosis of the spine, the roentgenogram is of great aid in establishing the diagnosis. The demonstration of the narrowing of the intervertebral disk and the lytic destruction of the adjacent vertebral bodies accompanied by paravertebral abscess is extremely suggestive. A positive reaction to the tuberculin test is corroborative evidence, especially in patients of the younger age group. A negative reaction to the tuberculin test, as mentioned before, is of greater value in eliminating the possibility of tuberculosis. Confirmation of the diagnosis occasionally may be obtained by aspiration of the abscess and recovery of the organism. A presumptive diagnosis is aided by the presence of tuberculosis elsewhere in the body, usually of the pulmonary or gastrointestinal type.

Conditions which simulate tuberculosis of the spine, especially in the adult, are: low-grade pyogenic osteomyelitis—the proliferative bony changes seen in pyogenic osteomyelitis are an aid in differentiation; malignant disease, chronic arthritis and fractures of the vertebral bodies; other granulomatous infections such as actinomycosis.

As in all forms of osseous tuberculosis, the treatment of tuberculosis of the spine should be divided into the general and local measures.

The general supportive measures are those mentioned for the treatment of systemic tuberculosis, including the use of the beneficial drugs, associated with supportive measures of rest, well-balanced diet and heliotherapy.

The spine should be given complete rest and, in the earlier phase of treatment of this disease, the patient should have bed rest either in a plaster shell, a Whitman type frame or Stryker bed (Figs 152 and 153). By means of these devices the patient can be turned for his bathing and general body care without putting torsional strain upon the infected area of the spine.

Figure 151. Tuberculosis of the spine with collapse and kyphosis.

Figure 152 Plaster shell a, Supine, b, prone.

Figure 153 Stryker bed with patient in prone position. Position may be reversed to supine.

In the past, many attempts have been made to hyperextend the spine gradually to prevent vertebral body collapse, however, it is generally felt at the present time that hyperextension of the spine is to be avoided, as the

incorporating one or two vertebrae above and below the involved area, is used after the active infection has become controlled. Operative fusion is a further means of fixation of the affected spine, using the bony fusion as an internal means of support in addition to the external support of braces or casts.

Prolonged immobilization of the spine after healing, either following conservative or operative treatment, is indicated. A brace or cast (Fig 154) is employed during the period of beginning ambulation and is continued over a period of eighteen to twenty-four months.

Tuberculous abscesses, as a rule, are not opened unless there is pain or threatening rupture. Most abscesses will retrogress under conservative treatment and frequently go on to complete healing by

the position of hyperextension used in an attempt to prevent deformity.

Recumbency with protection of the spine is maintained for prolonged periods until the disease process shows clinical and x-ray evidence of becoming arrested. The average period of recumbency is about eighteen months.

Operative fusion of the posterior processes of the spine throughout the diseased area,

Tuberculosis of the Sacroiliac Joint. Tuberculosis of the sacroiliac joint is quite rare in children but is occasionally seen in adults and sometimes may be bilateral.

Abscess formation is frequent in this infection and the tendency is to point anteriorly more often than posteriorly. The abscess may point into the groin; into the iliac fossa; into the buttocks, passing through the sacrospinous notch, and into the ischioanal fossa.

The onset of tuberculosis of the sacroiliac joint as a rule is slow and the abscess may be the first symptom. Pain in the back may be increased with sitting or walking and is accompanied by signs of chronic low-back pain with limited back motions. Pain is elicited on iliac compression, being felt on the affected side.

The x-ray changes seen in tuberculosis of the sacroiliac joint are atrophy of the bone on the adjacent margins of the sacroiliac joint and scalloping of the articular margins of the joint due to subchondral abscesses. The differential diagnosis must exclude the complaints of lumbosacral and sacroiliac strain and the intervertebral syndrome. Sciatica is frequently complained of by patients with this disease. Other types of infectious processes must be ruled out.

The usual supportive measures should be used and the patient should be treated in the recumbent position. The back and hips are immobilized by a bilateral hip spica cast and, later, operative fusion of the affected joint is undertaken either by the intra-articu-

lar or extra-articular routes when the disease process has shown evidence of subsiding.

Tuberculosis of the Hip. This type of tuberculous infection also is seen most commonly in children. It has been stated that 85 per cent of the cases occur in children younger than ten years of age. The remainder have approximately equal distribution in persons up to sixty years of age. In tuberculosis of the bones, the frequency of tuberculosis of the hip is second only to that of the spine.

The process may start as a primary synovial involvement or the original infection may lodge in the terminal vessels of the capital epiphysis of the femur or the marginal epiphysis of the acetabulum.

It is felt that trauma may be a localizing agent for the infection.

There may be three distinct types of the disease—acute, subacute and chronic. The symptoms vary accordingly.

The general symptoms of tuberculous infection are low-grade fever, malaise, loss of weight, anorexia and night sweats.

The local symptoms are limp and pain in the affected hip or pain referred to the knee. In children, night cries are occasionally noted. Deformity is frequently insidious. As a rule, abscess formation becomes apparent later in the disease. With the acute type, all symptoms are more pronounced, and with the rapid lysis of the bone, absorption of the femoral head or development of a "wandering acetabulum" may result.

X-ray examination frequently reveals capsular swelling with early decreased density of the adjacent portions of the ilium and acetabulum. Later, loss of joint space and gradual destruction of the femoral head or acetabulum, or both, are observed. The reaction to the tuberculin skin test may frequently be positive to the dilute strength of tuberculin. The diagnosis may be confirmed by aspiration and recovery of the bacilli either on smear, culture or guinea pig inoculation. Occasionally biopsy of the hip joint may be necessary for positive diagnosis.

The differential diagnosis of tuberculosis of the hip in children is frequently difficult. The more common hip afflictions which must be considered are: Perthes' disease; traumatic epiphysitis, low-grade osteomyelitis of the upper end of the femur; infectious arthritis; irritative lesions of the psoas muscle, seen occasionally in association with lymphadenitis in the iliac fossa, and arthrofibrosis (Luck).

Supportive measures previously described

Figure 154. Taylor type of back brace for support of spine.

Figure 155. Hip spica cast for immobilization of hip or knee

Figure 156 Extra-articular arthrodesis of the hip (healed).

should be used in conjunction with the chemotherapeutic drugs

Bed rest with immobilization of the affected hip, either by traction or hip spica cast (Fig 155), in the functional position should be instituted. This conservative treatment is reinforced by drug therapy until the patient shows evidence of general improvement with x-ray evidence that the disease process is arrested and improving. Efforts are made to maintain the red blood count, hemoglobin and serum protein at normal levels. When the sedimentation rate approximates normal, surgical treatment of the lesion may be considered.

Surgical fusion of the hip joint by intra-articular, extra-articular or combined methods may be considered at the point when the disease is under control. This is particularly warranted when there has been serious destruction of the articular cartilage. Operative fusion is undertaken maintaining the hip in a

functional position, which consists of approximately 25 to 45 degrees of flexion, neutral in regard to rotation, and 0 to 10 degrees of abduction (Fig. 156).

Following the operative procedure, the patient should continue to be kept in a protective cast for the period necessary to obtain solid bony union and the hip further protected for an additional six months to a year until solid healing has been completely obtained.

Tuberculosis of the Knee. Tuberculosis of the knee is the third most common type of osseous tuberculosis. It is predominantly a disease of children. Infection is secondary to pulmonary or gastrointestinal tuberculosis and the infection is considered to be blood borne. Bacterial emboli lodge in the epiphyseal cartilage and form tubercles. The infection enters the knee joint by extension along the capsular structures or directly through the articular cartilage. There are instances in which the infection may be primarily in the synovium and, when the infection enters the joint, the synovium becomes thickened and granulation tissue covers and destroys the articular cartilage. This goes on to a granulomatous process associated with tuberculous pus and produces a thick, boggy, swollen knee unaccompanied by heat or redness. Abscesses frequently develop.

The onset is usually marked by a slight limp with limitation of knee motion. This is followed by swelling of the joint associated with moderate pain and tenderness. The patient gradually develops a flexion deformity; the knee becomes progressively enlarged, boggy and painful. These symptoms are usually associated with the other general systemic manifestations.

The diagnosis of tuberculosis of the knee is aided by the knowledge of existing systemic tuberculosis. A positive reaction to the skin tuberculin test in early childhood also is suggestive. X-ray changes may or may not be present. If the disease is primarily synovial tuberculosis, the evidence will

be mild bone atrophy. In the more advanced disease of osseous tuberculosis, there is narrowing of the joint space, lytic destruction of the subchondral bone and fragmentation of the articular cartilage.

Positive identification of the tubercle bacillus in cultures from the aspirated material of the knee joint or from a guinea pig inoculated with the material confirms the diagnosis. When there is doubt as to the proper diagnosis, a tissue biopsy may be the only means of obtaining a positive diagnosis.

Tuberculosis of the knee may occasionally be difficult to differentiate from chronic synovitis, atrophic arthritis, rheumatic fever in children, low-grade pyogenic arthritis and hemophilia, with repeated bloody synovial effusions.

The usual supportive measures as previously described for other osseous forms of tuberculosis are essential.

Complete rest of the affected joint in the position of function is desirable. Immobilization of the knee may be obtained by either traction or a hip spica cast. If deformity has developed before the treatment is undertaken, it is necessary to correct the flexion deformity.

In the great majority of patients, bony ankylosis for a permanent cure is desirable. After the acute disease process has been brought under control with the supportive measures of proper drugs, heliotherapy, rest and immobilization, operative fusion of the knee is desirable, especially in adults.

Surgical arthrodesis is usually of the intra-articular type with removal of the synovium and articular and semilunar cartilages. The freshened bone ends are shaped and brought into contact. The patella is frequently used as a bridge graft from the femur to the tibia. The knee is fixed in a position of function somewhere between 145 and 170 degrees of extension, depending upon the type of occupation and the age of the individual. In children, it is advisable to fix the knee in more extension as further growth of the lower femoral epiphysis will tend to cause the knee to grow into flexion.

Occasionally, in patients with synovial tuberculosis who are seen quite early in the course of the disease, arrest and cure of the process may be effected without surgical management, however, this is extremely rare and one should watch these patients carefully for exacerbation of the disease process on resumption of activity.

Operative fusion may take from four to nine months to solidify and should be pro-

tected during this period with a long leg hip spica cast, subsequently supported by a caliper brace to avoid weight-bearing until complete bony union is obtained.

Tuberculosis of the Ankle and Foot. Tuberculosis of the ankle and foot is more common in males than in females and is not common in children under ten years of age.

The primary lesion in tuberculosis of the ankle and foot is most frequently osseous when it occurs in children and synovial when it occurs in adults. Occasionally, tuberculosis in the foot starts as tenosynovitis and subsequently enters the tarsal joints because of the intimacy of the tendons to these joints. There is a tendency for the infection to spread and it may involve the entire tarsus. Abscess formation in tarsal tuberculosis is extremely common.

When the infection remains restricted to the ankle or to one tarsus, the prognosis is good. When there is evidence of multiple infection and sinus formation, the prognosis becomes extremely poor and amputation may be the treatment of choice to prevent general spread of the infection.

In the child, conservative treatment with immobilization for at least twelve months is indicated, with the cast extending from the toes to above the knee with the foot in a functional position. When a single joint is involved, arthrodesis of the involved joint may be accomplished when the disease process shows evidence of being under control.

Extra-articular arthrodesis in tuberculosis of the ankle may be accomplished satisfactorily with a good end result provided there has not been too extensive destruction of the joint.

In patients having fulminating tarsal tuberculosis, early amputation may be necessary because of the great tendency for the disease to metastasize to other parts of the body.

Tuberculosis of the Shoulder. Tuberculous infection of the shoulder is most often of the chronic type (*caries sicca*) and involves the bone rather than the synovium of the joint. There is frequently no enlargement of the joint. This type of tuberculosis does not have the tendency to abscess formation.

The history is that of gradual onset of pain in the shoulder with progressive loss of motion. If an abscess forms, it usually points anteriorly. The diseases is usually associated with active pulmonary tuberculosis. The clinical picture of pain in the shoulder with

Figure 157 Shoulder spica cast.

gradual loss of motion associated with tuberculous processes in other portions of the body, accompanied with x-ray changes, aids in the diagnosis.

Differential diagnosis consists in ruling out the possibility of chronic subdeltoid bursitis, adhesive capsulitis and rheumatoid arthritis.

The frequent occurrence of nontuberculous adhesive capsulitis in patients with pulmonary tuberculosis under treatment with bed care is well known and it is a constant source of disturbance to the clinician to exclude the possibility of active tuberculosis of the shoulder in these patients.

Tuberculosis of the shoulder is treated by immobilization of the shoulder in a plaster spica cast with the shoulder held in a position of function of approximately 65 degrees of abduction, 35 degrees of forward flexion and 35 degrees of external rotation (Fig. 157). The patient is treated, as in other forms of osseous tuberculosis, in the position of rest until the disease process has come under control and evidence of other foci of tuberculosis does not contraindicate surgical management. Then operative fusion of the shoulder is indicated. Combinations of intra-articular and extra-articular types of arthrodesis are performed and, following the operative procedure, immobilization in a shoulder spica cast is continued until solid bony fusion is obtained. Occasionally, metallic internal fixation may be used, transfixing the head of the humerus to the glenoid process of the scapula, to provide stability while bony union is occurring. The functional result of arthrodesis of the shoulder is quite satisfactory when the shoulder has

been fused in the proper position. The mobility of the scapula on the thoracic cage allows for adequate movement of the arm up to a point of approximately 90 degrees of abduction and will enable the patient to get the hand to the head and mouth.

Tuberculosis of the Elbow. As in other types of osseous tuberculosis, this infection usually starts in the bone. The infection then extends to gradually involve the joint proper. Tuberculous infection of the elbow is more common than that of the shoulder and carries the best prognosis of any joint which may be involved by tuberculosis with regard to healing with some residual useful motion.

The usual symptoms are gradual swelling, pain and stiffness about the elbow, with doughy thickening of the elbow joint which may go on to abscess formation. Motion is painful.

If treatment is instituted early with immobilization and general supportive measures, the prognosis is good for healing and, if the disease occurs in childhood, useful motion may be obtained after healing is complete. In adults, it may be necessary to undertake operative fusion as a final definitive course of treatment. In some instances, extra-articular fusion may be accomplished with bone grafts extending from the humerus to the olecranon.

With surgical arthrodesis of the elbow, the arm should be maintained in a functional position with the elbow at a right angle and the forearm in midposition in regard to pronation and supination.

Tuberculosis of the Wrist. Tuberculous infection of the wrist is not common. It is usually secondary to infection of the carpus or metacarpal bones with extension into the wrist joint. The disease is frequently quite disseminated throughout all the carpal bones and, because of the superficial nature of the wrist joint, the swelling becomes quite marked. The symptoms of the disease are manifested by pain, swelling and restricted motion of the wrist. Frequently there is a flexion contracture of the wrist and there are large fusiform swellings extending in the tendon sheaths above and below the carpal ligament.

Carpal tuberculosis occurs in adults rather than in children and is associated with other tuberculous infections. Positive diagnosis can be rather readily obtained by aspiration of the joint and demonstration of the organism.

The prognosis in tuberculosis of the wrist must be somewhat guarded. General systemic treatment is indicated, but with drug

therapy. The wrist should be immobilized in a long arm cast and held in a functional position of 20 to 30 degrees of dorsiflexion, with the forearm in midposition. The cast should incorporate the elbow to eliminate motion at the distal radioulnar articulation.

After the disease has become quiescent, arthrodesis of the wrist may be achieved by operative procedure. A cancellous bone graft should extend from the radius to the metacarpal bones. It is preferable to delay operative treatment until the local process has become quiescent.

Bursal Tuberculosis. A bursal type of tuberculosis may be encountered in which there is a primary infection of the gluteal bursa lying over the greater trochanter of the hip. This occurs as primary tuberculosis and is manifested by pain and discomfort about the hip with local swelling. In the earlier stages, the bone is not involved, but, secondarily, the trochanter may become involved.

Positive diagnosis is made by aspiration or biopsy.

Treatment of this condition consists of the

general supportive measures as previously outlined and early surgical excision of the trochanteric bursa. If the bone of the trochanter is involved, partial excision of the greater trochanter may be undertaken. If the soft tissue or early bone infection is not treated, the disease may progress ultimately to involve the hip joint with much more serious results. This type of tuberculosis is one which is seen in adults.

There are rare occasions of tuberculosis of the metaphysal portion of the bone without involvement of the joints.

Tumors of the Bones, Joints and Soft Parts of the Extremities

By MURRAY M. COPELAND, M.D.,
and CHARLES F. GESCHICKTER, M.D.

MURRAY MARCUS COPELAND was educated at Oglethorpe University in his native state of Georgia. Graduating in medicine from Johns Hopkins University, he became a fellow in surgical pathology. This interest led him logically into the field of tumor surgery in which he developed his talents further at Memorial Hospital, New York, and Union Memorial Hospital, Baltimore.

CHARLES FREDERICK GESCHICKTER graduated from George Washington University and Johns Hopkins University. He is a product of the well-known school of surgical pathology developed in the surgical laboratory of Johns Hopkins made famous by Joseph Bloodgood. He is one of the few pathologists who have combined the discipline of pathology with the clinical application of its principles.

In appraising any method of therapy, it is necessary to know the essential pathology, the natural history of the disease and what influence specific therapy may have upon it. The classification of bone tumors based upon the relation of bone development and subsequent tumor formation separates the tumors into specific types, each of which follows a

definite course. A survey of these groups reveals the effect of treatment more accurately than would be possible otherwise and prognosis is thus placed upon a sound basis.

A brief survey will be given of each group, the treatment used and, where irradiation seems of benefit, the physical agent used. No comprehensive rule can be laid down as to

Classification of Bone Tumors*

whether a tumor process is radiosensitive. Experience has been our best teacher as to the behavior of tumors under radiation by radium, x-rays or radioisotopes.

They are not radiosensitive. Isolated tumors of this origin have been affected by irradiation or have been treated successfully using irradiation as an adjunct to surgery.

TUMORS OF OSSEOUS ORIGIN

In general, surgery offers the best method of treatment in tumors of osseous origin.

CARTILAGINOUS TUMORS

Osteochondroma (Exostosis). This tumor presents a surgical problem when treatment

is indicated. It forms the largest group of benign tumors arising from precartilaginous connective tissue in the skeleton and is found most frequently near the ends of the long bones of patients between the ages of ten and twenty-five years. The other sites of importance are the bones of the thoracic cage

and the small bones of the foot and hand. The distinctive diagnostic features include the pedicle of normal bone protruding from the bone cortex and the rim of cartilage overlying it. A similar structure may be seen microscopically. The roentgenogram demonstrates the characteristic differentiation of the tumor

Figure 160 Roentgenogram showing osteochondroma of the sessile type. Note the widened metaphysal region near the outgrowth of the tumor. The features of the growth depicted are typical.

of bone and an overlying cartilaginous cap flecked with calcium (Fig. 160). Instances of single osteochondromas without symptoms frequently go unnoticed. The tumor may be left untreated but should be watched by interval roentgenographic examination, since it may undergo secondary malignant change, particularly after the patient reaches the age of thirty years. Simple excision usually suffices to cure the osteochondromas which produce pain or dysfunction. Secondary malignant change occurs in about 8 per cent of these neoplasms.

In *hereditary or multiple osteochondromas* (Fig. 161), the regions most frequently and severely affected are those of the forearm and leg, the bones of which may be fused at one point. The prognosis as far as life is concerned is good, but there is no adequate form of treatment, except operation, for correction of deformities and removal of osteochondromas causing pain or dysfunction. In a few of the patients with multiple skeletal involvement, secondary malignant change is observed in one or more cartilaginous growths microscopically showing chondromyxosarcoma. Resection or amputation when necessary is the treatment of choice.

Chondroma. Chondroma, a common type of central cartilaginous tumor, is often classi-

Figure 161 Roentgenogram of hereditary deforming chondrodysplasia or multiple exostoses. Note the widening of the metaphysal regions of the long bones and tendency to develop outgrowths of osteochondromas.

Figure 162. Photomicrograph taken from the margin of the central chondroma of the phalanx seen in Figure 164. The tumor is composed of adult hyaline cartilage.

Figure 163. Roentgenogram of a large central chondroma of congenital origin occurring in a long bone. The defect shows longitudinal streaking, destruction of cortex and calcareous stippling, typical of chondroma. See Figure 164 for benign osteochondroma of the phalanx.

fied with benign exostoses or osteochondromas. It occurs in the small bones of the hands and feet, also in the long bones, spine, ribs and sternum. In the small acral bones

the tumor is composed of radiolucent cartilage and appears as a central lesion with rarefaction. It is visible in the roentgenogram as a cystic area, flecked with circumscribed, dense areas of calcification, within a shell of cortical bone. Histologically a central area of cartilage with orderly arrangement of cells is usually seen (Fig. 162). In some chondromas, fetal cartilage may be present in varying amounts. The lesions are rarely multiple and occasionally affect long bones (Fig. 163). In deciding whether a particular chondroma is to be treated from the benign or malignant standpoint, the location, rather than the pathologic changes, is given primary consideration. Lesions in the small bones of the hands and feet may be looked on as benign and curable by thorough extirpation by curettage and chemical cauterization (Fig. 164). Only rarely has a central chondroma of the phalanges, metacarpals or metatarsal bones shown malignant propensity. True chondromas of large size occurring about the sternum or in the long bones must be looked upon as potentially malignant. They should be removed if possible. Roentgen ray or telerradium therapy has been of benefit in retarding the growth in a few cases.

Maffucci's syndrome, or *dyschondroplasia* with hemangiomatosis, is a nonhereditary mesodermal dysplasia. Skeletal development may be retarded on one side or in individual bones, principally the bones of the extremi-

ties, thoracic cage, pelvis and vertebrae. Multiple central chondromas made up of fetal cartilage, associated with soft-part hemangiomas, are observed in the affected bones. The soft-part angiomatous tumors are cavernous to cellular in morphology and appearance. The deformities may appear in early life, becoming stationary in the second decade. Trivial injuries may cause fractures through the chondromatous areas. The patients present marked bone and soft-part deformities, occasionally requiring amputation of an extremity for comfort, because of loss of function.

Chondromyxoid Fibroma. This is a recently described benign tumor which appears to be a variant of central chondroma which arises from blastemal tissue (cartilage-forming connective tissue). The lesion is usually situated in the metaphysial region of a long bone, with the tibia and femur contributing more than half of the chondromyxoid fibromas seen. The small bones of the hands and feet occasionally reveal a similar process. The majority of patients affected fall within the first three decades of life. Pain is the chief symptom and, occasionally, palpable swelling is noted. The roentgenogram characteristically reveals an eccentric, sharply cir-

cumscribed, rarefied defect. The cortex may be completely destroyed, with or without a faint periosteal reaction (Fig. 165). Trabeculae may be seen traversing the defect. Calcific deposits are usually not visualized, in contrast to those seen in roentgenograms of central chondromas. Histopathologic study reveals fibrous, myxomatous and early forms of cartilaginous tissue (Fig. 166). The cells, in some cartilaginous portions of the tumor, may show bizarre nuclei of irregular shape and size. The periphery of the tumor may have a concentration of nuclei. Collagen changes of varying degrees are seen.

Where possible, the treatment of choice consists of en bloc resection of the affected portion of bone. In some lesions curettage, followed by chemical cauterization with or without insertion of bone chips, is carried out with good results.

Chondroblastoma--Benign and Malignant. Chondroblastoma arises from a proliferation of cartilage at the epiphysial line and usually occurs in persons between the ages of ten and twenty years. It is most frequently found about the upper end of the tibia, the lower end of the femur and the upper end of the humerus. Symptoms of pain, tumor and

Figure 164 Roentgenogram of central chondroma occupying the middle phalanx of the index finger. Note the thinning of the cortex and faint calcific deposits within the tumor area, successfully treated by curettage and chemical cauterization.

dysfunction average five months in duration prior to operation.

In the roentgenogram, there is a characteristic mottled cystic area of bone destruction, with expansion of the bone shell and usually some periosteal reaction (Fig. 167). Not infrequently the tumor bears a marked similarity to giant cell tumor. Microscopically,

one sees masses of young cartilage cells of chondroblastic type with areas of uncalcified matrix. Zones of chondroid material are present with characteristic lace-like calcification about residual lacunae. Some areas resemble adult hyaline cartilage. The tumor has areas of marked vascularity. About the vascular areas and the periphery of the cartilage, numerous giant cell osteoclasts are seen (Fig. 168).

Some of these tumors show malignant degeneration, differentiated from the benign lesions only by histopathologic study. Many investigators separate the benign tumors from the malignant variety, placing the latter with the chondrosarcoma group.

Radium or roentgen ray therapy is recommended in the benign lesions following exploration and curettage unless the tumor occurs in a bone which can be resected without sacrifice of function. The malignant variety of chondroblastoma has been uniformly fatal despite primary amputation.

Chondrosarcoma and Osteogenic Sarcoma. These include several subvarieties of malignant tumors which may arise either subperiosteally or centrally in the skeleton from

place and disrupt the pre-existing bone. They are characterized in the roentgenogram by varying degrees of bone destruction, new bone formation, and periosteal reaction. When bone formation predominates, the tumors are referred to as sclerosing or osteoblastic osteogenic sarcoma. When bone destruction predominates, the tumors are highly vascular and are referred to as osteolytic or telangiectatic osteogenic sarcoma. When cartilage rather than bone formation or destruction predominates, the tumors are called chondrosarcomas. Primary chondrosarcoma refers to a malignant tumor which affects pre-existing normal osseous structures. Secondary chondrosarcoma refers to similar tumors which arise in pre-existing osteochondromas or chondromas.

All forms of chondrosarcoma and osteogenic sarcoma are more frequent in the long bones, especially in the end of the femur, tibia and fibula about the knee joint. They tend to occur in the adolescent or postadolescent period. Sclerosing osteogenic sarcoma and primary chondrosarcoma are largely limited to members of this age group. Osteolytic and secondary chondrosarcomas tend to have a wider age distribution. Regardless of the subvariety or the point of origin, all forms of osteogenic sarcoma tend to affect

the cancellous, cortical and periosteal structures of the affected bone. The roentgenogram shows increased density, rarefaction or mottling, and the periosteal zone near the tumor infiltration shows lipping and elevation due to the density of reactive bone formation and the disease beneath it.

The patient usually suffers pain, swelling and lameness in the affected part. The symptoms are of increasing severity and vary from six weeks' to six months' duration. Trauma is usually coincidental with exacerbation of symptoms rather than being of etiologic significance. There may be a mild degree of fever and leukocytosis. Tenderness, swelling and limitation of motion are often apparent on physical examination. Skin changes and regional adenopathy are not present in patients with early disease. The tumors tend to metastasize to the lungs more often than to the lymphatics.

Adequate roentgenologic examination and surgical biopsy, under tourniquet, are the only definitive diagnostic procedures. None of the subvarieties of chondrosarcoma or osteogenic sarcoma are cured by radiation. Radical surgery (amputation, occasionally resection) is the treatment of choice. The five-year survivals vary from 10 per cent to 30 per cent.

Primary chondromyxosarcoma arises chiefly in young patients (aged fourteen to twenty-one years) and at the sites where tendons insert directly into the bone. The favorite sites are about the knee, the lower femur or upper tibia and also at the shoulder and pelvic girdles. Symptoms of pain average five months in duration before examination. Examination reveals swelling, usually rubbery in consistency. Pathologic fracture is extremely rare. The neoplasm is composed of tumor cartilage, some ossification and areas of cystic destruction.

In the x-ray film, the growth appears as a subperiosteal shadow streaked with calcium spicules. It does not involve the cortex until late in the disease, causing bone destruction (Fig. 169). Five-year cures in this group average 15 per cent. Most surviving patients have no further growth of the tumor and reduced soft part swelling.

Secondary chondrosarcoma arises from a pre-existing chondroma or osteochondroma, occasionally complicating Paget's disease and hereditary chondrodysplasia. Most of the patients are between the ages of thirty-five and fifty-five years. The tumor shows a tendency to occur about the upper humerus,

dysfunction average five months in duration prior to operation.

In the roentgenogram, there is a characteristic mottled cystic area of bone destruction, with expansion of the bone shell and usually some periosteal reaction (Fig. 167). Not infrequently the tumor bears a marked similarity to giant cell tumor. Microscopically,

one sees masses of young cartilage cells of chondroblastic type with areas of uncalcified matrix. Zones of chondroid material are present with characteristic lace-like calcification about residual lacunae. Some areas resemble adult hyaline cartilage. The tumor has areas of marked vascularity. About the vascular areas and the periphery of the cartilage, numerous giant cell osteoclasts are seen (Fig. 168).

Some of these tumors show malignant degeneration, differentiated from the benign lesions only by histopathologic study. Many investigators separate the benign tumors from the malignant variety, placing the latter with the chondrosarcoma group.

Radium or roentgen ray therapy is recommended in the benign lesions following exploration and curettage unless the tumor occurs in a bone which can be resected without sacrifice of function. The malignant variety of chondroblastoma has been uniformly fatal despite primary amputation.

Chondrosarcoma and Osteogenic Sarcoma. These include several subvarieties of malignant tumors which may arise either subperiosteally or centrally in the skeleton from the bone-forming tissues and produce bone, cartilage, osteoid material or preosseous connective tissue. These malignant tumors dis-

shaft regions of the long bones. It seems to be related to the formation of cancellous bone which normally follows in the wake of calcified cartilage.

Clinically, the tumor is usually observed about one year after the beginning of symptoms, which are not characteristic. Many of the patients show a sequence of symptoms

including pain, tumor, limp and fracture. The tumor has a wide age distribution, being most frequent in young adults. It has an unusual tendency to involve the shaft of bones and to produce a pathologic fracture.

The roentgenograms may be hard to interpret and the findings are often confused with those due to benign bone cyst, giant cell tumor, metastatic carcinoma and Ewing's tumor. The distinguishing features in the x-ray film are the melting away and perforation of the bone shell at an early stage when the lesion is asymmetrically located, the presence of a periosteal reaction and a slight degree of cortical expansion. In advanced cases, osseous destruction leaves little doubt of malignant change in the bone (Fig. 171).

External irradiation is an effective form of palliative therapy, but amputation only has permitted five-year survivals without disease (10 per cent).

BENIGN LESIONS OF FIBRO-OSSEOUS ORIGIN

Osteoma and Ossifying Fibromas. These growths usually occur in children or young adults in the frontal or parietal bones of the skull, in the bony walls of the frontal or maxillary sinuses and in the mandible. These tumors may be quite deforming and produce pain or pressure symptoms when they grow to large proportions.

The more rapidly growing osteomas are composed of cellular fibrous tissue in which small, round osteoid bodies are formed. The

Figure 170 Roentgenogram of sclerosing osteogenic sarcoma arising on the lateral aspect of the lower femur. The tumor mass is seen arising subperiosteally, causing a dense extracortical shadow.

Figure 171. Roentgenogram of osteolytic osteogenic sarcoma involving the lower end of the femur with marked destruction of the medial cortex, rarefaction of regional bone shaft and pathologic fracture. There is moderate periosteal reaction.

ribs, femur and heel. There may be a history of rheumatic pain for years with subsequent evidence of growth potential followed by pain, swelling or pressure phenomena.

In the x-ray picture, this tumor is most easily diagnosed when a portion of the primary lesion still remains and when the superimposed malignant change appears as a fuzzy infiltrating periosteal shadow flecked with calcium. Destruction of the cortical bone follows, occasionally with pathologic fracture.

The relative benignity of the lesion plays an important role in its cure, which is by means of resection or amputation. Irradiation may be of benefit as an adjunct to surgery. Thirty per cent of patients treated by radical surgery have passed the five-year survival period free of disease.

OSSEOUS TUMORS

Osteoblastic Osteogenic Sarcoma. This is the most highly differentiated type of osteogenic sarcoma. Fibrous elements may predominate microscopically, but usually proliferation of malignant osteoblasts and new

bone formation are seen, with rare islands of cartilage. This tumor is most frequent in persons between the ages of fifteen and twenty-five years and is usually situated in either the lower end of the femur or the upper end of the tibia. Other locations are the upper humerus, ribs, vertebrae and pelvis. The disease runs a fairly acute course with pain, tumor and dysfunction, perhaps preceded by trauma. The average duration of symptoms is ten months.

The x-ray picture is characterized by dense, radiating, new bone in the periosteal zone, giving a "sun-ray" appearance. Later the medullary cavity is obliterated by tumor bone, with some secondary destruction of the cortex (Fig. 170).

Cell differentiation of the tumor process plays an important role in the prognosis.

Radical extirpation by amputation or resection is the procedure of choice. The lesion is not radiosensitive. Cures have been achieved in 21 per cent of the patients.

Osteolytic Osteogenic Sarcoma. This is a destructive tumor arising in the region of the marrow cavity near the ends or in the mid-

Parosteal Osteoma and Myositis Ossificans.

Parosteal osteoma is a rare lesion composed of ossifying fibrous tissue and sometimes cartilage or myxomatous tissue. The tumor grows at a slow rate, giving rise to symptoms of tenderness, pain and ultimate dysfunction. A palpable lump is felt when the symptoms are first manifest or shortly thereafter. The roentgenogram reveals an ossifying mass, usually of considerable size, extending out into the soft parts with or without intimate connection to the neighboring bone (Fig. 174). A common site of this tumor is the region of the *l. femur*.

The tumor may be intermingled in areas which suggest osteolytic sarcoma. Close observation of the nuclei, however, is necessary to determine whether the lesion is benign. In a number of instances, malignant changes in the tumor may supervene and require amputation to eradicate the disease. In those tumors which appear to be benign, radical excision should be carried out, followed by intensive x-ray therapy. If renewed growth is seen, amputation must be performed because of eventual malignant change in these tumors.

Circumscribed *myositis ossificans* may be divided into the traumatic and atraumatic forms arising about the thigh, arm, elbow, neck and lumbar muscles. Occupation plays little or no role in the case histories studied. Injury is definitely an important factor in

60 per cent of the lesions. The age incidence varies between ten and seventy-two years. The earliest physical sign after injury is the development of a soft, compressible mass which soon becomes indurated. Bone may be detected in the roentgenogram within three weeks after the onset of the tumor formation. Small dense areas of calcification soon assume large proportions, forming a large spicule of bone, usually separated from the shaft of the neighboring bone (Fig. 176). Many lesions gain their maximum growth in six weeks or more and then spontaneously regress or become quiescent.

Histologically, degeneration of muscle, hyperplasia of connective tissue and organization of hemorrhage are early findings, while osteoid tissue with marrow spaces, osteoblasts about spicules of bone, occasional islands of cartilage (30 per cent of cases) and benign myxomatous tissue represent fully developed myositis ossificans. Malignant changes may complicate myositis ossificans, but these are exceedingly rare. Occasionally the disease is confused with parosteal osteoma.

Myositis ossificans progressiva, a special form of the malady, usually begins in childhood. It affects the spinal muscles primarily. As the name implies, it eventually involves the muscles of the entire skeletal system and is ultimately fatal.

Figure 174. Roentgenogram of a parosteal osteoma which reveals an ossifying mass extending out into the soft parts. Note the thickened cortex of the femur in the area.

Figure 175. Roentgenogram of a bone cyst in the shaft of the humerus. Note the central location with slight expansion of cortex. Trabeculations present suggest giant cell tissue activity.

Figure 172. Roentgenogram of an osteoid osteoma in the neck of the femur situated in the inferior intracortical zone. Note the discrete rarefied area with extensive sclerosis about it.

more slowly growing tumors form spongy bone and sometimes ultimately give rise to compact bone, frequently referred to as an eburnated osteoma. Roentgenographically they show a dense mass of new bone, smoothly outlined, with a sharply demarcated base formed by the thickened, slightly depressed inner table of the skull. When the tumor is present in the mandible, the roentgenogram reveals a radiolucence of regular contour projecting from the normal bony structure. The new bone is less dense than the normal bone. In the region of the antrum, the affected side shows increased density or cloudiness. In most instances, the tumor arises

outside the antrum and encroaches on the antral cavity or pushes downward toward the alveolar border, displacing the teeth downward. These lesions are often complicated by trauma or infection.

Osteoma and ossifying fibroma are benign tumors. Simple excision usually suffices to eradicate the disease.

Osteoid osteoma is a small, rarefying lesion, situated in a dense overgrowth of osteoblastic activity. The lesions are frequently found in the bones of the hands, feet, vertebrae and shafts of the long bones. The patients are usually young adults or adolescents. Localized pain is often the primary complaint and may be associated with tenderness without fever or leukocytosis. Individual lesions may persist for a period of months to one or more years before remedial action is taken. In the roentgenogram, a dense, sclerosing, opaque zone about a small oval or rounded area of rarefaction is seen (Figs. 172 and 173). The tumor may occur either as an intracortical lesion or in the cancellous portions of the bone.

The two principal theories on the nature of osteoid osteoma at this time are that the lesion is a primary neoplastic process of bone and that the process is inflammatory in origin. Another unverified interpretation holds that osteoid osteoma represents a healing area about a bone infarction of minute size. Local excision is adequate treatment for these lesions.

Figure 173. Low-power photomicrograph of an osteoid osteoma showing the central lesion composed of vascular fibrous tissue with proliferating fibroblasts in which trabeculae of new bone are found. The bone trabeculae about the lesion show increased thickening and proliferation.

A typical bone cyst discovered in the shaft of a long bone of a child as a result of pathologic fracture may be treated by simple splinting or surgical curettage and use of bone chips. Recurrence may take place following irradiation or curettage. If the lesion is explored, the lining should be stripped, the shell of bone crushed and the cavity obliterated with bone chips. The giant cell variant of the bone cyst responds well to deep x-ray therapy in moderate dosage. Latent bone cysts in adults usually require no treatment.

Diffuse Osteitis Fibrosa. While the term "osteitis fibrosa" is used loosely to refer to all types of cysts of the bone, there is now a tendency to restrict this term to a diffuse disease of the skeleton accompanied by adenoma or hyperfunction of the parathyroid glands. In such cases, the fundamental disturbance is a supersaturation of the blood serum with calcium, increased calcium excretion and a generalized demineralization of the bones. The blood calcium level may be elevated to from 13 to 20 mg. and the phosphorus lowered to 1 to 1.5 mg. per 100 cc. In isolated areas, the rarefied bones show localized cyst formation and, occasionally, giant cell tumors. In the x-ray examination, the diagnosis depends on evidences of diffuse osteoporosis, bending deformities and glob-

ular areas of cysts or tumor formation (Fig. 178).

In the diagnosis of this diffuse skeletal disease, determinations of the blood calcium and phosphorus values and also of the blood alkaline phosphatase value, which is elevated, estimations of the urinary excretion of calcium and demonstration of parathormone in the blood stream by the Hamilton rabbit test are important. If proper laboratory tests are carried out, confusion of this condition with metastatic carcinoma or multiple myeloma should not occur.

Treatment is directed at reduction of the parathyroid hormone output and recalcification of the skeleton. The parathyroids should be explored and the adenoma surgically removed. The patient should be placed on a high calcium and phosphorus diet, plus vitamin D.

Fibrous Dysplasia. There are two forms of fibrous dysplasia, the diffuse or polyostotic form, and the monostotic form.

In the diffuse or multiple form of fibrous dysplasia, the disease involves multiple bones in young individuals on one or both sides of the body. Albright and his coworkers have emphasized the extraskeletal features of the disease, which include pigmentation of the skin and endocrine dysfunction in girls, in the form of sexual precocity and hyperthy-

Figure 178 Roentgenograms of bone lesions in the lower femur, lower humerus, radius, ulna and bones of the hand associated with hypoparathyroidism. There is evidence of expansion of the bone sheath due to depletion of calcium and phosphorus.

Figure 176. Roentgenogram depicting myositis ossificans. Large calcified shadow noted paralleling cortex and separated from it when viewed stereoscopically.

A conservative form of treatment is desirable in the majority of patients with circumscribed myositis ossificans. Postoperative recurrences are frequent if surgical removal is employed too early (under six months) or if excision has been inadequate.

There are isolated patients who have had successful regression of recurrence following therapeutic dosages of x-rays. Insufficient experience with this agent in myositis ossificans prevents any final evaluation of the results.

RESORPTIVE TUMORS

Benign Bone Cyst. In children under fifteen years of age, a benign bone cyst occurring in the upper metaphysis of the humerus, femur or tibia is one of the commonest tumors of bone. Frequently, pathologic fracture is the first indication of the presence of the disease. Mild pain or dysfunction, running a chronic course over a period of two or more years, may be elicited in taking a careful history. When roentgenograms are made, a central defect appears, surrounded by an intact and symmetrically expanded cortex. The cavity in the bone is traversed by irregular trabeculae of dense fibrous tissue (Fig. 175). When a pathologic fracture is

Figure 177. Roentgenogram of a bone cyst on the shaft side of the epiphysal line in the upper end of the humerus. Note the trabeculated cystic area with expansion of bone shell and fracture through the thinned cortex.

present, signs of reossification are seen. Exploration discloses a cyst containing fluid, enclosed by a wall of osseous and fibrous tissue. Under the microscope, the proliferation of connective tissue and new bone formation suggest a healing reaction. Smaller cavities, when present, contain the remains

of a large cavity, a rare subvariety.

Cysts immediately adjacent to the epiphysal line on the shaft side (Fig. 177), which have been present for less than a year, show an even greater amount of vascularity and more numerous giant cells than are seen in polycystic osteitis fibrosa. These giant cell variants of bone cysts are to be distinguished from true giant cell tumor by their occurrence on the shaft side of the epiphysis in patients under twenty years of age. The prognosis is far better than in a case of typical giant cell tumor and the patient will respond more readily to curettage or deep x-ray therapy.

Arrest in the growth of a bone cyst without complete healing and obliteration of the cavity is accountable for the latent bone cyst seen in adults. These latent cysts are symptomless and are usually found accidentally in a routine x-ray examination.

Figure 180. Roentgenogram of a benign giant cell tumor of the lower end of the radius. Note the asymmetrical position of the lesion in the epiphyseal zone. Trabeculae are seen within the cystic area and the bone shell is perforated.

irradiation and the occasional contractures about the joints, have brought back into favor treatment by curettage, advocated by Bloodgood. Recurrent giant cell tumors in the ulna, fibula or radius should be resected.

Extraskeletal Giant Cell Tumors. A lesion similar pathologically to the benign giant cell tumor which occurs about deciduous teeth on the gums is known as giant cell epulis. Tumors of this type are seen in children or in young adults and are related to the normal loosening of the roots of the milk teeth by odontoclasts. Their treatment is similar to that just described for giant cell tumor, namely, curettage and cauterization.

TUMORS OF NONOSSEOUS ORIGIN TUMORS OF MARROW AND HAVERSIAN SYSTEMS

Ewing's Sarcoma (Endothelial Myeloma). This malignant tumor, which arises intracortically or subperiosteally, occurs in the first two decades of life; it involves the metaphysis primarily, most often affecting the long pipe bones, especially the tibia and femur. The disease never involves the epiphysis primarily. It shows the usual symptoms of pain and tumor, followed by dysfunction.

In the roentgenogram a widening of the shaft, with increase in cortical structure and onion-peel periosteal reaction, is an early finding followed later by varying degrees of

bone destruction (Fig. 181). Microscopically the tumor is composed of small, round cells with dense nuclei and scanty cytoplasm simulating a lymphosarcoma (Fig. 182).

Irradiation provides a good therapeutic test and the best available palliative therapy. Irradiation alone, however, is not sufficient to control the disease in the majority of cases.

A review of our patients, the Bone Sarcoma Registry cases and the cases of Coley leads to the conclusion that combined preoperative irradiation (Coutard method) in full therapeutic dosage, followed by amputation or radical resection, gives the best results (9 per cent five-year survivals).

Primary Reticulum Sarcoma of Bone. In our opinion, tumors described under this category are controversial as to origin. For the sake of completeness, however, a description of the process is included as distinct from Ewing's sarcoma, although we believe it to be an atypical form of the tumor first described by Ewing. Parker and Jackson first described primary reticulum sarcoma of bone as a separate entity.

Reticulum cell sarcoma of bone arises in both the long and flat bones but is commonly found involving the metaphysal portion of a long bone. Fifty per cent of the patients are under the age of forty years, though the disease is found in patients up to the eighth

Figure 179. Roentgenogram of monostotic fibrous dysplasia showing extensive bowing of the tibia and thinning and expansion of the cortex. Note the polycystic rarefaction traversed by many trabeculae.

roidism. These manifestations are not present in all patients. On roentgenographic examination, the bones are seen to be bowed and rarefied, with thinning and expansion of the cortex (Fig. 179). Pathologic fractures occur. The pathologic changes show the interior of the bone to be replaced by fibrous tissue of a gray or yellowish color, which may contain islands of calcification, cartilage, ossified bone or small cysts.

In monostotic fibrous dysplasia, the first evidence of the disease is usually a local swelling with occasional tenderness or pain of an arthritic character. Pathologic fracture may be the first sign of the disease. The lesion appears either to grow slowly or to remain stationary. Cutaneous and endocrine abnormalities are lacking. The flat as well as the long bones may be affected. The roentgenogram shows areas of radiolucency and/or expansion of bone shaft, sometimes traversed by delicate trabeculae of bone in the long bones. These changes may be centrally or eccentrically located, especially in the metaphysial area of the long bones.

Fibrous dysplasia is frequently recognized at the beginning of the second decade, though most often it comes under observation in the third decade. It appears to be a chronic disease, persistent throughout life.

All fibrous dysplasias are apparently true

dystrophies in which the tendency to normal ossification is prevented by a fundamental local disturbance yet to be demonstrated.

Surgical excision is justified in lesions which give rise to symptoms or interfere with functional activity. Resection or thorough curettage should be performed; incomplete removal leads to recrudescence of the process. Irradiation is given without benefit.

Giant Cell Tumor. Adults, usually between twenty and thirty years of age, may have a tumor of bone which produces a globular area of rarefaction in the epiphysis of the lower femur, upper tibia or lower radius. There is a history of trauma, pain, swelling and occasionally pathologic fracture—the typical clinical picture of benign giant cell tumor of the long bones. In the x-ray picture, the tumor produces a more or less circular defect, asymmetrically situated in the epiphysis, overlaid by a thin shell of bone, which is usually perforated at one or more points (Fig. 180). If the tumor persists without treatment for a period of more than fourteen months after the onset of symptoms, extension into the soft parts is the rule. Under a microscope, many large multinucleated cells are seen embedded in highly vascular stroma with small round and spindle cells. Histogenetically the tumor is related to the resorption of calcified cartilage by giant cells, which occurs as a step in normal growth of bone in the region of the epiphysis until late in life. Healed giant cell tumors, following irradiation, show the formation of a typical bone cyst. This and other pathologic considerations indicate that the bone cyst and giant cell tumor are closely related lesions; the two may coexist in von Recklinghausen's disease of the bones.

In the first two decades of the present century, the standard treatment for giant cell tumor was curettage followed by chemical (50 per cent zinc chloride) or thermal cauterization. Satisfactory results were obtained in about 70 per cent of the patients. About a decade ago, irradiation was introduced as a method of treatment. Fractionated deep x-ray therapy results in satisfactory reossification in many instances. This treatment does not afford microscopic confirmation of the diagnosis and sarcoma may masquerade under the diagnosis of giant cell tumor. Moreover, repeated courses of irradiation over a period of one or more years may result in malignant transformation with the development of osteogenic sarcoma at the tumor site. Such errors in diagnosis, coupled with the long period required to

results with

ent in from 65 to 70 per cent of the subjects. The plasma proteins may be markedly increased.

Roentgen ray examination of the tumors reveals areas of bone destruction which appear as multiple punched-out defects, varying in size from that of a pea to that of an orange (Figs. 183 and 184). Pathologic fracture occurs in 62 per cent of the patients, a rib being most often affected. Microscopic study shows that the tumors are composed of plasma-like cells, each with an eccentric nucleus containing a spoke-like arrangement

of chromatin. There is a very scanty amount of stroma.

Prognosis is uniformly unfavorable, though some patients have lived as long as seven years after the diagnosis was made. The prognosis seems to be little influenced by treatment, although roentgen ray or radium therapy may bring about remissions. The average duration of life is three years after the patient comes under observation. Among palliative measures other than irradiation is the administration of stilbamidine and Pentamidine in conjunction with a diet low in animal protein. More recently, urethane given in protracted dosages has shown promise in inhibiting the progress of the disease. In a few patients, radioactive phosphorus has relieved pain and retarded the disease for a limited time. Deep roentgen ray therapy is the most valuable form of treatment in bringing about symptomatic improvement.

Chloroma and the Leukemias. Chloroma is a rare form of bone disease usually involving the skull, vertebrae, spine, sternum, pelvis and long bones and associated with leukemia. There is a special tendency to infiltration of muscles and tendinous attachments near the affected bones. The disease usually occurs about the time of puberty. It frequently involves the orbital structures, causing exophthalmos. Enlargement of the lymph nodes, liver and spleen is also found. Roentgen ray examination reveals areas of bone destruction or areas of rarefaction. Occasionally a periosteal reaction may be seen. The tumor tissue is definitely green in color and on section shows an increase in fibrous stroma with a crowding of large, atypical monocytes everywhere. The disease seems to be a form of myeloid leukemia in which bone manifestations are a prominent feature. The process is radiosensitive and roentgen ray therapy is recommended for palliation.

Bone changes associated with *lymphatic* or *myeloid leukemia* are relatively rare. They frequently appear late in the disease. In *lymphoid leukemia*, bone changes are found more often than in the myelogenous variety. Apparently there is no correlation between the early development of changes in the bone and the duration of life after such changes appear. When bone manifestations are prominent and appear early, the diagnosis is apt to be confused with that of multiple myeloma or chloroma. The total white count usually remains low in these patients, varying from 5000 to 12,000 cells per cc. of blood. In lymphoid leukemia, the long bones are more frequently affected than

Figure 183 Roentgenogram showing multiple punched-out areas in skull typical of multiple myeloma, at times these defects may reach several centimeters in size.

Figure 181 Roentgenogram of Ewing's tumor located in the fibula. There is widening of the shaft with increase in the cortical structure and onion-peel periosteal reaction.

Figure 182 Photomicrograph showing the fibrous stroma and small round cells resembling lymphocytes seen in typical Ewing's sarcoma.

decade. Pain, swelling and subsequent disability are the cardinal symptoms.

Roentgenographically the lesions appear to be extensive but without characteristic appearance. Bone destruction is the predominant feature, giving the bone a mottled and worm-eaten appearance with occasional new bone reaction. Periosteal reaction is variable. The cortex may be thickened in about 25 per cent of the lesions seen. Grossly, extraosseous extension is often found in the metaphyseal region.

Microscopically the tumor is often difficult to differentiate from Ewing's sarcoma. Reticulum cell proliferation, demonstrated in the section, is considered crucial for making the diagnosis. Typical Ewing's tumor has proliferation of small round cells with no fibrous stroma.

Primary reticulum cell sarcoma, appearing as single lesions in bone, has a five-year survival rate of 40 per cent when adequately treated by surgical resection or amputation. Irradiation has also been effective in

ablating the disease in a large number of cases. A clear-cut indication for the use of either radiation or surgery cannot be defined at this time, except in those instances in which resection or amputation cannot be performed.

Multiple Myeloma. This rare and fatal condition, as the name implies, produces extensive involvement of the skeleton. The systemic manifestations are equally widespread. In adults, multiple foci of destruction are usually found limited in distribution to the red bone marrow. Rheumatic pains of increasing severity, usually in the back or lower limbs, discovery of a tumor by the patient, sharp pains following exertion, fracture after injury and general weakness with anemia are the cardinal features marking the onset of the malady. As the disease progresses, gradual collapse of the spine permits the lower ribs to sink to the pelvic brim, giving a characteristic habitus. The patient stands with protruding abdomen, flaring ribs, shoulders braced back and feet widely apart to assist in standing. The chin is thrust forward and may sink to the chest. Involvement of the spine and ribs is accompanied by radiculitis, paraplegia and emphysema of the lungs. Nephrosis with nonprotein nitrogen retention and low blood pressure, associated with an albuminous substance in the urine known as Bence Jones protein, is present.

Figure 187. Roentgenogram of anterior rib involved by eosinophilic granuloma. Note the expanded and thinned cortex with bone resorption extending along the rib.

frequently observed. Mild leukocytosis and mild eosinophilia are usually present. Radiologically the lesions in the bones are eccentric. Osteolytic and irregular defects are observed, quite well circumscribed or punched out in character. The cortex may be expanded or perforated (Fig. 187). Varying degrees of periosteal reaction may be observed. Histologically the lesions show sheets of eosinophils with varying degrees of fibrosis and histiocytes interspersed through the lesion. Surgical excision or curettage promotes healing. Mild roentgen ray therapy also will control the disease. Spontaneous healing is rare.

METASTATIC DEPOSITS

Metastatic Carcinoma. Metastatic carcinoma of bone is usually seen in late adult life. It affects the bones in an extremely variable manner. About half of the lesions may occur as a single focus in the ends of the long bones, producing a central area of bone destruction, while the other half may involve the skeleton diffusely, producing either osteolytic or osteoplastic changes. The source of the tumor varies, but the most frequent sites of the primary growths are cancer of the breast, hypernephroma, cancer of the prostate, cancer of the thyroid and some location in the female genitals or gastrointestinal tract. Solitary areas of metastatic carcinoma to bone occur most frequently in the spine

and in the upper end of the humerus or femur and are extremely rare below the knee or elbow. They may also involve the trunk or the skull. A central area of bone destruction, as seen in the x-ray film, rapidly increases and destroys the cortex outwardly from within, with little bone expansion. Multiple areas of skeletal involvement by metastatic tumors may also be osteolytic in character and central in location. Such lesions have a tendency to involve the pelvis and the spine, in addition to the upper ends of the humerus and femur (Fig. 188). Pathologic fracture is common. In the roentgenogram, metastases are visible as confluent and mottled areas of bone destruction in medullary locations. Osteoplastic involvement of the bones by skeletal metastases is most frequently a diffuse affair and, in addition to the absorption of bone always present, there is a laying down of irregular new bone of moderate density.

Roentgen ray therapy offers varying degrees of palliation in bone metastases. The disappointing results have stimulated investigators to seek other therapeutic measures. Testosterone and castration have proved beneficial in bone metastases from prostatic cancer. Radioactive phosphorus, combined with

Figure 185. Roentgenogram of tibia and fibula showing rarefaction with slight periosteal reaction, associated with chronic lymphoid leukemia. Such changes are less common with myeloid leukemia.

are the pelvis, skull or vertebrae. The roentgenogram reveals rarefaction in the long bones with a slight periosteal reaction (Fig. 185). Occasionally the changes resemble those due to an early Ewing's sarcoma. In the skull, osteoporotic changes, diffusely scattered, with neighboring periosteal elevation or thinning, form the characteristic picture. Microscopically the disease resembles lymphosarcoma or Ewing's sarcoma of bone. The involvement of other organs, however, is diagnostic when considered with findings in the blood. Fractionated doses of roentgen rays over the affected bones and lymph glands are excellent palliative therapy.

Granulomatous Lesions of Bone. This group of bone lesions is often associated with disturbances in lipid metabolism. Organs connected with the reticuloendothelial system reveal a variety of changes.

There appears to be a close relationship between Letterer-Siwe's disease, Hand-Schüller-Christian disease and eosinophilic granuloma. Further it seems logical to as-

gradations
ism and in
lipid histi-
ocytosis, is a rapidly fatal disease of infancy, seldom seen in individuals older than the age of two years. The clinical features are

Figure 186. Roentgenogram of upper tibia in a child with punched-out area associated with Hand-Schüller-Christian disease.

fever, skin rash, purpura, and rapidly developing and severe anemia. There is marked proliferation of cells in the reticuloendothelial system, namely, the spleen, lymph nodes and also lymphoid tissue in the skin. Bone lesions are encountered, identical with those of Hand-Schüller-Christian disease. Patients seen at this age invariably die.

Hand-Schüller-Christian disease usually makes its appearance in late infancy and is rarely seen after childhood. The clinical manifestations are variable. Exophthalmos, diabetes insipidus, pigmentation of the skin and splenomegaly may be observed. Bone changes are a constant finding and roentgenographically appear as large, rarefied defects, clearly demarcated in the skull and in other flat bones. Diffuse cystic areas may also be seen in the long bones, with thinning of the cortex (Fig. 186). There is no periosteal reaction. The blood picture may show severe anemia. Transfusions are frequently indicated during the period of active roentgen ray therapy. In the x-ray treatments, small divided doses are best tolerated. Many of these patients survive for an indefinite time with relative quiescence of the disease as they grow older.

Eosinophilic granuloma occurs in children and young adults. It is a relatively benign lesion localized in the skeleton. It frequently appears first as a single lesion arising in the medullary cavity, though often it may appear in multiple bones. A complete skeletal survey in all patients will probably reveal that it is a multiple lesion of the bones in most of the cases. The symptoms are unreliable, though pain, swelling, and atrophy are

rounded by varying degrees of increased density, representing healing bone. Biopsies of the bone lesions show varying stages of disease activity. While irradiation is still the treatment of choice, other forms of palliation include the nitrogen mustard-like compounds and radioactive phosphorus therapy. The disease has been found to be uniformly fatal following bone involvement.

Lymphosarcoma. Bone involvement in lymphosarcoma is rare. In a large series of patients having lymphosarcoma, only 10 per cent were ultimately found to have involvement of the bone. Pain is an early symptom, following its onset there is a variable interval before definite roentgenographic changes can be seen. Most of the patients die before the third year of the disease. Demonstrable changes in the bone are noted from twenty days to one year prior to death. As in Hodgkin's granuloma, the systemic manifestations of the disease are superimposed on changes brought about by osseous involvement, such as localized pain, girdle pain and symptoms of cord compression. The bones involved, as in Hodgkin's granuloma, are those containing red marrow. Roentgenographically the lesions are either predominantly osteoplastic or osteolytic. As the disease progresses, the entire bone is frequently involved. The osteolytic changes are seen more frequently than are the osteoplastic. The microscopic picture is characteristic of lymphosarcoma—a diffuse growth of lymphoid cells lying in reticular tissue. The treatment of lymphosarcoma consists in irradiation and other palliative forms of therapy which are used for Hodgkin's granuloma.

BONE INVOLVEMENT BY TUMORS OF NONOSSEOUS ORIGIN DUE TO INCLUSION OR DIRECT INVASION

Fibrosarcoma. Fibrosarcoma occasionally arises as a central medullary lesion, but more often may be of periosteal (fascial sheath) or neurogenic origin. It may extend in two directions, both outside and beneath the periosteum. This form of sarcoma represents only about 1.5 per cent of all neoplasms of bones. The majority of central and periosteal fibrosarcomas are of a low degree of malignancy. The age of the patient is usually well over thirty years. Only two of the patients studied by us were children. The average duration of symptoms is about one year. The disease most frequently involves the femur and tibia, but other bones may be affected.

In the x-ray picture, there is usually a large, soft-part shadow. The bone shows ero-

sion from without. The reaction of the bone is variable. The periosteum may show varying degrees of distorted ossification or no response at all. Bone destruction may be extensive. The ratio of soft-part tumor to bone destruction is important (Figs. 189 and 190).

Microscopically the spindle cell varies from

Figure 189 Roentgenogram of the upper portion of the tibia showing marked destruction of the inner, upper tibia with extensive soft-part tumor (fibrosarcoma).

Figure 190. Microphotograph of fibrosarcoma involving the tibia, depicted in Figure 189. Marked proliferation of malignant fibroblasts with pleomorphism is noted.

testosterone therapy, also has been valuable in relieving bone pain in breast metastases.

Hodgkin's Granuloma. The bone marrow is more frequently involved in Hodgkin's granuloma than is usually supposed, the reported incidence ranging up to 40 per cent

changes were noted from two months to two years prior to death. Superimposed on the systemic manifestations of Hodgkin's granuloma may be the changes brought about by

ranging from leukopenia to marked leukocytosis. Marked secondary anemia is present in some patients. The bone changes as seen in roentgenograms are either osteoclastic or osteoplastic. Roentgenograms of the skull usually show a predominant osteolytic reaction. Rarefied areas in the bone are sur-

of life following bone involvement in this disease. Some patients are living with bone changes which have existed from three to four years. In the patients who died, skeletal

Surgical excision is the treatment of choice, but recurrence is the rule.

Liposarcoma of Bone. Primary sarcomas thought to arise from fat in bone structure have been reported by Stewart, Geschickter and Copeland and also by Dawson. No unequivocal liposarcoma of bone, however, has been described. The tumors reported have their primary origin based on circumstantial evidence, such as the peculiar gross appearance with alveolar characteristics. They follow an unusual clinical course, having a tendency to appear as multiple primary tumors and to metastasize to other bones. In treating liposarcoma of bone, amputation rarely may prove curative. Irradiation of metastases is an effective palliative procedure.

Myosarcoma. This tumor is occasionally found invading bone and must be considered in the differential diagnosis of a variety of conditions under which neoplastic invasion of bone may occur.

TUMORS OF THE JOINTS AND BURSÆ

Tumors of the joints correspond pathologically to those found in the tendon sheaths but are more rare. The following classification shows the variety of lesions which may be found:

- Osteochondromas or chondromatosis
- Cartilaginous cysts
- Synovial cysts and ganglia
- Giant cell tumors
- Xanthomatous giant cell tumors
- Lipomas
- Fibroma and fibrosarcoma
- Synovial sarcoma
- Hemangioma and lymphangioma

Chondromatosis of the joint synovium is usually found in adults between the ages of twenty and fifty years and is more frequently seen in males than females. The joints involved, in the order of frequency, are the knee, elbow, ankle, hip and shoulder. The disease arises in the capsule and synovial membrane, it sometimes involves the neighboring bursae and tendon sheaths. The symptoms are usually mild and progressive and nonarticular in occurrence. Pearly bodies varying in number from a few to more than a hundred may be found free or attached to the synovial membrane. Various stages in the development of cartilage and bone are noted in the free bodies.

In the roentgenogram, the structures enclosed by the joint capsule show numerous spotted calcareous deposits, while stippling may extend along the surface of the bones or along the neighboring tendons for some dis-

tance. The condition can be eradicated by removal of the loose bodies and excision of the synovial membrane or bursae containing the cartilaginous masses. Recurrences are seen but are infrequent.

Chondromatosis of the joint synovium occasionally gives rise to chondrosarcoma.

Cysts are occasionally seen in the articular cartilages of the knee. The patients are usually between fifteen and thirty years of age. The cysts are from 2 to 4 cm. in diameter and usually involve the external meniscus. A few have been found on the internal side, some involving both menisci; rarely is the lesion bilateral. Limitation of motion, pain and atrophy of the thigh may occur. Microscopic examination shows that these cysts are due to mucoid regression in the joint cartilage. Treatment consists in excising the cyst and the involved meniscus.

Cysts in the synovial membrane within the joint are similar to those found in tendon sheaths. They may recur after excision and some are true neoplasms. One cystic tumor within the synovial membrane proved to be a lymphangioma and was connected with a bursa surrounding the joint. Baker's cyst is a posterior herniation of the synovium of the knee joint and often connects with the knee joint through a fibrous channel.

Synovial cysts are treated by surgical excision. Baker's cyst should be isolated by careful dissection and excised. The pedicle should be ligated if it connects with the joint cavity.

Excepting benign cartilaginous tumors of the synovium, the majority of benign synovial tumors are *giant cell xanthomas* and are characterized histopathologically by giant cell proliferation, accumulation of foam cells (xanthoma cells) and connective tissue derived from the synovial membrane. Some of these synovial tumors, characteristically of the benign giant-cell xanthoma type, show a tendency to involve neighboring bone. Of nine patients studied with giant cell xanthoma and fibroxanthoma with giant cells about the joints, five patients had associated bone involvement.

Radical excision may be resorted to in the treatment of these tumors, but, if recurrence supervenes, a resection of the joint and affected soft parts usually suffices to eradicate the disease. When synovial tissue predominates in a tumor of the joint, the lesion is usually malignant.

Hypertrophic out-pouchings of synovial tissue distended by fat are frequently observed in association with arthritic changes. True

the more aggressive oat cell type to the large fusiform spindle cell, with transition cell forms. Usually no bone or cartilage is seen in the fibrosarcomas. A definite percentage of the fascial sheath tumors are not sarcomas but cellular fibromas. This accounts in part for the unusual number of cures of so-called fibrosarcoma.

These tumors are not highly radiosensitive. The cell differentiation is all-important in this group. There is some evidence that irradiation inhibits tumor growth for a time, producing a slow sclerosing reaction in the fibrospindle-cell type of lesion. Patients with the fibrospindle-cell variety of tumor will survive five years or longer, irrespective of the inadequacy of the treatment. Amputation or radical resection cures the majority of patients.

The undifferentiated oat cell type of fibrosarcoma is extremely aggressive and neither x-ray treatment, radium therapy, nor local excision offers a permanent cure. Primary amputation when possible is the treatment of choice.

Malignant Neurilemmoma (Neurogenic Sarcoma). The nerve sheath sarcomas, invading bone, are differentiated microscopically by myxomatous structure intermingled with fibrous tissue. The nuclei are longer and deeper staining than are those of other sarcomas invading bone. Many tumor giant cells are seen.

Clinically and roentgenographically these neurogenic tumors bear a close resemblance to the fibrospindle-cell tumors, although more pronounced destruction of bone is noted in the neurogenic lesions. As in the fibrospindle-cell tumors, there is a gradual transition among the neural tumors from the benign neurofibromas to the most malignant form of neurogenic sarcoma. The more malignant and cellular forms predominate the picture when bones are involved.

Neurogenic sarcomas as a group are highly radioresistant tumors. Interstitial irradiation by buried radon implants has been almost uniformly disappointing. A certain number of cases have shown some regression following external irradiation alone.

It may be stated, however, that clinical cures in neurogenic sarcoma are obtained only by surgical intervention. The best results are obtained by early amputation and, even with this radical form of treatment, permanent cures are not numerous.

Angioma of Bone. Angioma of bone is considered rare. The ages of the patients vary between four and forty years. The tumors observed have been located in the humerus,

ulna, radius, femur, os calcis, skull and vertebrae. The vascular tissue obtained is characteristic of angiomatous tissue elsewhere.

On reviewing the literature, one gains the impression that the majority of the angiomas of bone are of the cavernous type. Many, however, show the capillary type of angioma and there are lesions with proliferative changes, suggesting malignant disease.

Angiomas affecting bone are essentially benign. They show varying degrees of radio-sensitivity and the younger the patient the more effective the irradiation. This is also characteristic of angiomas found in other parts of the body.

Isolated patients may be pointed out who have been cured by x-ray therapy alone or by surgical intervention.

Lymphangioma. Occasionally lymphangioma involving one or more bones with changes much like those seen in angioma is noted. In one patient, marked resorption of bone structure was seen in the ischium and ilium. The surrounding soft parts showed invasion by the lymphangiomatous process. Microscopically, lymphangiomatous channels were noted, some of which were quite dilated. The lymphangiomatous tissue was associated with accumulations of lymphocytes and lymphoid tissue. Bone surrounding resorption areas revealed little evidence of osteoblastic activity. The treatment is largely limited to roentgen ray therapy.

Chordoma. Chordoma is a rare malignant neoplasm, found near the spheno-occipital or sacrococcygeal regions, thought to arise from remnants of the notochord. Rarely, these tumors have been found at various levels of the spinal column. Young adults and children are usually the persons affected by the disease. The symptoms vary with the location. Intracranial symptoms or symptoms from spinal cord and nerve involvement may be observed. A tumor in the cervical region may produce pharyngeal symptoms. The chordoma grows slowly but kills by invasion of vital structures. Twenty-seven per cent of the growths are said to metastasize. The roentgenogram usually shows destruction of bone associated with a soft part shadow. The microscopic picture is variable. Solid cords of polyhedral and globular cells, in some instances becoming more vacuolated and having a homogeneous intercellular mucinous matrix resembling hyaline cartilage, are seen. Great difficulty is experienced in differentiating these tumors from atypical chondromas and mucoid carcinoma arising in the gastrointestinal tract.

Irradiation has little effect.

an outer fibrous layer and an inner layer of synovial cells which often form pseudo villi. Fibrous tissue is constantly present throughout the tumor, manifested either as dense sheets of malignant spindle cells (Fig. 193), fibrosarcoma-like in appearance, or merely lending support to pseudoglandular tufts of synovial tissue forming the central core of the papillary projections. In instances where the tumor has a fibrosarcoma-like appearance, careful search is often needed to find the pseudoglandular clefts typical of synovial sarcoma. The more characteristic tumor consists of epithelial-like cells upon supporting stroma about spaces resembling slits.

The tumor has a propensity for metastasizing to regional lymph nodes in about 15 per cent of patients. Vascular metastases occur in the majority of patients not successfully treated (pulmonary metastases, 65 per cent; bone metastases, 10 per cent). Simple excision followed by irradiation has been the treatment of choice until recently; the prognostic outlook is very poor. Adequate surgical resection is the method of choice in the treatment of early synovial sarcoma. If the tumor is deep seated or extensive, amputation, where possible, should be performed. The clinical stage of the disease determines the form of ablation. When regional lymph nodes are involved a radical lymph node dissection is recommended, with en bloc dissection of the primary lesion or with a regional amputation. Postoperative irradiation

is advisable when local resection has been carried out. Therapeutic survival rates in large series of studied cases vary but average between 22 per cent and 25 per cent.

SOMATIC SOFT-PART TUMORS OF THE EXTREMITIES

The soft-part tumors of the extremities may be divided into a broad classification of benign and malignant fibromatous, lipomatous, angiomatous, myomatous, neuromatous and synovial tumors.

The majority of soft-part sarcomas originate as such. The benign neoplasms rarely become malignant.

Malignant soft-part tumors, in the order of their frequency, include: sarcomas of undetermined origin (36 per cent); liposarcoma (15 per cent); rhabdomyosarcoma (14 per cent); synovial sarcoma (9 per cent), Kaposi's sarcoma (7 per cent), neurogenic sarcoma (6 per cent), fibrosarcoma (5 per cent), and others (8 per cent).

Sarcomas of undetermined origin account for approximately 36 per cent of all malignant tumors of soft somatic tissues. The rapid and abundant growth of fibrous tissue frequently obscures the primary origin of a tumor. Poor differentiation of anaplastic tumors, organoid origin, with numerous elements of a given organ present; origin from primitive mesenchyme—these, among other factors, prevent accurate histologic classification.

Liposarcomas constitute about 15 per cent of all primary malignant tumors of the soft somatic tissues in which exact histogenic definition is available. They may occur wherever fat is present. The thighs, buttocks and shoulder girdles are sites of greatest frequency. About 13 per cent of cases involve the retroperitoneum and trunk. Rarely is liposarcoma found arising from a pre-existing lipoma. The pseudoencapsulation of liposarcoma, when found, usually reflects a relatively benign course for the tumor. The primary disease is often located deep in the intermuscular zones or in the areas about the joints. Recurrent liposarcomas, following incomplete removal, are more likely to show invasive characteristics. Histopathologically the tumors may show (1) well-differentiated fat cells associated with varying numbers of embryonal stellate cells, (2) embryonal stellate cells or spindle-shaped lipoblasts with many bizarre nuclei, or (3) a round cell type of morphology, the cells having a central nucleus with abundant foamy cytoplasm.

Liposarcoma in the peripheral tissues of

Figure 193 Microphotograph depicting synovial sarcoma with marked spindle cell proliferation but with typical epithelial-like cells producing pseudo-glandular formations.

Figure 191 Gross specimen showing synovial sarcoma involving knee joint and invading the femoral condyles and metaphysis

Figure 192 Roentgenogram of same amputated specimen seen in Figure 191, showing invasion of the femur with marked soft-part tumor proliferation along the bone shaft

articular lipomas are uncommon, however. Isolated instances of the occurrence of lipomas about the knee joint in adipose women have been noted. The tumors are accompanied by fluid in the joint, which is relieved by excision of the growth.

Hemangiomas and *lymphangiomas* are of rare occurrence and are usually benign. They are composed of a diffuse mass of blood vessels held together by loose connective tissue or there may be a mixture of vessels of both vascular and lymphatic type. Cystic changes may occur within the synovium. Such tumors create a considerable hazard during surgical extirpation. Surgical excision has proved successful in the majority of cases, but irradiation may be utilized if surgical resection fails.

Fibroma and *fibrosarcoma* are rarely found about the joint, in our experience, only one instance of fibroma has been noted and in one patient fibrosarcoma developed about a joint. Individual case reports may be found in the literature. Fibrosarcomas which involve the synovial membrane also have invaded the neighboring periarticular structure and may well be regarded as cellular synovial sarcomas.

Synovial sarcomas (synoviomias) arise from synovial tissue and occur with the greatest frequency in the lower extremities (80 per cent). The joint synovia are rarely involved (Fig. 191). The tumors often occur

in bursae about the knee and ankle joints in addition to arising from synovial tissues about the foot and hand. Synovial sarcoma is essentially a disease of younger adults. No specific etiologic factor is known. There is no characteristic clinical syndrome. A mass with or without pain, or pain without a palpable tumor, may be the patient's chief complaint.

The tumor, grossly, may be encapsulated or may show varying degrees of aggressive infiltration into surrounding structures. The tumor often produces distortion of bones from pressure or there may be marked invasion of the osseous structure (Fig 192). Pseudoencapsulation does not represent localization of the disease. More obvious tumor infiltration is apparent in the majority of cases. The cut surface of the tumor appears grossly firm, grayish pink, with areas of hemorrhage. Small or large cystic cavities may be present filled with gelatinous fluid of variable color. Occasionally one may find foci of yellow xanthomatous-like tissue and also small areas of calcification.

Histopathologic study is influenced by the two layers observed in -tissue of origin,

presence of fibrils with cross-striations (Fig. 195), (2) the presence of giant cells, (3) the presence of spindle cells and (4) pleomorphism of the tumor cells. Special stains are often helpful in distinguishing either the cross-striations or the longitudinal myofibrils which are important from the diagnostic viewpoint.

As with liposarcoma, the choice between radical surgical dissection and amputation depends on the regional location, fixation of tumor to surrounding tissues, whether the lesion is primary or recrudescence, the presence of regional or distant metastases and the experience of the surgeon. Wide radical excision is indicated in localized lesions. It is strongly recommended that a complete muscle group be resected when the tumor involves one or more of the components, such as the adductor muscles of the thigh. While prognosis is poor, recrudescence of the disease is amenable to operative cure, as are primary lesions. Five-year survival rates without disease vary widely. Pack has a remarkably successful five-year "cure" rate of 33.8 per cent (twenty-two of sixty-five cases). A great number of the patients living five years had had previous inadequate excision of the tumors, followed by adequate surgical treatment. Operable untreated lesions were relatively rare in this series. An increasing percentage of five-year survivals should follow adequate treatment of early lesions. Postoperative irradiation is not ef-

fective in altering the course of the disease although, in isolated instances, preoperative irradiation has reduced a primary tumor to the status of successful operability.

Synovial sarcomas represent about 9 per cent of definable soft-part sarcomas. Since they have already been discussed, they are included here only to complete the classification.

Kaposi's sarcomas are atypical sarcomas manifest in the skin of extremities of patients over age forty years (70 per cent). The disease may be found in the viscera and lymph nodes before classic skin lesions are discovered. The initial dermal lesion is a reddened well-demarcated nodule. Progression of disease includes: change in color (bluish red), multiplicity of nodules involving symmetrical areas of both extremities; edema and ulceration, ultimately, with bleeding. Death generally results from intercurrent infection, progressive weakness or hemorrhage from the cutaneous, gastrointestinal or lung lesions. Kaposi's sarcoma appears to be a dysplasia of the reticuloendothelial system.

Wide radical excision of the early lesion is indicated and results in a few five-year survivals. If the disease is extensive, conservative irradiation yields reasonable palliation. Overtreatment with x-ray should be avoided to prevent massive necrosis and gangrene.

Neurogenic sarcomas (malignant neurilemmomas) have for their site of predilection the extremities. The nerve trunks anatomically demonstrated to be associated with malignant neurilemmomas are, in their order of frequency: median, peroneal, sciatic (Fig. 196), ulnar and femoral. There are no clinical symptoms characteristic of the disease. The histologic features of the tumor influence prognosis. Tumors arising in major nerve trunks are clinically more malignant than peripherally situated tumors. The best results in treating malignant neurilemmomas are obtained by early amputation and, occasionally, by hemipelvectomy. Five-year survivals without disease are few and do not necessarily reflect the complete control of the disease. Recrudescence has been noted as late as eight years after apparent control of the primary lesion.

Fibrosarcomas comprise about 5 per cent of malignant tumors of the soft somatic tissues. They occur most frequently in the extremities (80 per cent). The peak of incidence is noted in patients about the third and fourth decades of life.

Fibrosarcomas develop without obvious relation to any etiologic factor save, occasionally, previously damaged tissue. Satellite le-

the body usually begins as an inconspicuous swelling, growing gradually larger. Pressure symptoms ultimately supervene. Pain is usually not an early symptom. Early recognition is made difficult by the similarity between the aggressive tumor and its benign counterpart.

The best prognosis is found in patients with superficial tumors which are radically excised or in those whose tumors are amputated. Patients having deep-seated or incompletely excised tumors have a poor outlook.

The choice between radical surgical excision and amputation depends on a variety of factors such as (1) the surgeon's experience, (2) the degree of malignant change, (3) location of tumor, (4) whether the tumor is primary or recrudescant and (5) the presence of regional or distant metastases. Irradiation is considered an important postoperative adjunct in treating recrudescant tumors and in the case of distant metastases. Pack and Ariel report 35 per cent of patients with liposarcoma are living five years without disease following adequate surgical removal and with postoperative x-ray therapy in selected cases.

Rhabdomyosarcomas are infrequent when the relative amount of skeletal muscle tissue making up the body soft parts is considered. About 14 per cent of histogenically definable soft-part sarcomas are from striated muscles. They occur at all ages but have a peak

incidence between forty and seventy years of age. They are most often located about the lower extremity, including the buttocks and groin (54 per cent), and the upper extremity, including the shoulder (36 per cent). The individual muscles most often affected are the quadriceps femoris, the adductor muscles of the thigh, the muscles of the lower leg, the deltoid, triceps, biceps and brachialis muscles of the arm. Other muscle sites are less common (Fig. 194).

Pain is an infrequent complaint. The tumor is usually first noticed as a painless localized swelling which often reaches a considerable size before medical advice is sought. Interference with function is a late manifestation. On examination the mobility of the tumor disappears when the involved muscle contracts. The tumor may occasionally infiltrate the skin and produce necrosis.

The gross appearance of rhabdomyosarcoma is variable. The tumor may appear multilobulated or multicentric, it may appear as a discrete nodule or as a diffuse widespread process. The tumor is also variable as to its palpable density. A highly vascular tumor may be soft and compressible, whereas an increase in the connective tissue components gives a sense of firm induration. Hemorrhagic necrosis may be massive.

Many of these tumors go undiagnosed because of the anaplastic or atypical morphology which they display. The diagnostic morphologic characteristics (1) the

Amputations and Artificial Limbs

By CHARLES O. BECHTOL, M.D.

CHARLES ORVILLE BECHTOL, born in Chicago, was educated at Stanford University and its medical school. Trained in orthopedic surgery, he served on the faculty of the University of California and then became chief of the Division of Orthopedic Surgery at the Yale Medical School. He has now returned to the University of California, Los Angeles, as Professor of Orthopedic Surgery and chairman of that division in the medical school.

The reason for amputation is commonly stated as being to save life or to improve function. With improved types of prostheses developed in recent years the great improvement in function which can be offered to the amputee places an added burden on the surgeon to perform amputation with the greatest possible skill. This means that the surgeon must know the present concept of the sites of election for amputation, the amputation technique to be used under varying conditions and the great importance of proper postoperative care. The amputee clinic team must be utilized in prescribing the proper prosthesis to fit the amputee's particular requirement and to institute and guide his training in the use of the prosthesis.

AMPUTATION LEVELS

Amputation levels previously unacceptable are now considered to be desirable because of improvements in prostheses which allow their use. In the upper extremity (Fig. 197) all possible lengths should be saved down to and including the level of wrist disarticulation. The carpal bones should be saved only if the amputee will be doing some sort of labor and may not be wearing a prosthesis a good part of the time. Beyond this level, through the hand, all possible lengths should be saved which are compatible with good amputation technique. Because of the great importance of sensation, prosthetic replacement of portions of the hand is usually not successful except for cosmetic purposes. In the lower extremity (Fig. 198) less

change in the classical sites of election has occurred. Disarticulations through the knee joint, although leaving a satisfactory stump, still do not have an entirely satisfactory prosthesis available. Very short below-knee stumps give trouble in fitting and below-knee stumps longer than 7 or 8 inches may produce circulatory difficulties or difficulties in the alignment of the prosthesis. The area of partial foot amputations has been greatly improved by the addition of fusion of the ankle in 5 or 10 degrees of dorsiflexion, thus avoiding the fixed equinus position so frequently seen with this type of amputation.

SURGICAL PRINCIPLES OF AMPUTATIONS

The surgical principles of amputation are similar at any level. Varying conditions indicate three general types of amputation.

Open or Guillotine Amputation. This amputation is recommended in the presence of already established severe infection or in a wound so severely contaminated that infection seems inevitable, particularly if adequate hospital care will not immediately be available for the patient.

The various layers of the extremity are divided by successive circular incisions, each layer being retracted so that the next incision is made at a slightly higher level. The entire end of the stump is in the shape of an inverted cone with the apex pointed proximally.

There are two essentials in the postoperative care of this type of amputation. First is a dressing over the open end of the wound

Figure 196 A, Gross specimen following hemipelvectomy for malignant neurilemmoma of the sciatic nerve sheath. Note the bulky tumor in the thigh below the sciatic notch B, Microphotograph of malignant neurilemmoma showing anaplastic tumor proliferation with concentration of nuclei. Malignant giant cells are frequent.

sions ultimately occur with growth of the tumor in many instances. There are no symptoms characteristic of the disease. The diagnosis must depend upon surgical biopsy, though soft-part roentgenograms may direct the surgeon to a more exact location for biopsy. Pseudoencapsulation is often noted at surgery, lending false security to the operator. Neighboring bone, muscle, skin and, occasionally, the synovium of joints may be invaded. On cut section, the tumors are firm and grayish pink. Areas of hemorrhage with cystic changes and bone and cartilage may be present occasionally.

The histopathologic findings vary from well-differentiated, relatively benign forms of fibrosarcoma to a high degree of anaplastic malignant transformation. In the latter

creasingly malignant potential through surgical insults. Over 50 per cent of fibrosarcomas seen in our clinic are recrudescence ones. The relative five-year survival rate is approximately 60 per cent.

Amputations and Artificial Limbs

By CHARLES O. BECHTOL, M.D.

CHARLES ORVILLE BECHTOL, born in Chicago, was educated at Stanford University and its medical school. Trained in orthopedic surgery, he served on the faculty of the University of California and then became chief of the Division of Orthopedic Surgery at the Yale Medical School. He has now returned to the University of California, Los Angeles, as Professor of Orthopedic Surgery and chairman of that division in the medical school.

The reason for amputation is commonly stated as being to save life or to improve function. With improved types of prostheses developed in recent years the great improvement in function which can be offered to the amputee places an added burden on the surgeon to perform amputation with the greatest possible skill. This means that the surgeon must know the present concept of the sites of election for amputation, the amputation technique to be used under varying conditions and the great importance of proper postoperative care. The amputee clinic team must be utilized in prescribing the proper prosthesis to fit the amputee's particular requirement and to institute and guide his training in the use of the prosthesis.

AMPUTATION LEVELS

Amputation levels previously unacceptable are now considered to be desirable because of improvements in prostheses which allow their use. In the upper extremity (Fig. 197) all possible lengths should be saved down to and including the level of wrist disarticulation. The carpal bones should be saved only if the amputee will be doing some sort of labor and may not be wearing a prosthesis a good part of the time. Beyond this level, through the hand, all possible lengths should be saved which are compatible with good amputation technique. Because of the great importance of sensation, prosthetic replacement of portions of the hand is usually not successful except for cosmetic purposes. In the lower extremity (Fig. 198) less

change in the classical sites of election has occurred. Disarticulations through the knee joint, although leaving a satisfactory stump, still do not have an entirely satisfactory prosthesis available. Very short below-knee stumps give trouble in fitting and below-knee stumps longer than 7 or 8 inches may produce circulatory difficulties or difficulties in the alignment of the prosthesis. The area of partial foot amputations has been greatly improved by the addition of fusion of the ankle in 5 or 10 degrees of dorsiflexion, thus avoiding the fixed equinus position so frequently seen with this type of amputation.

SURGICAL PRINCIPLES OF AMPUTATIONS

The surgical principles of amputation are similar at any level. Varying conditions indicate three general types of amputation.

Open or Guillotine Amputation. This amputation is recommended in the presence of already established severe infection or in a wound so severely contaminated that infection seems inevitable, particularly if adequate hospital care will not immediately be available for the patient.

The various layers of the extremity are divided by successive circular incisions, each layer being retracted so that the next incision is made at a slightly higher level. The entire end of the stump is in the shape of an inverted cone with the apex pointed proximally.

There are two essentials in the postoperative care of this type of amputation. First is a dressing over the open end of the wound

Figure 197 Amputation levels in the upper extremity.

Figure 198. Amputation levels in the lower extremity.

using petrolatum gauze or some similar substance with copious dressings to absorb the drainage. The second is the application of skin traction to prevent the elasticity of the skin from retracting the edges of the wound. After a granulating surface is established on the end of the stump, this may be covered with split-thickness skin graft and when the danger of infection is considered to be passed the stump may be revised by fashioning flaps and achieving a proper closure.

There are two great pitfalls in this revision. The first is the attempt to save too much bone length, thus leading to inadequate covering of this bone with skin and soft tissue. The second is the failure to dissect out meticulously all of the scar tissue which has been laid down in the process of granulation of the wound, and particularly the failure to identify and dissect free from scar tissue all of the nerves of the stump. Neglect of the first precaution leads to a stump with a prominent bone at its end covered only by skin, subcutaneous tissue and muscles of the stump, which have not obtained attachment to this bone and therefore may move up and down a considerable distance with each step. This leads to abrasion of the skin inside the socket and a most uncomfortable stump. Failure to carry out adequate removal of the scar tissue at the end of the stump with dissection free of all nerves may lead to extremely painful stumps with a great amount of phantom pain.

Elective Flap Type of Amputation. This amputation can be carried out if the danger of infection is not great and if adequate hospital care is immediately available for the patient. Flaps are so fashioned as to leave the scar over the end of the stump in almost all cases. Advantages of bringing the scar anteriorly or posteriorly are usually outweighed by the extensive undermining of the skin necessary and may lead to subsequent breakdown of the skin because of poor circulation. In such an amputation the bone should be divided at such a level that muscle tissue can be closed over the bone end, using sutures in the fascia of the muscles since sutures in the muscle itself usually will not hold. Exceptions to this are cases in which no muscle tissue is present, such as disarticulations of the wrist, or the anterior flap in a tibial amputation where no muscle tissue is present. Redundant skin should not be left expecting traction at a later date. The skin should be sutured under moderate tension and this tension relieved in the early

postoperative period by the application of skin traction.

Amputations for Vascular Gangrene. Amputations in this category require an entirely different technique because here the aim is dictated by the desperate need to obtain healing in skin which has at least moderately impaired circulation, and by the knowledge that this is merely a palliative procedure in a disease process which will progress. Flaps can be fashioned in the same manner as in elective amputations. Great care should be taken not to dissect the planes between the various layers of the soft tissue. Catching of bleeding points should include the minimum amount of tissue in the hemostat and the use of forceps or retractors on the skin should be avoided. Closure of the skin edges should be so loose that no traction will be necessary and no circumferential bandages should be used. In placement of the skin sutures the skin should be held in the fingers rather than in a forceps while the needle is driven through. During postoperative care, prevention of flexion contractures of the joints is of the greatest importance. This can be accomplished in the upper extremity by having the patient carry his joints through a full range of motion as soon as possible, and in the lower extremity by having the patient lie on his abdomen.

In vascular amputations the patient will frequently be found to have developed flexion contractures during the course of the gangrene and it is therefore important that such an amputee lie on his face during the preoperative treatment as well as in the postoperative period. Sutures should generally be removed in ten to twelve days and the stump wrapped with an elastic bandage to encourage shrinking except in cases in which circulation is precarious.

In nonvascular amputations, fitting can usually be carried out somewhere between eight and sixteen weeks postoperatively and should not be delayed too long. During this period the patient should have active rehabilitation treatment with supervised exercises to the stump muscles, stretching of contractures and active joint motion three times a week. Prescription of the prosthesis should follow consideration of the individual problems of the amputee and is best carried out by a team consisting of the physician, therapist and prosthetist, each of whom contributes his specialized knowledge. This same team should determine what type of therapy may be necessary before fitting and

the extent of training when the prosthesis is received. The team also carries out a check-out procedure to insure that the prosthesis conforms to the prescription and fulfills satisfactory functional standards.

UPPER EXTREMITY FUNCTION AND PROSTHETIC REPLACEMENT

Man has been described as the animal who uses tools. The function of the upper extremity is largely the manipulation and transportation of tools. The function of the hand is to grasp these tools. This is accomplished in most cases between the tips of the thumb, index and middle fingers. The remainder of the arm acts as a crane and moves the hand about to its various positions. In the prosthetic replacement a terminal device is substituted for the hand. The most functional terminal device is the so-called split hook to allow the amputee to carry out all the ordinary activities of daily

metically superior, none of them approach the split hook in function. The functions of the remaining joints of the arm are reproduced to a limited degree. The most important function is that of the elbow in

which is so designed that movements of the stump only are necessary to control the prosthesis.

LOWER EXTREMITY FUNCTION

The lower extremity is primarily concerned with locomotion and in walking on level ground. Reserve power and function of the leg are so great that even a patient with a hip disarticulation can walk reasonably well using a properly designed prosthesis. The increased energy requirements in walking on stairs or ramps is immediately reflected in a marked increase in the amputee's limp. Stability of the lower extremity is achieved by aligning the joints in such a way that the knee is inherently stable in the standing position.

Man's leg is classified as being graviportal, which means that in the standing position the joints lock so that little or no muscular activity is needed to prevent buckling of the hip and knee. Thus, during the stance or weight-bearing phase of walking, the amputee walks with the knee in slight hyperextension to maintain stability and uses the muscles of the stump to maintain this hyper-

extension and to help in forward progression. The muscles of the remaining leg are called upon to supply additional power for progression.

During the swing phase of walking, the muscles around the knee act to damp excessive flexion of the knee. In the amputee this action can be duplicated by a mechanical brake placed in the knee.

AMPUTATIONS IN CHILDREN

Amputations in children are usually indicated either because of congenital anomalies or because of trauma. With present available prosthetic techniques, children should be fitted at a much earlier age than formerly thought feasible. Leg amputees should be fitted with standard prostheses as soon as they have standing balance on the remaining leg or, if they are bilateral amputees, as soon as they give evidence of being able to balance themselves on their stumps. Arm amputees should be fitted with a simple socket to use in crawling as soon as they begin this activity. As they begin to use their hands more actively they can be given a prosthesis with a simple clamping type of hook. Between the ages of three and four they can usually be given a prosthesis with full type of adult controls. It is important not to let children with arm amputations become accustomed to using the stump bare since they may then never achieve a satisfactory adjustment to the prosthesis.

With modern amputation and prosthetic techniques the great majority of all amputees can be successfully fitted. A small percentage of patients who cannot be fitted are usually unsuitable because of some severe type of general physical or psychologic disturbance.

THE HAND

By MICHAEL L. MASON, M.D.

MICHAEL LIVINGOOD MASON has devoted himself to extending the principles laid down by Kanavel in the treatment of infections, injuries and deformities of the hand. His training and experience in the teaching of anatomy particularly suited him for this role in surgery. A patient conservator of damaged tissue in preserving the function of the hand, he is extravagant in his use of color in following his hobby of painting. Dr. Mason serves his undergraduate and medical alma mater, Northwestern University, as Professor of Surgery

In the past fifty years, the surgical care of conditions of the hand has developed from a consideration of infections to a definite subspecialty in general surgery. A significant factor has been the realization of the great functional value of the hand and an appreciation of its economic significance. The difficulties to be overcome before surgical therapy could be established on a sound basis were a lack of appreciation of the anatomy of the hand, an imperfect knowledge of wound and tissue healing and lack of appreciation of the technique necessary for dealing with the tissues of the hand.

The care of diseases and injuries of the hand demands techniques developed in several other fields of surgery, e.g., orthopedics, plastic surgery and neurologic surgery, as well as expert knowledge in the handling of wounds. In the past, hand injuries were usually entrusted to the least experienced, whereas it is now recognized that usually the most expert care is required even in "minor" injuries.

The first epoch-making advance in surgery of the hand was the publication of Kanavel's book, *Infections of the Hand*, the first edition of which appeared in 1907, and the seventh edition, at the time of the author's

death, in 1938. It would be difficult indeed to estimate the influence which this book has had in the development of surgery of the hand. In the experimental and clinical observations contained in this volume, a sound anatomic basis was laid for the understanding and treatment of the crippling and baffling processes of infections of the hand.

Advances in wound care and a firm knowledge of infections soon led to greater attention being paid to the care of wounds of the hand and to the surgical treatment of disabilities of the hand.

INFECTIONS

Infections of the hand are important because of the serious disability which may follow, particularly if treatment has been late or inept. The spread of infections in the hand is determined by three factors: the anatomy of the area involved, the resistance of the host tissues and the virulence of the invading organism. The peculiarities of the structure of the hand determine certain pathways of spread which must be understood by the surgeon if he is to diagnose and treat infectious processes correctly. If only the cellular and subcutaneous tissues are involved, the immediate result is quite like similar

processes elsewhere. If, however, the subcutaneous tissues happen to be the pulp of a digit, or the palm, a quite different situation obtains. If the deeper tissue, planes and spaces are affected, the spread and possible consequences of the condition are again far different. This applies especially to the tendon sheaths and deep fascial spaces of the palm which in a few hours may be the site of an extensive infection from a very insignificant wound. Consequently it is necessary to know these anatomic pathways to understand properly and "outguess" the possible course and site of an infectious process.

If a knowledge of anatomy is necessary to know where an infectious process is likely to localize, it is equally necessary to know the anatomy of the part in order to secure surgical drainage should this be indicated. The intricate and compact anatomy of the hand is such that irreparable damage may be done to tactile areas and to nerves and tendons if the surgical approach is not the correct one.

Some estimate of the virulence of an infection is likewise essential to intelligent care. In the infirm or debilitated patient with little resistance to an invading organism, an infection may spread very rapidly and lead to serious complications in a short time. Similarly, when a very virulent bacterium is involved, e.g., from scratches with autopsy knives or pinpricks while dressing patients with virulent infections, a fulminant process may develop in a few hours even in persons in the "pink" of condition. In the days before antibiotics were developed, many surgeons, pathologists and nurses suffered severe infections and not a few lost their lives from hand infections. It is important to know if an infection is being brought under control by the body forces, i.e., if it is being or has been localized, or if the bacteria are multiplying and extending into the surrounding tissues as diffuse cellulitis or into the lymphatics as lymphangitis. When localization is occurring or has occurred, a favorable outcome may be anticipated and surgical drainage can be instituted. On the other hand, if the process is diffuse and spreading and particularly if there is evidence of invasion of the lymphatics, the surgeon knows he has to deal with a more serious problem. He must direct all of his efforts toward favoring localization and increasing the patient's resistance. Furthermore, he must avoid all manipulation of the part and making an incision until localization has occurred. Fortunately, the antibiotics are of great value in bringing these

spreading infections under control. Nevertheless, even under an antibiotic umbrella, too early active surgical treatment is to be religiously avoided.

A determination of the exact organism responsible for the infectious process should be made whenever possible; routine culturing, both aerobic and anaerobic, will lead to more intelligent care. The development of the chemotherapeutic and antibiotic agents has served to emphasize further the need for accurate knowledge, not only of the infecting organism, but of its sensitivity to these agents.

GENERAL PRINCIPLES OF CARE

Certain general principles of care apply to all types of hand infections.

An early diagnosis must be made of the location of the process and whether it is spreading or is localized.

The anatomic location of the site of infection is of great significance since only by knowing this can adequate and proper drainage be carried out and the possible course of extension be predicted and anticipated. The need for determining whether the body immune processes have succeeded in localizing the infection is likewise of great importance. In the adequately localized process, prompt drainage is usually indicated. In the acute spreading processes or in any infection in its early stage before the spread has been stopped, surgical intervention is contraindicated. In the acute spreading infections, surgical intervention during the stage of spread may be disastrous and lead to death of the patient or serious extension of the process. In the early stages of less severe infections, such as a carbuncle or furuncle, early incision may lead to extension of the process, increased tissue injury and delay in healing.

The proper treatment for the infection should be started at once when the patient is first seen. Delay in instituting care may lead to serious sequelae such as tenosynovitis, felon and acute spreading infections. In any infection, recovery is more prompt and complications less likely to occur if therapy is started early than if it is delayed for fear of discommoding the patient. Prompt care does not mean immediate incision necessarily; on the contrary, it may mean strict avoidance of incision.

Rest of the part is an integral element of care in the treatment of any infection. In an infection of the hand, proper splinting is a necessary feature. The extent to which splinting is carried out and the means of obtaining

Figure 1 The position of function. An important milestone in the development of surgery of the hand was the establishment by Kanavel of the importance of this position in immobilizing the hand.

rest will vary with the location and severity of the infection. In infections involving only one digit, such as a paronychia or felon, it may be necessary to put only the digit at rest. In the more extensive processes, the whole hand and forearm must be immobilized. If the process is lymphangitis or acute spreading infection, the hand, forearm and arm must be immobilized and the patient put to bed.

Whenever the hand or any of its parts is put at rest because of an infection, it is essential that it be splinted in the position called by Kanavel "the position of function" (Fig 1). This, briefly put, is the position of grasp and not the position of rest. The wrist is dorsiflexed about 45 degrees, the metacarpophalangeal and interphalangeal joints are flexed about 30 degrees and the fingers are slightly separated from each other. The thumb is abducted from the side of the hand and rotated forward so that its pad faces the pads of the other digits. The advantages of this position are several. If any stiffness results from the infection, the hand will be capable of some use even with a minimum of motion. With a hand in this position, restoration of function is much easier. The ligaments of the various joints are in the position of maximum length when the hand is in the grasping position, hence, if they become involved, they do not restrict motion. If the joints are in the extended position, the ligaments are short in that position and, if they become fibrosed, hold the joints stiffly in extension and restoration of function is difficult, if not impossible (Fig 2). With the wrist in moderate extension, the grasping power of the fingers is greatest and diminishes as the wrist is straightened and flexed (Fig 3).

This position of function is applicable, likewise, if only one or two digits or the wrist only is to be splinted. Fingers should be splinted in slight flexion, the thumb in rotation and apposition, the wrist in extension.

Figure 2 When the joints of the digits are flexed, the collateral ligaments are lengthened, when the joints are extended, these ligaments are shortened. Hence, when a joint is put at rest in a straight position, the ligaments are shortened and flexion may be difficult or impossible if immobilization is prolonged.

Figure 3 The grip is strongest with the wrist in slight extension.

The position of function will be found to be of importance in the care of all conditions of the hand which require splinting. In fact if a hand is put on a splint in any other position, definite indications must be present for it.

The use of warm moist packs to favor localization of the infection, probably by leading to increased blood flow, is a time-honored therapeutic measure. The packs are of greatest value when they are applied as continuous dressings rather than intermittent

soakings, particularly in the acute and post-operative periods. They should be applied in such a manner that warm, sterile physiologic saline solution may be poured into the dressings from time to time without the need of removing them (Fig. 4). Measures should also be provided to keep the dressings warm by external heat such as a therapeutic baker or hot water bottles. The need for maintaining sterility is particularly important following incision of an infection.

Operation to secure drainage of an infection is done with the care accorded an aseptic operative procedure. As a rule, except in an early paronychia in which a tiny incision may be made without employing any anesthetic, general anesthesia is needed. Local infiltration is somewhat hazardous in an infected area and injection about the base of a digit may be followed by the development

pumped up to 280 to 300 mm. Hg after the arm has been elevated for thirty to sixty seconds (Fig. 5). This bloodless field is necessary since the incision must be made with the care of an anatomic dissection. Hasty incisions within a field obscured by bleeding

are almost certain to cause trouble. Especially is this true of incisions for tenosynovitis or of the palmar fascial spaces where nerves, blood vessels and tendons are liable to serious injury.

Drainage is secured by adequate incision and not by the use of drains. When an incision has been made, it is usually wise to insert a thin strip of rubber or petrolatum-soaked, fine-mesh gauze into one corner of the wound to keep the edges from becoming agglutinated. The strip is left in the wound not over forty-eight hours, being usually removed at the first or second dressing. To be strictly avoided are stiff rubber or other hard drains that press against nerves and tendons. Likewise, through-and-through drains must be avoided.

After-care is of as much importance as the incision. Following incision, the warm moist packs are maintained for two or three days, or until it is evident that the process is receding. This is manifested by recession of swelling and reappearance of the skin creases near the area of inflammation. As soon as recession begins, the surgeon must start at once to secure mobilization in all joints not directly involved in the process. This can usually be accomplished by reducing the splinting to only those digits affected and leaving the other digits free. It is often necessary to stimulate the patient in the use of the

Figure 4 Warm moist dressings should be so applied that they need not be disturbed for the addition of warm sterile fluid (physiologic saline solution). The warmth is maintained by some sort of external heat (Mason, M. L.: *Infections of the Hand*. In *Sayous' System of Medicine, Surgery and the Specialties*. J. B. Lippincott Company)

Figure 5 The use of a blood pressure cuff to maintain a bloodless field.

the arm which is then elevated for thirty to sixty seconds to favor venous drainage. The pressure is then rapidly raised to 280-300 mm. Hg and the operation is carried out in a bloodless field.

Figure 6 All examinations and dressings are done under aseptic precautions with surgeon and assistants masked and using sterile instruments to handle all dressings

uninvolved fingers which may have become quite stiff if the infection has been severe. Warm soapy baths in which the patient actively moves the fingers are instituted once or twice daily. It is when mobilization is attempted that the surgeon will be happy to have kept the hand in the position of function during the acute phase.

As soon as the bacterium causing the infection has been identified, sensitivity tests should be made to determine which antibiotic is the most effective.

TYPES OF INFECTION

Folliculitis. This relatively minor infection of the hand involves only the dorsal surface which alone is supplied with hair follicles. It responds to simple care, usually it is enough to cover it with a small dressing. The temptation, however, is for the patient to pick and squeeze it or to pull out the hair. Not infrequently such treatment leads to extension of the infection, usually staphylococcal in nature, into deeper tissues.

Furuncle. The furuncle, or boil, frequently stems from a follicular infection which has been to some extent neglected. It is due to a staphylococcal infection. It is a star-shaped abscess.

In the early stage, the process may subside completely if covered with a dressing and if the hand is put at rest on a splint. Sometimes an injection of penicillin will bring about subsidence. More often, however, the process leads to necrosis of the surrounding tissues and a "core," or

be accorded aseptic care. Every precaution is taken to preserve asepsis while removing and applying dressings and, of course, at operation. A mask should be worn and an instrument technique observed when the wound is being dressed (Fig. 6).

Antibiotics should be considered only as part of the treatment of an infection. In most instances, before the offending organism has been identified, it is customary to give penicillin. It is given once or twice daily, in gradually increasing doses. The use of antibiotics has posed a real problem. They reflect the widespread use of antibiotics and appear to be especially prevalent in hospital hands. Many patients are given antibiotics which are not indicated.

material, will require release. Warm moist packs and a splint may produce spontaneous evacuation of the necrotic plug; if not, an incision will be required. It is best to incise the furuncle with the patient under light general anesthesia since the area of necrosis and the cavity are usually much larger than external appearances would lead one to believe.

Subcutaneous Abscess on Dorsum of a Finger. Folliculitis, or a furuncle, may give rise to a deep abscess on the dorsum of a finger, usually on the proximal phalanx (Fig. 7). This process overlies the extensor tendon and may spread subcutaneously over the whole of the dorsal surface of the phalanx. Operative drainage is indicated and must be done with the patient under a general anesthetic with bleeding controlled by means of a blood pressure cuff on the arm so as to enable the surgeon to visualize the whole extent of the abscess cavity.

Carbuncle. This oversized furuncle occurs on the hand only on the dorsum, usually on the ulnar side, or over the dorsal surface of the proximal phalanx. It may start out as a tiny follicular infection and frequently there is a history of trauma. This type of infection should make one immediately suspicious of diabetes. The patient with a carbuncle should be put to bed with the hand immobilized on a splint and in warm moist packs kept continuously warm in a baker or similar apparatus. If diabetes is present control measures should be started. Penicillin or another antibiotic should be given in adequate doses parenterally. Under this regimen, the carbuncle may drain and evacuate itself spontaneously. If this does not occur, incision will be required. It is seldom necessary to employ the wide cruciate incision usually required in the past, because warm

packs and splinting, plus an antibiotic, tend to minimize spread and favor localization.

Collar-Button Abscess. The skin on the palmar surface of the hands, and to some extent on the digits, is thick and horny, especially in the working man. It is subject to trauma, and small cracks, puncture wounds or blisters are frequent. These favor the deposit of bacteria beneath the thickened epidermis. Here a small abscess may form which spreads beneath the cuticular layer to form a purulent blister or *subcuticular abscess*. Such a blister causes few serious symptoms and usually subsides if it is deroofed. However, the blister may represent simply the subcuticular accumulation of pus which has found its way from beneath the corium into the subcuticular area. Arriving at the epidermis which is thick and impenetrable, it spreads out beneath, raising it up as it goes (Fig. 8). In a similar fashion, although infrequently, a simple subcuticular abscess unable to rupture to the surface may perforate the corium and form a deeper abscess. In either case, the subcuticular purulent blister is simply the superficial manifestation of a more deeply lying process. An infection of this sort is known as a collar-button abscess, since there are two lakes of pus connected to each other by a narrow neck passing through the derma vera.

Collar-button abscesses occur typically at the distal end of the palm, usually in the region between the metacarpal heads. They may lie, however, directly over the flexor tendons at the base of the digits (Fig. 9). The deep portion of the abscess lies in the web space, from which it may extend distally to the dorsum and also into the subcutaneous tissues of the proximal phalanx which may be completely encircled.

Figure 7. The dorsal subcutaneous abscess on the finger usually starts as a follicular infection which spreads over a much larger area than the superficial process would seem to indicate.

Figure 8 Any subcutaneous abscess on the hand may rupture through the corium and lead to subcuticular accumulation of pus. Drainage of this alone will not adequately evacuate the deeper pocket.

Figure 9 The frog felon or collar-button abscess is a typical type of bilocular abscess occurring at the base of the digits. A superficial subcuticular accumulation of pus simply indicates a deeper pocket (Mason, M. L. *Infections of the Hand*. In *Sajous' System of Medicine, Surgery and the Specialties*. J. B. Lippincott Company.)

Treatment of such a process therefore consists in drainage not only of the purulent blister, but of the deeper process as well. The surgeon should suspect the presence of such a deep abscess from the extensive swelling and redness and be prepared to drain the deeper pocket. It is always necessary when opening a purulent blister, even if there are no signs suggestive of a deep abscess, to inspect carefully the floor of a blister to be certain that there is no tiny sinus leading to a deeper cavity.

Paronychia or "Run-Around." This infection starts in the nail wall or just between the nail and cuticle at the base of the nail. It is called "run-around" because it tends to spread under the cuticle from one side of the nail to the other. It is usually only moderately painful and the patient tends to temporize with it. If it is seen quite early, pain may be quickly relieved and the process of infection may be arrested in the nail bed.

If the paronychia is neglected a more serious extension of the abscess takes place.

Figure 10. In its early stage, paronychia starts as a tender swelling in the nail wall which may usually be unroofed easily with a sharp scalpel or scissors without employing an anesthetic.

Figure 11 When the paronychia has extended beneath the nail, it is necessary to raise up the eponychium and excise the overlying nail to secure adequate drainage.

The pus finds its way under the nail, raising it up at the base and separating it from its bed. Treatment of such an infection requires meeting two indications. The cavity must be drained and the undermined nail must be removed since it acts as a foreign body which simply keeps up the process despite otherwise adequate drainage. The cavity is drained by making incisions to either side of the nail base and then lifting up the eponychium and turning it proximally (Fig. 11). The nail is then inspected and, if it is undermined, it is removed. Care must be taken to remove all

nail that has been undermined, which usually necessitates removal of the proximal one-third. In any case, sufficient nail should be removed that when the eponychium drops back it does not overlie the distal remaining portion of the nail and thus create a closed pocket. Following incision, the hand is put at rest on a splint in a voluminous warm moist pack for twenty-four to forty-eight hours until the acute symptoms have subsided. Thereafter, light dressings, which may be first moistened with Dakin's solution, are applied. The nail will regenerate satisfactorily, provided surgical drainage has not been too long delayed. The nail at first is likely to be quite rough and irregular, but as it grows and slowly pushes off the distal portion, it becomes smoother and eventually is quite a satisfactory nail.

The neglected paronychia which has been allowed to persist for weeks or even months without adequate drainage presents one of two pictures. The nail at the base may have been partly destroyed so that an exuberant plug of granulating tissue protrudes from the nail fold, covered with purulent discharge, or the eponychium at the base may be raised, red and swollen and an occasional drop of pus may be expressed from beneath it. In either instance, adequate drainage is called for and the classical incision with nail removal and after-care should be carried out.

Chronic ulceration or exuberant granulations involving the nail bed may not be chronic paronychia, however, and a careful history of the development of the process should be taken. For example, a chancre of the nail bed is seen occasionally in physicians who have exposed themselves while carrying out vaginal examinations. A carcinoma of the nail bed may occur, usually following an injury which has refused to heal after many months. A malignant melanoma of the nail bed, Hutchinson's melanotic whitlow, is suggested by the black pigmentation, especially around the border. Rarely, a subungual exostosis will raise up the nail and lead to a granulation tissue plug. A nail which has been subjected to excess irradiation will frequently break down and ulceration will occur.

Subungual Abscess. This process, as distinguished from the subungual infection which occurs with paronychia, is usually seen as the result of a splinter or needle prick which enters the finger at the tip beneath the nail. Not infrequently a small bit of foreign material is carried in or the splinter breaks off. A painful infection develops which soon

leads to an abscess that can be visualized beneath the nail which is raised above it. It subsides rapidly when the process is unroofed by excising a small triangular slip of nail overlying the abscess. This may often be done without anesthesia, although it is sometimes so painful that brief general anesthesia is required.

Felon. In order to understand the felon and to treat it intelligently, one must know the anatomy of the anterior closed space in the pulp of the finger (Fig. 12). The felon is a staphylococcal infection involving the resilient cushion which covers the volar surface or pad of the finger tip. Examination of this pad will readily show that it is uniquely adapted to the functions which it subserves, namely, grasp and fine touch. The finger pad enables the individual to pick up or cling to large or small objects, giving a firm resilient grip with tissues which do not slip or slide. As for touch, we are all cognizant of the fine stereognostic sense of the finger tips which enables one to distinguish size, shape, consistency and texture of various objects. This pad, or cushion, occupies approximately the distal two-thirds of the tip of the finger and is made up of a tough meshwork of connective tissue fibers, somewhat like sponge, attached

Figure 12 The pulp of the finger is a firm pad made up of interwoven fibrous trabeculae which run from the undersurface of the skin to the surface of the bone. It forms an admirably firm cushion useful in grasping. Since this area is unyielding, an infection leads to tense, painful swelling and early blockage of blood supply to the distal phalanx beyond the epiphysal line.

on one side to the corium of the overlying skin and on the other to the volar surface of the distal phalanx. This latter insertion ends just distal to the point of attachment of the flexor profundus tendon. The anterior closed space is not connected with the tendon sheath of the finger.

The digital vessels and terminations of the digital nerves run through this space and, since this area is practically nonexpandable because of the dense fibrous cords which run through it, they are quickly pressed upon when inflammation occurs. This leads to early severe pain and, if tension is not soon released, to interference with the blood supply, particularly to the bone.

The felon usually starts from a puncture wound of the finger tip which leads to throbbing pain within twenty-four to forty-eight hours. Along with the pain is tenderness and tension in the involved pad which can swell only moderately. The pain becomes progressively more severe and it is usually after a sleepless night that the patient sees his physician.

Examination will show the involved tip to be only slightly swollen, but tense, hard and tender. There will be little redness and the original puncture wound may be invisible.

Treatment should be started at once, since the combination of a closed infection, interference with blood supply and a necrotizing invading organism soon leads to necrosis of the soft tissues of the pulp and involvement of the bone. This is probably the most frequent cause of osteomyelitis of the bones of the hand. If the patient has reported early for care, it may be permissible to apply a splint, continuous warm moist packs overnight and to administer an antibiotic. The infecting organisms are usually staphylococci. In an occasional case, the process may subside overnight under conservative management. If, however, the symptoms are no better or are worse, or if the tip is just as tender and tense as before, incision should be carried out at once.

Immediate incision is called for in the patient seen late or if very acute symptoms are present. The incision for the felon should divide the fibrous tissue bands or retinacula cutis which bind the undersurface of the skin to the anterior surface of the distal phalanx (Fig. 13). It should be placed along the lateral side of the phalanx midway between the anterior surface of the bone and the volar skin. After incising the skin, the knife enters the closed space parallel to the bone surface and sweeps across the space dividing the

Figure 13 Drainage of a felon is accomplished by a single hockey stick shaped incision, along the side of the phalanx, which is designed to divide the fascial septa. Care must be taken not to make the proximal end of the incision too far proximally lest the tendon sheath be opened (Koch, S. L.: J.A.M.A., vol 92)

retinacula. It is not necessary to divide the skin on the opposite side of the phalanx. Caution should be exercised not to carry the incision too far proximally lest the tendon sheath be opened and infected.

Following incision, a small rubber strip or strip of petrolatum gauze is placed in the wound to prevent agglutination of the edges. The hand is then placed on a splint in the position of function in continuous warm moist dressings. The originally administered antibiotic is continued unless sensitivity tests indicate that another is more efficacious.

If drainage has been adequate and early, the process subsides fairly rapidly. If, however, a large necrotic plug has formed, this may take a considerable time to separate. If there is involvement of the bone, a conservative attitude is indicated. If drainage has been adequate, the dead bone will slowly sequestrate or absorb, if drainage is not adequate, further incision of soft tissues is required.

Osteomyelitis. Osteomyelitis of the bones of the hand is seen particularly in the distal phalanges following a felon or occasionally in association with other infectious processes which have been neglected. It may also occur following severe wounds which have become contaminated. It is practically never seen as a hematogenous infection. As a sequela to a felon, it is evidenced by persistent drainage and a granulomatous plug coming out of the drainage incision or from a sinus tract. Early x-ray films may show rarefaction in the distal phalanx which may be mistaken

for osteomyelitis. However, while it is important to make the diagnosis early, the treatment of this condition is the same as that for felon without osteomyelitis. Under no circumstances should the bone be attacked surgically. The soft tissues must be adequately drained down to the bone surface, but the bone itself must not be curetted or otherwise tampered with. Following drainage, the part is immobilized and sequestrum formation awaited. As soon as this is discharged, the wound closes. Occasionally in children the lost bone reforms, but this seldom, if ever, occurs in adults.

Tendon Sheath and Fascial Space Infections. In order to understand these infections, a clear picture of the anatomy of these spaces is necessary (Fig. 14).

Figure 14 The tendon sheaths and fascial spaces of the volar surface of the hand and forearm form definite pathways for the spread of infection in the hand. When infectious organisms gain entrance into a tendon sheath, the process soon spreads throughout the whole sheath. When any of the three central digits are involved, the process comes to a momentary halt in the palm. If drainage is not soon provided, the process then ruptures into one of the fascial spaces in the palm—the middle palmar space if the middle or ring finger is implicated, the thenar space if the index finger is the original site. The pathway from the ulnar bursa on the little-finger side, however, ends in the lower forearm and an infectious process originating in this bursa ruptures into the retroflexor space here, similarly, a process from the radial bursa extends into the lower forearm. To be remembered also is the fact that the radial and ulnar bursae usually communicate with each other and, hence, when one is primarily involved, the other is quickly invaded (Mason, M. L. *Infections of the Hand* In *Sajous' System of Medicine, Surgery and the Specialties*. J. B. Lippincott Company).

The flexor tendons of the hand are enclosed over a greater or lesser part of their extent by synovial-lined sheaths, the synovial tendon sheaths. These structures are long, closed sacs which are invaginated by the tendons in such a way that the tendon is covered by a layer of the sac much as the bowel is covered by peritoneum. The sheath is then folded back on itself to line the space in which the tendon lies. Along the area through which the tendon invaginates the synovial sheath there is a space through which blood vessels enter and leave and this is often stretched out to form a wide membrane similar to the mesentery (Fig 15). It has been called the mesotendon. In the digits, this mesotendon is reduced in the region of the joints to ligament-like structures known as the *vincula longa et brevia*.

The tendon sheaths of the index, middle and ring fingers extend from the insertion of the flexor profundus tendon on the distal phalanx upward into the palm where they end just proximal to the metacarpophalangeal joint, which lies at the level of the distal palmar crease. Within the digit, the tendon and its synovial sheath lie within a dense osteofibrous tunnel formed by a fibrous tendon sheath on the volar surface attached on either side to the phalanx.

The little-finger sheath does not terminate in the palm but proceeds on upward through the palm, beneath the transverse carpal ligament and into the lower forearm for an inch or so. As it passes through the *carpal tunnel*, the sheath invests the tendons of the ring, the middle and then the index finger. This sheath is known as the *ulnar bursa*.

The sheath surrounding the thumb flexor likewise continues upward through the carpal tunnel to end in the lower forearm, an inch or so above the wrist. This sheath is known as the *radial bursa* and it usually connects with the ulnar bursa as the two pass side by side through the carpal tunnel.

Three fascial spaces lie deep to these ten-

Figure 15. A cross section of a sheath-enclosed tendon shows the synovial sac which encloses it and also the thin membrane which forms the mesotendon through which pass the blood vessels nourishing the tendon.

Figure 16 The relationship of the tendon sheaths to the fascial spaces in the palm (after Kanavel)

don sheaths and the relationship of them to each other is of importance. Two of these spaces lie in the palm in relation to the sheaths of the index, middle and ring fingers; the other lies in the lower forearm in relation to the radial and ulnar bursae.

In the palm (Fig. 16), a sheet of fascia from the palmar aponeurosis attaches to the middle metacarpal bone along the line of origin of the adductor pollicis muscle. On strictly anatomic grounds, such a sheet is difficult to demonstrate, but, from a clinical standpoint, the presence of such a barrier is unquestioned. The retroflexor space to the radial side of this fascia is known as the *thenar space* and in its roof lie the flexor tendons to the index finger. The space to the ulnar side of the sheet of fascia is known as the *middle palmar space* and in its roof lie

the flexor tendons of the middle and ring fingers. The proximal ends of the digital tendon sheaths therefore lie in the roof of the two spaces.

The *retroflexor space* in the lower forearm lies just above the wrist beneath all the flexor tendons and in direct relation to the ends of the radial and ulnar bursae (Fig 17).

Infections starting in a tendon sheath tend to travel throughout the whole length of the sheath almost at once—the sheaths are liquid tunnels in the fingers, palm and wrist (Fig 18). In any of the three central digits, the infection is confined to the one digit until tension gets too great or the synovial sheath ruptures from some other cause. When it ruptures, it does so as a rule through the least protected area, which is its proximal end, in the palm. When rupture occurs, the fascial space in relation to the sheath is involved. This means that if the index finger is involved the *thenar space* will be invaded, while if the middle or ring finger is implicated the *middle palmar space* is involved. Occasionally, infection in the middle finger sheath will lead to infection of the *thenar space*.

The situation with regard to the *ulnar* and *radial bursae* is somewhat different. When these bursae are infected, the process extends upward through the palm and into the lower forearm. Since the radial and ulnar bursae are usually connected with each other at the wrist, involvement starting in one is almost certain to affect the other, a condition which is called by the Germans a *V-phleg-*

Figure 17. The relationship of the radial and ulnar bursae to the retroflexor space in the lower forearm (after Kanave)

mon. When either the radial or ulnar bursa ruptures, it ruptures in the lower forearm into the *retroflexor space*.

Acute Tenosynovitis. This infection starts usually from a puncture wound, most often at the site where the sheath is nearest the surface, namely, on the volar surface of the finger at the proximal or distal interphalangeal joint. Once in the sheath, the infectious organisms quickly set up a reaction and the whole of the sheath is soon the site of inflammation. The sheath forms a liquid channel through which infection may spread.

As the inflammatory process develops and fluid accumulates in the sheath, the tension increases and, since the synovial sheath is surrounded by a dense fibrous vaginal sheath, expansion is impossible. This is an example of the phenomenon of the closed-space infection. Extrinsic pressure upon the tiny *vincula* which carry blood to the tendons leads to blockage of the vessels and, hence, if not soon relieved, to necrosis of tendon. Since rupture of the synovial sheath is retarded by the vaginal sheath, the synovial outpocketing in the palm or lower forearm bulges and ruptures. Thus, the infection is introduced into one of the three retro-tendinous fascial spaces, depending upon

which tendon sheath is involved. In case of the index, middle or ring digits, the fascial spaces in the palm are involved. The process from the index finger invades the *thenar space*, that from the middle finger ruptures into the *middle palmar* or occasionally the thenar space, and that from the ring finger into the *middle palmar space*. If the radial or ulnar bursa is involved, the retro-tendinous space of the lower forearm is invaded.

In case of radial or ulnar bursa invasion, the course of events is somewhat more extensive than indicated above. It should be recalled that these two bursae are very closely associated at the wrist where both pass through the carpal tunnel. In most instances the two bursae actually communicate there and consequently an infectious process starting in one is quickly transmitted to the other. The extent of area involved is therefore much greater than that of the digital sheaths of the index, middle and ring fingers. The retro-tendinous involvement in radial-ulnar infection is in the forearm; in index, middle and ring sheaths, in the palm.

Before these processes were well understood and logical methods for draining them established, these infections led to most serious crippling of the hand and occasionally to loss of life. The infection itself usually led to necrosis of tendons which would eventually be extruded through adventitious sinus tracts or be removed by surgical intervention. The "finger worms" of Paracelsus were necrotic tendons in infected digits which refused to heal until the "worm" was removed, usually by spontaneous separation. If tendons do not become necrotic, but somehow manage to survive both the effect of the infection and the vascular shut-off, they become frozen in the sheaths and functionless. Not only the tendons but the whole fabric of the digit, palm and lower forearm may be involved in the matting of exudate consequent upon infection, and the whole hand may become frozen and stiff, usually in a vicious position.

Added to the havoc wrought by infection itself were the damages due to inadequate, inept and incorrect surgical care. Until the surgeon understood the process, its site and localization, drainage was often delayed for long periods, either to permit the process to point, or because he did not know where to drain. It was not appreciated that early drainage was essential to saving tendons and forestalling widespread extensions. If drainage was attempted without a clear idea of the site of infection, inadequate or illogical

Figure 18 The spread of infection through the various tendon sheaths and fascial spaces of the palm and forearm is shown diagrammatically

Figure 19 The cardinal signs and symptoms of acute tenosynovitis are represented in these sketches 1, the finger is uniformly swollen, 2, it is held slightly flexed at all its joints, 3, any attempt to extend the finger passively causes exquisite pain, 4, the maximum area of tenderness maps out the anatomic outline of the sheath

incisions were made which either drained poorly or left serious scar contracture in their wake. Most common was an incision straight down the front or volar surface of a digit which drained the sheath but which permitted the tendon to bowstring forward out of the incision and become necrotic. If this tendon necrosis did not occur, the mid-line incision still led to flexion contracture of the finger and an almost irreparable situation obtained. It was not infrequent for incisions to be made through and through either finger or palm and for hard rubber drainage tubes to be led from side to side in the digit or from palm to dorsum of the hand. These drains led to pressure necrosis and further increased the already crippling effects of the process. Those in the fingers caused tendon necrosis; those in the palm carried infection to the dorsum where it was not at the start, and frequently caused osteomyelitis of the metacarpals.

It not infrequently happened also that incisions were made hastily and without due appreciation for the intricate anatomy of the hand. They were usually made without benefit of a bloodless field and many blood vessels, nerves and tendons were not visualized.

The recognition of acute suppurative tenosynovitis is not difficult if one remembers the nature of the process and if one keeps in mind the four cardinal symptoms established by Kanavel (Fig. 19). The patient with acute suppurative tenosynovitis usually reports fairly early to his physician because of the pain and inability to secure relief from simple home remedies and be-

cause he usually feels sick. It is apparent to the patient that he has something seriously wrong with the finger or hand.

Upon questioning, the patient will usually give a history of a minor injury, pin or needle prick or knife injury to the volar surface of the involved digit twenty-four to forty-eight hours previously. Usually nothing was done about it. Aching pain will have begun in the finger the night following the injury and will probably have been severe enough to interfere with sleep.

On examination it will be noted that the patient is protecting the finger, that he holds it slightly flexed and that the wrist likewise is flexed, the forearm is supinated and supported on the opposite forearm. Jarring, motion and dependency of the part are all avoided. The patient is reluctant to permit any except the gentlest examination. The finger itself will be swollen and this swelling will involve the whole finger, which assumes a sausage-like shape. Attempts to straighten the finger passively lead to marked pain. Finally, if the examiner takes a blunt probe and gently tests out the digit for an area of maximum tenderness, he will find this to coincide with the anatomic extent of the involved sheath.

These symptoms and findings hold true for all tenosynovitis, however, there are some extra features in case of infection of the radial and ulnar bursae. These bursae almost always communicate with each other; hence, while the initial symptoms and findings occur in the bursa first affected, it is not long before the other is also involved and one will find evidence of its invasion. Thus, with suppurative tenosynovitis of the radial bursa, the thumb will be swollen, flexed and resist passive extension and there will be typical tenderness, which will extend from the distal phalanx of the thumb upward into the wrist and just above the transverse carpal ligament. Added to this will be evidence of ulnar bursa invasion which will present evidence of tenosynovitis, though in the early stages not as severe as it may become later if adequate therapy is not carried out. Kanavel pointed out that the earliest sign of ulnar bursa invasion is an area of maximum tenderness in the palm at the point where the flexor tendon sheath of the little finger comes closest to the surface. This point lies in the palm where the distal flexion crease crosses the hypothenar eminence. Gentle pressure here leads to pain if the ulnar bursa is infected.

If the infection

little finger

and first involves the ulnar bursa, the chain of events is just the opposite; first there will be maximum symptoms and findings on the ulnar side of the hand and, later, evidence of radial bursa invasion.

It is important not only to be able to make the diagnosis of these cross-bursal infections, but very important to suspect them in any patient in whom one of these bursae is involved.

The general symptoms associated with acute suppurative tenosynovitis are those associated with other types of surgical infections. However, the rapid extension of the process within a closed space with relatively large surfaces of absorption often makes for quite marked general symptoms out of proportion, it may seem, to the small wound of entrance.

The treatment of acute suppurative tenosynovitis must be prompt and efficient if tendons are to be saved and extension prevented. Penicillin or another antibiotic is started at once and preparation is made for immediate drainage. Only in exceptional circumstances should drainage be delayed twelve to twenty-four hours.

As with all hand infections, incision is made in a bloodless field, secured by means of a blood pressure cuff pumped up to 280 to 300 mm. Hg after the hand has been elevated for sixty seconds. The actual incision is made with all the care of an anatomic dissection since important nerves,

blood vessels, tendons and uninvolved spaces of the hand must not be damaged (Fig. 20).

The incisions vary somewhat, depending upon the space or spaces to be drained. The incision on the digits must be made on the lateral or medial side of the finger and, since the fingers are quite swollen, it is often difficult to know just where the lateral side is. As landmarks, the surgeon takes the ends of the transverse creases of the fingers which appear at the joints. Since it is a rule never to cross flexion creases in incisions of the hand, this guide for incisions is not difficult to remember. Without following these guides, the incision on the side of a badly swollen digit will be found to lie very close to the midline when the swelling subsides. Such incisions lead to midline contracture scars which produce flexion deformities of the finger.

Incision on the index, middle and ring fingers (Fig. 20 a) extends from the base of the distal phalanx up to the proximal flexion crease of the digit. It does not extend into the palm. The proximal cul-de-sac of the sheath of these fingers is drained by a transverse incision in the palm at about the level of, or slightly distal to, the proximal flexion crease in the palm. Since this incision passes directly across nerves (Fig. 20 e), vessels and tendons, it is obvious that a bloodless field permitting clear vision is necessary.

On opening of the finger, the edematous

Figure 20. Incisions for drainage of the tendon sheath and fascial spaces must be made with the care of an anatomic dissection. The incision on the index, middle, and ring fingers must be made with the care of an anatomic dissection. The incision on the palm must be made with the care of an anatomic dissection.

fat will bulge out into the operative field. The surgeon must have assistance to keep this fat retracted so that he can first identify the digital nerve and vessels. Passing volar to these structures, the tendon sheath is exposed and opened throughout its length in the digit. It is thought by some to be important to attempt to save parts of the vaginal ligament or fibrous sheath. To this end, some surgeons advise making the distal half of the incision on one side of the digit and the proximal half on the other.

When the incisions have been made and culture taken for identification and sensitivity tests, warm moist compresses are held in the wounds and the blood pressure cuff is released. After a few minutes the incisions are inspected for arterial spurs which are ligated. A soft petrolatum gauze strip is laid in the incision to prevent agglutination of the edges and a voluminous moist pack is applied with the hand laid on a splint in the position of function.

The radial and ulnar bursae call for further incisions than those on the digit. The digital portion of the incision is made as described, however, drainage of the palmar and forearm prolongation of the two bursae is also required. The palmar portion of the ulnar bursa is opened by an incision which roughly parallels the hypothenar eminence (Fig 20 c) and its distal end may have to cross the proximal palmar crease to secure an adequate opening. Proximally this incision ends at the level of the transverse carpal ligament. The forearm portion of the ulnar bursa is then drained by an incision (Fig 20 d) about 3 inches long just anterior to the ulna on the medial side of the wrist.

The palmar portion of the radial bursa is drained by an incision which skirts the ulnar border of the thenar eminence (Fig 20 b). It extends from the region of the proximal flexion crease of the thumb upward to within a thumb's breadth of the transverse carpal ligament. It must stop there, otherwise there is danger of dividing the motor branches of the median nerve to the thenar muscles. In fact, this portion of the incision of the radial bursa is difficult since the sensory rami of the median nerve to the thumb also cross the tendon sheath and must be visualized.

The proximal, or forearm, portion of the radial bursa is opened along the radial side of the wrist by an incision about 3 inches long, made just anterior to the radius. Usually if the ulnar bursa is to be drained at the same time, the ulnar incision will suffice for

drainage of the proximal ends of both bursae.

The middle palmar space usually is involved by extension from a digital sheath and the thenar frequently is. However, the thenar space is just as frequently, if not more often, primarily involved.

Evidence of middle palmar involvement may be surmised if, in association with tenosynovitis of the middle or ring fingers, there is brief relief from the pain followed quickly by exacerbation of both local and general symptoms. Locally the normal palmar concavity is lost and the palm becomes flat, tense, hard and gray. The tenderness, which at first was confined in its maximum intensity to the tendon sheath, becomes localized also in the center of the palm. The general symptoms increase in intensity, pain becomes more severe, and the swelling of the whole hand increases. The patient becomes very ill and the fever increases along with other symptoms of a severe infection.

The involved thenar space produces similar, but usually not quite such severe, symptoms. The swelling is typical. The hand looks as if a golf ball had been inserted in the soft tissues between the metacarpals of the thumb and index finger. The thumb is pushed away from the hand and the whole area is markedly edematous. Maximum tenderness is in the first interosseous space, particularly in the palm. Early drainage of these spaces is indicated. If the associated tendon sheath is infected and requires drainage, the fascial space is drained at the same time.

The middle palmar space is opened through the same incision which drains the proximal cul-de-sac of the sheath (Fig 20 e). Forceps are inserted beneath the tendon and passed proximally, and enter the space. In the case of the thenar fascial space, the incision is made on the dorsal surface of the web space between the first and second metacarpals on a line joining the metacarpal heads and about $\frac{1}{2}$ to $\frac{3}{4}$ inch proximal to the border of the web (Fig 20 b). A hemostat is passed forward over the first dorsal interosseous muscle and posterior to the flexor tendons of the index finger into the thenar space.

The after-care of these infections is the same as for tenosynovitis: warm moist packs, sp

tic
small diffuse process which soon becomes localized to certain areas of the hand or lower forearm. Many of these require a

longer or shorter period of rest and immobilization; often the use of warm moist packs is permissible to favor adequate localization before drainage. The one real exception to this is suppurative tenosynovitis, which demands early incision.

Acute lymphangitis and acute spreading infections are caused by highly virulent organisms which spread rapidly in lymphatic and tissue spaces before body resistance can be developed to combat or control them. Many are due to bacteria of highly developed virulence against which the body has no resistance. These are the infections which, in the days before the chemotherapeutic agents and the antibiotics, often led to the death of the patient.

The courses of extension of these two processes are essentially the lymphatic system of the hand and the associated areas through which the lymphatics pass. The problem of the lymphatic spread was carefully studied by Kanavel. On the basis of Rouvier's original work, the various typical patterns of spread and eventual localization of the acute spreading infection were described by Koch.

The hand is richly supplied by lymphatic vessels, especially on the palmar surface (Fig. 21). The lymphatics from the palm drain roughly in two directions. Those on the heel of the palm, that is, the proximal portion of the palm, drain upward along the volar surface of the forearm toward the elbow and axilla, following in general the main venous channels. The remainder of the lymphatics of the palm and those of the digits pursue the shortest course to the dorsum of the hand and then pass upward to the axilla, some passing through the epitrochlear nodes, others through the axillary nodes, while some skip both axillary and epitrochlear nodes to empty directly into lymphatic channels in the neck. Kanavel pointed out that the lymphatics of the ring and little fingers pass first through the epitrochlear nodes before reaching the axilla and that those of the thumb and index finger pass directly to the axilla. Those from the middle finger may skip both sets of nodes and pass directly into the neck. It was for this reason that the middle finger was known as the "dangerous finger," since lymphangitis starting there may quickly lead to systemic infection unless brought under early control.

The acute spreading infections start as lymphangitis which quickly leads to diffuse involvement of the soft tissues of the ex-

tremity. The patterns of the different types of involvement were established by Koch and are explicable on the basis of lymphatic drainage.

The source of infection for the acute spreading process is usually a minor injury of some sort, frequently one whose treatment has been neglected. At the start there will usually be lymphangitis which will be manifested by the usual red streaks in the areas of drainage of the involved part. Soon, however, this process will be complicated by a much more diffuse and tense swelling, particularly of the back of the hand and forearm. Unless the infection is so fulminant as to cause death rapidly, localization of the infection follows certain predictable patterns, depending upon the original site of inoculation (Fig. 22).

Figure 21 The lymphatics of the hand pursue the shortest course to the dorsum, where they form into a number of channels which pass up the forearm and

pass first through the epitrochlear nodes before emptying into the axillary nodes. Those from the middle finger may miss both sets of nodes and drain directly into the lymphatic vessels in the supraclavicular area (Mason, M. L. *Infections of the Hand In Sajous' System of Medicine, Surgery and the Specialties*. J. B. Lippincott Company).

Figure 22 The acute spreading infections show several quite definite patterns of spread and localization as described by Koch. This illustration shows diagrammatically the various typical pictures seen in these dreaded infections

If inoculation has occurred on the volar surface of a finger, the lymphatics in passing from volar to dorsal surface lead to a tenosynovitis of the digit. They then pass on to the dorsum of the hand and the infection not infrequently becomes localized on the dorsal surface of the hand and wrist. In fact, in practically every instance, localization occurs over the dorsum of the wrist and is associated with extensive necrosis of subcutaneous tissues and sloughing of overlying skin. This necrosis of subcutaneous tissues and skin may in some instances be very extensive and involve almost the whole of the subcutaneous tissues of the dorsum of the hand and forearm. Such extensive invasion and local necrosis do not, of course, always develop. There may be simply marked lymphangitis and inflammation of epitrochlear and/or axillary nodes, which may occasionally break down into abscesses. When treatment is started early no localization whatever may occur; there will be the streaks of lymphangitis and the nodal areas will show swelling and tenderness, but the process subsides, often as rapidly as it began, without any abscess formation. This latter course is the one usually seen today when antibiotics are readily available and are promptly administered.

These infections, which were among the most feared of all and ranked with peritonitis as the cause of death of victims, have tended to disappear since the advent of the

antibiotics. While it is no doubt true that antibiotic agents are used much too promiscuously and often unnecessarily, it cannot be denied that their use has forestalled the blossoming of many a case of lymphangitis with a serious life-threatening infection. Although one is tempted to accord to the antibiotics the major credit, it must be apparent that there are other factors which have helped to reduce the development of the acute spreading infection. A significant factor has been a real appreciation of the importance of hand infections and a more cautious attitude toward the care and management of even small wounds of the hand, which in the past have been the most potent source of the serious infections.

Other factors may also be at work which are as yet not completely understood. It may be likely that the greatly improved nutritional status of the general population and possibly even differences in the bacterium-human relationship are of great significance.

The therapy for acute spreading infections must be aggressive but conservative—aggressive in that measures must be instituted at once to combat the process, conservative in that the process must be handled with the greatest gentleness and that all temptations and attempts at persuasion to operative intervention must be firmly resisted. Operative intervention before the process has been brought to a standstill is certain to lead to disaster. In the preantibiotic days, not a few patients, and among them many doctors and nurses, lost their lives and many patients became hand cripples from the sudden and uncontrollable spread which followed ill-advised active intervention.

The patient with a spreading infection must be immobilized immediately, preferably in bed in a hospital, and measures instituted promptly to favor localization of the process. The hand, forearm and arm are placed on a splint, enclosed in a voluminous warm moist pack and kept at rest to prevent any motion and the consequent milking of lymphatics and the breakdown of whatever barrier is being laid down by the body defense processes. Proper administration of fluids and sedatives for pain constitute the general measures which are instituted. Antibiotics are given in large doses from the start. When no bacteriologic diagnosis can be made, penicillin is the agent of choice, given in doses of 400,000 to 600,000 units once or twice daily. If material is available for bacteriologic identification and study of sensitivity, the appropriate

process has been brought under control, which may occur in twenty-four hours or may require several days. The subsidence of the process will be evidenced by the disappearance of local signs of lymphatic inflammation and diminution of the general symptoms. In many instances no localization whatever will occur and the findings and symptoms subside completely over a period of several days. If localization occurs, the involved area, usually over the dorsum of the wrist, suddenly softens; the overlying skin may show areas of necrosis and, when these are opened, copious discharge of necrotic subcutaneous tissue and pus will take place. If the infection had its onset on the volar surface and a suppurative tenosynovitis has been present, its presence will have been evident and the severe pain associated with it will have pretty well subsided.

At this time, drainage should be instituted if necessary. Drainage is especially needed when suppurative tenosynovitis has been present. The dorsal subcutaneous processes often drain spontaneously, although incisions will speed up the process and broken-down lymph nodes will need incision. Following drainage, the warm moist packs and splints are maintained for a further two or three days, following which they may be discontinued and dry dressings or dressings moistened with Dakin's solution are instituted.

Human Bite Infections. Injuries to the hand from contact with the teeth of an opponent are not particularly infrequent. If these wounds are not recognized for what they are when first seen or if the individual neglects to seek help, very serious infections may occur. Most often the wound is received when one person strikes another, his knuckles coming in contact with his opponent's teeth. The skin and tendon are tightly stretched over the metacarpophalangeal joint and are easily perforated, leading to direct contamination of the joint cavity (Fig. 23). Likewise, at the same time, several other spaces

are entered above and beneath the extensor tendon. As the joint straightens out, the tissues slide back in layers and effectively seal off the wound. From here may develop suppurative arthritis, subfascial and subtendinous infection and, if the process lasts long enough, extension of the infection may lead into the palm via the lumbrical canals.

The tissues are not just perforated, but crushed, and hence are not resistant to infection. In the second place, the organisms introduced into the tissues are extremely virulent and immediately invasive. Both aerobic and anaerobic streptococci and staphylococci, as well as various spirochetes and numerous other organisms, will be found on smear and cultures. These lead to immediate development of infection characterized by production of foul-smelling pus. Unless soon brought under control, a severe acute spreading infection supervenes and may lead to a fatal process. Locally the process invades and destroys bones and joints.

When these injuries are seen early, they should be widely opened, excised and irrigated. Under no circumstances should these wounds be closed. The extensor tendon, which is not infrequently divided, should not be repaired. The hand should be splinted in the position of function and a voluminous warm, moist dressing applied. There is evidence that the use of zinc peroxide is of value locally if applied according to Meleney's directions. The patient is preferably hospitalized. Antibiotics should be started at once in large doses. Penicillin is usually chosen initially and it would seem advisable, in view of the mixed nature of the infection and the presence of gram-negative organisms, to add streptomycin. Bacitracin, applied locally, has proved of great service in these cases. As soon as bacteriologic studies have been completed, it may be necessary to change the antibiotic therapy.

The further management consists in securing proper drainage when and if required. There will be a temptation to attack bones surgically when osteomyelitis appears. It must be remembered that the roentgenologic findings may simply represent calcium absorption and not actual destruction. The osteomyelitis is managed, as in the case of felon, by watchful waiting and maintaining adequate soft-tissue drainage, and removing sequestra when they appear.

Chronic and Unusual Infections. Although most chronic infectious processes may involve the hand, only a few of them

Figure 23 Human bite injuries (more correctly human tooth injuries) of the hand usually result from tooth perforation over a knuckle. The tooth penetrates several different spaces in its passage—first, the subcutaneous space, then the subfascial space beneath the tendon, then the joint space. Serious involvement of all these areas soon occurs (redrawn from Mason, M. L., and Koch, S. L., *Surg. Gynec. & Obst.*, vol 51)

are of sufficient importance or sufficiently peculiar to the hand to deserve special description. Such infections as actinomycosis, blastomycosis, coccidiosis, leishmaniasis, anthrax and syphilis may be seen on the hand. Tuberculous tenosynovitis, erysipeloid, sporotrichosis, tularemia and milkers' granuloma are more common.

Tuberculous tenosynovitis. Tuberculous tenosynovitis is a specific chronic infection of the bursae and tendon sheaths of the hand and foot.

It is slightly more frequent among females than males, is most often seen in young adults and involves the right hand more than twice as frequently as the left. Tuberculosis is not often found elsewhere, but it is imperative to examine carefully for other foci, especially in the chest. Direct inoculation may rarely occur from safety pins (attendants in sanatoriums) or bone spicules (butchers); usually, however, there is no clue as to the source of the lesion.

The radial and ulnar bursae of the hand are the most frequently involved, next in frequency are the dorsal tendon sheaths of the hand, then the digital sheaths of the index, middle and ring fingers and, lastly, the tendon sheaths on the foot. The radial and ulnar bursae are almost always infected together, but their distal prolongations into the thumb and little finger may remain free from disease. The process is so rarely bilateral that the presence of such involvement practically excludes tuberculosis.

The sheaths may be but slightly thickened and injected and contain a moderate amount of yellow serous fluid. More often, however, both parietal and visceral layers are thick and shaggy and the enclosed tendons are gray and lusterless, while in the small amount of yellow fluid are fibrin flakes and rice bodies. There may be extensive formation of granulation tissue with caseation and destruction, with or without rice-body formation. As the disease progresses, the tendons are invaded; in fully 75 per cent of the patients, serious tendon destruction will be found and, in some 50 per cent, whole segments of tendon will be destroyed or so badly fragmented as to require removal. In neglected cases, the associated structures—bones, joints and muscles—are invaded and cold abscesses form, with their attendant danger of secondary infection. The median nerve, though compressed and swollen, is never infiltrated.

The rice bodies or melon-seed bodies found

in about 50 per cent of cases are small, shiny, grayish, ovoid or kidney-shaped, flattened or faceted masses, varying in length from 1 to 15 mm., and in number from one or two to many hundreds. They are probably the result of the mechanical action of the moving tendons on villi and fibrin-encrusted products of necrosis of the tendon sheath.

The disease is characterized by the insidious development of a slowly progressive, painful or painless swelling over the anatomic area of the involved sheaths. In one-third of the patients the swelling is preceded by sensory or functional disturbance, such as pain, tingling, numbness or prickling sensations or by stiffness in one or more fingers. These premonitory symptoms may persist for many weeks or months before the actual swelling appears. A leathery crepitus, as in traumatic tenosynovitis, may occasionally usher in the tuberculous process.

The swelling often appears as a sudden diffuse edema which responds to heat and rest, only to be replaced later by the more tense localized, persistent swelling. With involvement of the radial and ulnar bursae, the swelling begins at the wrist and extends slowly into the palm, whence it may proceed down over the volar surfaces of the thumb and little finger. With involvement of the digital sheaths of the index, middle and ring fingers, the swelling first appears over the proximal phalanx and then extends upward into the cul-de-sac of the sheath in the palm. In cases of long standing, the disease spreads beyond the limits of the sheaths and leads to swelling in the middle palmar space, thear space or fascial spaces of the forearm.

The pain is often quite mild or even absent. In some patients a severe burning or throbbing pain occurs which radiates upward over the extremity and is increased by use of the involved hand. It may occur only at night or in the early morning hours and lead the patient to seek relief by the application of heat or cold. After persisting for several months or a year, the pain usually subsides even though the swelling slowly increases.

In the early stages of the disease, the patient has good use of the part except for the associated pain. Stiffness, weakness and difficulty in closing the fist soon develop, while later on, swelling interferes mechanically with movement and destruction of tendons leads to its actual loss.

If the disease is allowed to progress, bone and joint destruction may render the hand

useless and the formation of cold abscesses and secondary infection may necessitate amputation and threaten the patient's life.

Tuberculous tenosynovitis produces a fusiform swelling which in the early stages may not be apparent unless compared with the sound side. The swelling at the wrist is incompletely divided into a proximal and distal half by the transverse carpal or dorsal carpal ligament. On the dorsum of the wrist the several longitudinal compartments can be made out. The tendon produces

tosa. If rice bodies are present they give a sensation resembling lead shot in a leather bag and produce a peculiar grating crepitus when the patient is asked to move his fingers. A moderate amount of atrophy of the associated muscles occurs. There is little or no increase in the temperature of the part and the skin is normal unless cold abscesses, sinuses or secondary infection is present.

Tuberculous tenosynovitis must be differentiated from other forms of chronic tenosynovitis and from tumors of the tendon sheaths.

Chronic traumatic tenosynovitis, most often on the dorsum of the hand, is diagnosed by the history of an acute onset following unaccustomed strenuous use and its rapid response to immobilization.

Chronic nonspecific tenosynovitis produces a clinical and gross pathologic picture so closely resembling that of tuberculosis that microscopic section is required to make the diagnosis. Bilateral chronic tenosynovitis is almost always nonspecific.

Syphilitic tenosynovitis is very rare and may produce a clinical, gross and microscopic pathologic picture so closely resembling that of tuberculosis that the differentiation is extremely difficult. An acute or subacute inflammation may occur in the early secondary stage and the syphilitic hygroma and chronic gummatous type in the tertiary stage. The condition is likely to be bilateral, is rarely painful and causes few or no functional symptoms. The diagnosis is established by the presence of associated lesions, a positive serum reaction and response to specific therapy.

Gonorrheal tenosynovitis occurs most often in males, is metastatic, secondary to a urethral infection or, more rarely, to vaginitis or ophthalmitis, and may follow instrumentation. The onset is acute with rapidly developing pain and loss of function. A tender swelling is produced over the course of

the tendon sheath with little or no change in the overlying skin. Aspiration of the swelling yields a cloudy, serofibrinous or even purulent fluid.

The common dorsal ganglion produces a tense, circumscribed, globoid swelling on the dorsum of the wrist, most often on the radial side, and rarely reaches greater than hazelnut size.

Xanthomatous tumor, or villinodular synovitis, of the tendon sheaths may occasionally lead to confusion when it occurs as a diffuse tumor at the wrist instead of a circumscribed smooth nodular swelling of a finger. It is, however, firmer and more nodular than tenosynovitis and fluctuation is absent.

Arborescent lipoma is a rare condition in which a fatty branching tumor spreads throughout the sheath. It grows slowly and insidiously and causes few or no functional symptoms.

Extrasynovial lesions are rarely confused with tuberculous tenosynovitis. A roentgenogram of the hand and wrist should be made to determine the presence of bone or joint involvement.

The prognosis for tuberculous tenosynovitis is good. Few patients will be found with active tuberculosis elsewhere and unless grossly neglected the local process should not threaten life. If the condition is treated early and properly, a primary cure should be obtained in the majority of patients, but repeated operations will be necessary in a few. The functional results are good. In an occasional patient, amputation of a digit or an extremity may be necessary.

Management should be directed both toward the local lesion and toward the general state of the patient, as emphasized by Adams, Jones, and Marble. The treatment of choice for the local lesion is complete surgical excision of all diseased tissue. If the diagnosis is uncertain, the surgeon may temporize for a short time with immobilization and heat, but this should not be persisted in after the diagnosis is made. Complete surgical excision is extensive and time consuming but, if carried out thoroughly, justifies the pains taken. The operation is performed, with the patient under general anesthesia, in a bloodless field secured by means of a blood pressure apparatus. Appropriate incisions are made, avoiding as much as possible midline incisions and incisions crossing flexion creases, and great care is taken to identify and isolate all important nerves and blood vessels. The tuberculous sheath is opened and each tendon taken in

Figure 24. Details of operative treatment of tuberculous tenosynovitis. After the median nerve has been carefully retracted, each tendon is taken in turn as in A and the tuberculous tissue removed. Great care must be exercised to remove the visceral layer of the sheath as in B (Kanavel, A. B : Surg. Gynec. & Obst. vol. 37)

turn and carefully stripped of diseased tissue (Fig. 24), after which the parietal portions of the sheath are excised. Fragmented and diseased portions of tendons must be removed and it may be necessary to repair tendon defects by means of a suture or tendon graft.

Other, less radical, procedures are not to be recommended. Partial excisions, simple drainage, simple removal of rice bodies and injection of various medicaments have not proved successful.

Following operation, it seems advisable to give a course of streptomycin or streptomycin and PAS, since it is doubtful if even the most meticulous dissection removes all diseased tissue.

Erysipeloid. This condition, resembling a chronic type of erysipelas, is occasionally ob-

served in fishing towns among fishermen or fish handlers, dealers of poultry, cooks and veterinarians and in others who come in contact with fish.

The site of inoculation becomes red and indurated and burns and itches in a manner similar to that attending any type of bacterial inoculation. Few general symptoms are present, although the patient may complain of malaise and there may be a slight elevation of temperature. As the disease progresses, lymphatic streaks may be present. The lesion takes on a purplish color, the borders become raised and papular and the condition tends to spread. As extension occurs, the central portion clears and heals.

The disease is self-limited and usually subsides in a few weeks. Immunity to further attack

minant attacks may occur and the condition may become chronic.

Tularemia. This infection, known commonly as rabbit fever, is a widespread disease, having been described in almost all countries of the world, although it has been recognized only since 1910. The natural habitats of the causative organism—*Pasteurella tularensis*, which is carried among wild life by such vectors as ticks, lice and deer flies—are rabbits, squirrels, woodchucks, muskrats and wild rats.

Inoculation may and frequently does occur in the hand in persons who handle and skin wild game. Rabbits, and to a lesser extent squirrels, have been the source of most human infections.

The site of inoculation becomes manifest in from one to six days after injury as a red papule, producing moderate pain. There may be chills, fever, headache and general aching, such as occurs in many infections. The general symptoms usually last for two to three weeks and subside gradually.

The local lesion, at first apparently subcutaneous, becomes larger, more indurated and attaches to the overlying skin. The induration increases and the center of the nodule breaks down into a necrotic core which soon sloughs out, leaving a granulat-

ing ulcer that heals slowly. The lymphatics leading from the area may become inflamed; the epitrochlear and axillary nodes may enlarge. There may or may not be splenic enlargement.

Some six types of the disease are described, depending upon the manner of the original inoculation and the virulence of the infecting strain. The ulceroglandular type is seen on the hand and upper extremity. Other types described are the pulmonic, glandular, ingestion, typhoid and oculoglandular.

Treatment of the condition consists first in avoidance of contamination with the organisms. General measures of treatment for the condition when it once develops consist in bed rest and general supportive treatment. Before the introduction of the antibiotics, Foshay's serum was the mainstay in the therapy and was remarkably efficient. It has been replaced by streptomycin.

Diagnosis is made on the history of exposure plus identification of the organism from the secretions and guinea pig inoculation. The intradermal test of Foshay is specific and should be carried out in all suspected cases.

Sporotrichosis. *Sporotrichum schenckii* is responsible for this fungus infection which is peculiar to the hand and forearm, being

Figure 25. Sporotrichosis from thorn injury of the hand.

seldom seen on any other portion of the body. It is a common fungus of plants and shrubbery and seems to be particularly frequent on roses. A number of the patients whom we have seen have been pricked by rose thorns.

The condition starts as a subcutaneous nodule several days or so following injury (Fig 25). The nodule may reach an inch or more in diameter before it becomes fixed to the overlying skin. It produces few symptoms, little pain or tenderness and eventually breaks down into a dirty ulcer or sinus tract, discharging gummy brown pus. Soon the lymphatics leading from the area become thickened and cordlike and nodules develop along their course. The nodules may likewise break down as did the original lesion. The associated lymph nodes also enlarge but seldom actually break down.

The general reaction to the disease is remarkably slight; the patient is not sick and there is little if any elevation of temperature.

Diagnosis is made on the rather typical findings and is confirmed by demonstration of the organisms in a smear. The reaction to the agglutination test is positive.

The disease runs a slow, chronic course and tends to be self-limited but prolonged. Large doses of potassium iodide, 60 to 150 grains a day, should be administered and are quite helpful.

Milkers' nodule and hair granulomas of barbers. Injuries to the palm due to the penetration of hair are known to occur in association with two occupations—milking and barbering. The mode of penetration of hair is obvious, the explanation of the chronicity of the process is likewise obvious when one considers the make-up of hair. The hair is a scaly structure in which the scales lie on the surface like shingles on a roof. The free ends of the scales point away from the distal end of the hair. Consequently, when the hair penetrates the palm, the scales act like the barbs on a fishhook, they tend to penetrate deeper and deeper, but retraction is hindered by the scales.

These injuries produce chronic tender red nodules and tiny draining sinuses in the creases at the bases of the fingers and in the interdigital clefts. They may become acutely inflamed and require surgical drainage, they are cured only by removal of the offending hair.

INJURIES

Injuries to the hand account for 35 to 50 per cent of all wounds. When one considers the great economic importance of the hands

and the fact that all of us make our living with our hands, the need for special attention to wounds and infections is evident. The very fact that the hands are our tools which come into contact with all the objects of our daily life subjects them to many hazards.

Injuries to the hand may be conveniently divided into sharp, clean, lacerated wounds, such as those caused by broken glass, knives and tin cans, and crushing, tearing, lacerating wounds (Fig. 26). This distinction between the "tidy" and the "untidy" injuries is of considerable significance insofar as treatment is concerned. In the sharp wounds, the damage to the tissues is confined to the actual line of division. The tissues themselves are not devitalized except insofar as vascular supply may be interfered with. With crushing and tearing wounds, there is the tissue division as seen in the sharply lacerated wounds, but added to this is the extensive damage to the tissues which extends beyond the area of actual tissue division or destruction. The significance of this difference is reflected in the manner of healing of the different types of wounds and the treatment afforded them.

The management of acute open wounds of the hand is based upon certain principles of care which apply to all open injuries. Since, however, many open injuries of the hand are often small, and to the uninitiated, simple, there is a tendency to take too casual an attitude and not to afford such injuries the care they demand.

The care of open wounds of the hand begins with first aid and is not completed until the hand and patient have been restored to the greatest degree of function compatible with the injury. First aid should be simple and confined to measures which prevent secondary contamination of the wound: the control of bleeding and swelling and the insurance of rest of the injured part. The wound should be covered at once with a voluminous compression dressing bandaged on snugly but without constriction and a splint should be applied to put the hand or digit in the position of function (Fig 27).

Control of bleeding is often overstressed to the detriment of the wound. Actually, most bleeding is controlled by a firm compression dressing and elevation of the extremity. The use of a tourniquet should be restricted to those patients in whom compression will not work or as a purely temporary measure until compression can be applied. If a tourniquet is applied, it should be put on correctly, firmly enough.

and left on until the patient reaches a place where it can be removed under aseptic surgical conditions. This means the patient with a tourniquet must be transported at once to a hospital where the tourniquet is removed immediately. The practice of releasing a tourniquet from time to time on the journey to the hospital has resulted in fatal hemorrhages. The danger of shutting off the blood supply to the part by the tourniquet is not as great as that of compressing the nerves by the tourniquet, which may lead to paralysis from which recovery is very slow. Obviously, both dangers are im-

portant. Curiously enough, it usually happens that a patient with a tourniquet is brought into the emergency room with the wound still bleeding. As soon as the tourniquet has been removed, the bleeding stops, indicating that the tourniquet has merely served to obstruct venous return and does not control arterial inflow.

When the patient is brought to the emergency room for care, a history is secured at once. This history should include first of all the circumstances of the injury itself and then a general history of the patient. This latter is of particular importance in patients

A

B

Figure 26 A convenient classification of wounds of the hands has been suggested. A, the tidy wounds are those produced by sharp fields. A, the tidy wounds are those produced by sharp fields. B, the untidy injuries, due to crushes, tears, abrasive loss of covering skin, severe devitalization of tissues and

Hand in physiological position.

Application of voluminous dressings and splint

Snug wrapping

Figure 27 First aid consists in the application of a voluminous compression dressing, wrapped on snugly enough to control bleeding, and a splint to put the hand at rest

with extensive injuries requiring operative care under a general anesthetic

The object of the history is obviously to assist the surgeon to care properly for the injury and the patient. The nature of the injury is of great importance, since wounds due to sharp objects, such as knives and glass, are different from those due to crushing forces, crushing abrasions and brush burns. Crushed, abraded and burned tissues heal poorly; sloughing may occur if too great demands are put on them, while sharply lacerated wounds are frequently amenable to extensive primary repair.

It is essential to find out the degree of initial contamination of the wound. Initial contamination is usually not with immediately invasive bacteria but there are some instances in which virulent invasive bacteria may be immediately introduced on the traumatizing agent; for example, in a person working in a meat-packing or butcher shop who cuts himself with a knife used to cut up meat, a plumber working in sewers or toilets; a pathologist working on a cadaver,

a person who sustains a tooth injury of the knuckles.

The interval following injury is also of importance. It is known that bacteria accidentally introduced into wounds require a certain amount of time to acclimate themselves to life in human tissues. A certain latent period obtains which is usually assumed to be six to eight hours. A wound seen before the period of acclimatization is over can be assumed to be merely contaminated and not infected. After this time has elapsed, however, one should assume that the wound is infected. The extent of reparative surgery permitted in the wound which is simply contaminated is greater than that which may be carried out in a wound in which infection has already developed.

The nature of first aid and any other treatment previous to admission is also important. The surgeon is especially interested in discovering any possible secondary contamination or injury which the wound might have sustained subsequent to its incurrence. Was the wound exposed to contamination from human sources, e.g., droplet infection from nose and throat of patient, onlookers, doctors or nurses? Was the wound promptly covered so as to prevent this contamination? Was the patient taken to an office or elsewhere and treatment started under unsterile conditions? Occasionally a patient is received who has had an attempt at surgical repair, at which time the wound was found to be more serious than expected, a dressing was applied and the patient was sent elsewhere for treatment. It is usually wise to assume under such circumstances that secondary contamination has occurred and that extensive repairs, especially of tendons, are contraindicated.

It happens not infrequently that previous operative procedures will make diagnosis difficult. The injection of a local anesthetic may produce an anesthesia which simulates that due to a sensory nerve division. A reduction of an open dislocation of a joint may confuse the examiner who cannot make the diagnosis even on x-ray examination. This may be important in open dislocations, since the reduction may have carried dirt and contaminants into the joint cavity. The surgeon can never be sure of the conditions under which the previous operation was carried out and repairs which may be permissible in a wound not previously tampered with may be contraindicated because of possible contamination.

If simple first aid was not, consist-

ing only of covering of the wound with a sterile dressing, the possibilities of secondary contamination may be safely ruled out.

A general history of the patient is important if anything more than a simple laceration is present. The possibility of complications due to diabetes, hypertension and other general diseases cannot be overlooked.

Examination of the wound should be carried out under aseptic precautions. The surgeon, his assistants and the patient should be masked. Mouth and nose organisms are easily introduced by droplet contamination and, being acclimatized, may lead to more or less serious infection.

The wound itself should not be meddled with at this examination. Diagnosis of its extent and some idea as to need for preparation for skin grafting can be secured by observation without poking around in the wound with probes and forceps. Diagnosis of nerve and tendon division is made by testing for function of the wrist and fingers and this may be done with the wound covered.

A sufficiently accurate diagnosis of sensory nerve division may be secured by touching the patient's finger tips gently with a wisp of cotton (Fig. 28). It should be remembered that not only must the examiner test

for the median and ulnar nerves, but, when injuries involve the palm and digits, each side of each digit must be tested. The individual common digital or lateral digital nerves may be involved. The examiner must always suspect the possibility of nerve involvement whenever a wound lies in a likely location. Motor functions of the median nerve may be tested by asking the patient to rotate and appose the thumb to the tip of the little finger. This tests the integrity of the motor branch of the median nerve to the thenar muscles. It must be recalled in this connection that a complete median nerve lesion may be present in the forearm and still the thenar muscles may not be paralyzed because of crossed innervation from the ulnar. The motor function of the ulnar nerve may be tested by requesting the patient to abduct and adduct the digits. This function is never taken over by the median nerve (Fig. 28).

By and large, the sensory findings are by far the most important, since, if the tests are carefully made and the patient is cooperative and intelligent, the findings are unequivocal. In children, the examination is quite difficult and conclusions as to nerve division must often be made on probability.

Figure 28. Diagnosis of nerve damage in acute injuries may be made by testing for light touch with a sterile cotton applicator and testing for motion of the intrinsic muscles. Nerve damage must be suspected and carefully sought for when wounds are present over the course of any of the nerves of the hand

Figure 29 Diagnosis of tendon injury is made by testing motion of the fingers and wrist against slight resistance.

Examination for tendon division is made by testing the action of the fingers against slight resistance (Fig 29) The patient is directed to flex each joint. It is sometimes difficult to make the diagnosis of sublimis tendon division in the presence of an intact profundus tendon, although it will usually be noted that the initiation of flexion may be somewhat delayed. The metacarpophalangeal joints, being flexed by the interossei and lumbrical muscles, may act normally even if the tendons are divided, provided the median and, particularly, the ulnar nerves are intact.

It should be remembered that it is possible to have a complete median and ulnar nerve division at the wrist and still have flexion of the digits if the tendons are intact, since innervation of the sublimis and profundus muscles comes from the nerve trunks in the forearm well above the wrist. The superficial position of the median nerve at the wrist, just beneath the palmaris longus tendon, renders it susceptible to injury and, if any tendons have been divided at the wrist, it is almost certain that the median nerve is involved.

X-ray examination of the hand should be carried out in any patient in whom there is the slightest suspicion of fracture. Certainly,

any hand with a crushing wound should have a roentgen ray examination, as should one with a saw cut or deep laceration.

Examination should not stop with the hand, but a general examination of the patient must be carried out. Blood and urine tests are essential, especially if a general anesthetic is to be administered. It must also not be forgotten that the patient may have other wounds which require care and, at times, these may take priority over the wound of the hand.

It is rare for a wound of the hand to lead to sufficient hemorrhage to cause shock; however, this possibility should be kept in mind and, if present or threatening, measures should be taken to combat or prevent it.

With the diagnosis made and all other necessary factors under control, the surgeon then proceeds to take care of the wound itself. This operative care must be given under strict operating room conditions, whether it be a small wound requiring simple cleansing and closure or an extensive wound demanding multiple nerve and tendon repair and requiring two to three hours of the surgeon's time. The surgeon scrubs and wears cap, gown and gloves whether he is putting in two sutures, laying a small graft on a finger tip or carrying out open reduction of several fractured metacarpals. Except for brief and small procedures, a general anesthetic is preferable. The anesthesia need not be as deep as that required, for example, in abdominal surgery, since the amount of relaxation needed is not so great.

The operation should be carried out in a bloodless field secured by means of a blood pressure cuff pumped up to 280 to 300 mm Hg. The cuff is applied rather loosely to the upper arm, which is then elevated for a minute or so, and is then rapidly inflated to the desired pressure. A bloodless field has a number of advantages. It enables the surgeon to identify structures which ordinarily would be covered with blood. It obviates the necessity for constant, time-consuming sponging and, by reducing sponging to a minimum, it automatically reduces the amount of trauma to the tissues from coarse gauze. The blood pressure apparatus is left inflated until the initial phases of the operation have been carried out and all dissection has been accomplished. The cuff is then deflated. After maintaining sponge pressure on the wound for from five to ten minutes, the wound is examined and all bleeding points are ligated. This

accomplished, the arm is again elevated and the cuff reinflated. The operation is completed and a splint and compression dressing are applied before the cuff is finally released.

The first act in the surgical operation on the wound consists in a thorough cleansing of the hand and forearm and then of the wound itself (Fig. 30). This cleansing is carried out in the operating room under aseptic technique, with the individual who is doing the washing scrubbed for surgery and wearing rubber gloves. It may be necessary to anesthetize the patient before the cleansing is carried out, although often cleansing may be done before the anesthetic has been started. For extensive wounds, it is usually preferable to have the patient asleep. It may be necessary to have the blood pressure cuff inflated during the washing since this maneuver may loosen clots and bleeding may begin again.

Large cotton pledgets and liberal amounts of soap and water are used and the washing is done as carefully as the surgeon washes his own hands before operation. First, the wound is covered and the skin of the hand and forearm exclusive of the wound is carefully washed for some ten minutes. At the end of this time, the part is rinsed with warm sterile water. Then the dressings are removed from the wound and after the surgeon dons fresh gloves and obtains a fresh basin of soap and water, the wound itself is carefully and gently washed. This is not a scrubbing with brushes, but gentle washing

with well-lathered cotton squares which are frequently changed. After ten minutes, the wound is thoroughly irrigated with warm normal saline solution and the part is ready for surgical draping. Under no circumstances are antiseptics used in the wound and they are not necessary on the surrounding skin.

The wound is now ready for careful study and for the first step in surgery, which is excision of tissue so badly damaged by the trauma that it is certain to become necrotic. It is now that the surgeon first really realizes the significance of the distinction between the sharply lacerated and the crushed wound. In the former, with little tissue damage, very little tissue will require excision. In the crushing wounds, however, there will be flaps of crushed or brush-burned skin which must be excised, and muscle, fascia and even digits so severely damaged that they cannot survive. Wound excision is a most important and most difficult procedure. Upon its careful performance will depend the healing of the wound. Excision must be thorough but not reckless, all tissue which will not survive is removed and, at this stage of the operation, all tissue which will live is retained. Considerable experience is required to make the decision; to err on the side of conservatism may lead to serious wound disturbance and to even further tissue loss from infection. To err on the side of radicalism may lead to needless sacrifices of structures and even fingers which could have been saved with proper care.

Each tissue is taken in turn and all that will obviously succumb is sharply excised. Probably the greatest difficulty will be experienced in the care of the skin where two temptations present themselves. The first temptation is to be too conservative, since wide excision of skin will cause great difficulty in closure. The other temptation which must be resisted is excessive excision of skin, particularly of irregular tabs and flaps which do not seem to be of any value, or sacrifice of skin from digits which must be amputated. In sharply lacerated wounds, very little skin excision is required. Often it is not necessary to remove any of the skin edge. In crushing injuries, however, the judgment as to the amount to excise is somewhat difficult. The surgeon can get some idea as to the desired extent of excision from a knowledge of the severity of the injury. Heavy weights and crushes, severe abrasions and degloving injuries usually leave the skin not only torn loose from underlying and lateral blood supply, but so

Figure 30 The surrounding area and then the wound are cleansed with soap and water under aseptic conditions. This process will require fully ten to fifteen minutes or longer and is not a perfunctory "washing" with soap water, but careful, actual, thorough but gentle washing. No antiseptic is applied either to the wound or to the surrounding skin.

FIGURE 27. Contour-plasty.

should be planned so as to produce flaps of skin and subcutaneous tissue to overlie the operative area. The same principles apply to enlargement of accidental wounds which should be incorporated as well as possible into the general pattern of ideal incisions (from Surg. Gynec & Obst, vol 70).

severely damaged that survival is impossible. It is a real error simply to replace this skin. It is likewise seldom feasible to attempt to use it later as a free graft since it is not only badly crushed but seriously soiled and contaminated. One can often get some idea as to viability of skin by watching the return flow of blood into it after the blood pressure cuff has been released.

Subcutaneous tissue and fascia also require removal and judgment here is likely to be very difficult. Muscle which is non-contractile and gray should be excised. Bones, however, are sparingly removed. Even tiny fragments, if they are connected with some connective tissue, are likely to survive and may be molded into the reconstruction of digits and metacarpals that have been badly damaged. Tendons are not excised unless the digits to which they are

less they too are destined for areas which are already gone or will likewise be sacrificed. If nerves are excised, care is taken to divide them high and away from the area of trauma so they may retract into healthy tissue, preferably muscle.

When wound excision has been completed, only viable tissue should remain so that the surgeon can consider then what reconstruction he can carry out. The wound is carefully surveyed and all structures are identified. It is wise at times to insert fine sutures into the nerves and tendons to permit easier, exact and rapid recognition when the time comes for repair.

Decision as to the permissible amount of deep repair is made on several considerations. This concerns largely the matter of nerve and tendon repair, since fracture reduction and closure of joints are indicated in every patient except those with already developed severe infection. The surgeon must be capable of carrying out this repair. He must know how to do it. He must have the patience to carry it out and the assistance and equipment to do so. It is not possible to speed up these repairs and unless a surgeon is willing to spend the time in doing so, he should not undertake surgery of the hand. Assistance is necessary. These are not procedures for a surgeon operating by himself in an emergency room. Proper instruments, fine needles, fine suture material, fine forceps and small retractors are needed, since the usual equipment of the general operating room is not suitable for this fine surgery.

It is never feasible to repair tendons over the site of a fracture since the repaired tendon will surely become adherent to it and the repair be useless. With badly crushed wounds, tendon repair is likely to prove a failure since the tissues heal poorly and adhesions are sure to develop. Likewise, with badly crushed wounds or extensively lacerated ones, the blood supply may be so precarious that the enlarging incision necessary to expose tendon stumps may be more than the tissues can withstand.

The matter of infection and contamination is another important factor. In wounds over six to eight hours old, it is wiser to conclude that one is dealing with a potentially infected rather than a contaminated wound and only under exceptional circumstances is tendon repair permissible. The site of tendon injury is also important. In general, one can be somewhat more liberal so far as time limits are concerned with

wounds of the dorsum of the hand than with those on the volar surface. This is because dorsal wounds involve tendons surrounded by paratenon rather than by synovial sheaths. The paratenon-covered tendons do not retract as far as do the sheath-covered tendons and, hence, it is not necessary to make such a wide exposure to secure retracted stumps. On the digits, careful consideration should be given to indications for primary flexor tendon suture. Only under exceptionally favorable circumstances is primary repair to be undertaken and then only by one well skilled in the art.

Repair of the nerves should be carried out at the primary operation in all but grossly infected wounds. This too requires a special technique and is to be undertaken only by one who understands it and only if proper suture material is available. If proper repair is not possible, it is well to tack the nerve ends together with a fine suture passing only through the perineurium at the very tip of the divided ends. This will prevent retraction during healing.

Some types of wounds are so severely contaminated initially that repair, or even closure, is out of the question. These include wounds inflicted by human teeth and wounds from objects similarly contaminated such as autopsy knives.

While the surgeon is considering the feasibility of primary nerve and tendon repair, the wound is covered with warm compresses and firm pressure is applied. The blood pressure cuff is then deflated and manual compression is maintained for from five to ten minutes. During this time, the hand first becomes hyperemic and then this slowly recedes. When this happens, the compresses are removed and bleeders are caught and ligated with firm, nonabsorbable ligatures. As soon as bleeding has been controlled, the arm is again elevated for a minute or so and the cuff is again inflated to 280 to 300 mm. Hg and the operation completed.

One further consideration should be in the surgeon's mind when excising wounds of the hand. Many tissues of the hand may be quite valuable for later reconstruction. An obviously irreparable digit may form a valuable "bank" of material for this purpose.

If deep repair has been decided upon, the tendons are usually repaired first (Fig 32), then the nerves, although the order of repair will depend somewhat upon the individual case. Since the hand and fingers must be held in such a position as to relax the structures which it is sought to repair, the surgeon

may be at some disadvantage if more deeply lying structures are not repaired first.

Following whatever deep repair is indicated, the next step consists in the closure of the wound. Here again the surgeon is called upon to exercise judgment since, in wounds already infected when first seen or wounds contaminated initially by virulent invasive organisms, closure at first instance is not permissible. All other wounds, however, are to be closed primarily. Lacerations and wounds in which there has been minimal skin loss may be closed by suture. When it comes to closure, the surgeon will be happy if he has not sacrificed skin unnecessarily, but has saved even irregular tags and flaps. These may often be dovetailed into each other to secure cover and will often serve well since hand skin is best for closure of the hand (Fig. 33). In instances in which digits may require amputation because of irreparable damage, the skin of much of the digit may often be left attached and drawn into the palm or over the dorsum to cover defects which would otherwise have to be covered by means of grafts.

Figure 32 Tendon repair is carried out with the finest possible nonabsorbable sutures, the tendon is handled with extreme care to avoid traumatizing the delicate tissue.

Figure 33 Wound closure by suture is carried out wherever it can be accomplished without tension. The dovetailing of irregular flaps will often secure adequate closure with hand skin, which is always preferable.

Figure 34 When bones, joints and tendons are exposed, rotation flaps may be used to cover the area and the bed from which the rotation flap is raised is covered with a split graft

If the wound cannot be closed by suture, some type of skin graft is indicated. The type of graft used will depend upon the bed upon which it is to be placed. If the bed is composed of soft tissues, it is usually possible to lay a split-thickness skin graft over it and secure satisfactory healing. If raw bone, joints or bare tendons are exposed in the wound, however, it is not possible to lay free skin grafts over the surface. Instead, a flap of skin and subcutaneous tissue carrying in its own blood supply is indicated. This may be accomplished in one of several ways.

If the defect occurs on the dorsum of the

hand, it is often possible to rotate a flap of skin from the side of the defect and bring it over the bone or tendon. The bed from which this flap is raised is then covered with a split graft (Fig. 34).

At other times there is no possibility of bringing a flap in from the side of the wound and, in these instances, it is necessary to raise a flap from some other part of the body, usually the abdomen, and to place the hand under it (Fig. 35).

Following closure of the wound, the hand or part is placed in a voluminous compression dressing on a splint in the position of function (Fig. 36). If only one finger is injured, only that digit is immobilized; if several fingers are involved, the entire hand is put at rest under a compression dressing in the functional or grasping position. Care is taken to keep the fingers separated by gauze so that maceration does not occur where skin surface lies against skin surface.

The compression dressing helps to reduce the swelling which always accompanies injury and which is such a factor in the subsequent stiffness which may occur. Compression likewise helps to control the capillary oozing which, if unchecked, may separate apposed surfaces despite every effort at adequate hemostasis at the time of operation. Compression obliterates dead spaces and

Figure 35. A pedunculated flap may be needed when there has been great loss of covering tissue.

Figure 36 A voluminous compression dressing is useful in all phases of surgery of the hand. When it is desirable to cover the whole hand, it is put at rest on a splint (1) in the position of function (2), the fingers are separated by fluffed gauze (3) and a large amount of resilient dressing is laid over the hand (4 and 5). This is then bandaged on firmly and evenly without producing constriction (6 and 7).

brings the tissues into correct relationship and under normal tension. The dressing will also hold fractured bones in position, a feature especially valuable in the severe crushes in which the surgeon molds the hand into the position of function over a suitable splint. The dressing is applied before the blood pressure cuff is finally released so that the hand is not engorged with blood in the reactive hyperemia which follows sphygmomanometer release.

Finger Tip Amputations. Preservation of the length of digits is important in preserving function of the hand. A common injury is an amputation of a segment from the tip of a finger. Since it is not possible to close these wounds by suture, a common temptation is to amputate the bone higher up in order to procure flaps to cover over the tip. This produces a good stump, but necessitates sacrifice of length. The preferred procedure is to cover the amputated tip with a split-thickness skin graft taken usually from the

Figure 37. Amputations through the finger tips may usually be closed with small split grafts taken from the forearm.

volar surface of the forearm (Fig. 37), a procedure which can be done with the patient under local anesthesia and without special equipment.

Abrasive Burns of the Hand. These injuries are frequently due to a worker catching his hand in a pulley belt or to falls from moving vehicles. Areas of skin, usually from the dorsum, are either completely removed or so badly crushed and affected by heat that they cannot survive. Such areas should be immediately excised and replaced at once with split grafts (Fig. 38).

Extensive Crushing Injuries. These present some of the most difficult surgical problems. At first glance many of these wounds look as if nothing could be done in the way of repair and, if a pessimistic attitude is assumed, needless sacrifice of tissue may result. It is frequently not possible to assess these injuries until the hand has been cleansed and after all nonviable tissue has been excised. Great care is taken in this excision to leave all viable tissue, even though it may appear that much of it will be useless eventually. When complete excision has been accomplished, the surgeon then reviews what is left and tries to fashion from the viable remnants as functional a hand as the tissues left by the trauma will permit.

The approach to the problem is to restore function, not appearance. To make the decision on function, the surgeon must understand what the functions of the hand are. Decision in such cases must be made on the basis of the most essential or primary functions. The finer functions and motions may eventually be restored, but, in cases of this type, effort is first made to restore the basic ones of sensation, grasp and pinch.

If these principles are followed in the crushing injuries, it follows that in all instances nerve repair should be carried out, since a hand without sensation is almost useless. Restoration of grasp and pinch may seem hopeless, especially in the presence of multiple tendon injuries which must await secondary repair. Loss of skin may be extensive and repairs of tendons must await not only healing of the wound, but also the application of a pedicled flap under which tendon repair may be safely undertaken. Multiple fractures and loss of bone and digits may leave a poor framework and little to work with. However, the surgeon need only remember that molding the hand or its remnants into the position of function will give the part the best chance of function. This molding will bring fractures into alignment and digits or their remnants into the grasp-

Figure 38. Abrasive or brush burns often lead to damage over large areas. Such badly damaged skin is irreparable and must be adequately excised and the defect covered by a split-skin graft.

and can utilize flaps to the best advantage. If no more than closure can be accomplished with fractures reduced and the hand in the position of function, a great step will have been achieved.

Later, flaps of skin may be applied to replace skin grafts and to make a suitable bed for tendon repair. If such are needed, a hand in the position of function makes the best possible starting point.

Tendon Injuries. Repair of divided or ruptured tendons of the hand is based upon a knowledge of tendon healing, an appreciation of the delicate structure of the tissues to be dealt with and a willingness to follow a strict and careful technique in handling these tissues. It is not a question of simply obtaining union of tendon to tendon or tendon to bone. This will occur quite readily if these structures are kept in contact for a sufficiently long time. It is a matter of obtaining union where it is wanted and free gliding along the remainder of the course. It is a

matter of obtaining primary, reactionless healing at all stages of surgery, of maintaining mobility of joints which stiffen with rapidity when they are kept immobile. It is a matter of knowing when to start motion and how and when to encourage active and purposeful use—when to permit full function. The surgeon must continually watch, encourage and, if necessary, chastise his patients. He must not permit his own patience to be worn down in the process.

When severed tendons are first brought together or when tendons are sutured to bone, a definite healing process begins which may conveniently be divided into four phases (Figs. 39 and 40). The first, or exudative, phase of union is characterized by an outpouring of body fluids at the site of union. This exudate soon coagulates into fibrin which glues the ends of the tendons together rather weakly so that they can be separated by very slight pull. Soon, however, this fibrinous area is infiltrated by fibroblasts which come from various sources, more especially at the onset by fibroblasts from the surrounding tissues and sheath elements of the tendon.

This fibroblastic union forms the second phase of repair and, while it is much stronger than the fibrinous phase, it is still quite weak and reacts to motion by becoming more and more prolific and may produce heavy callus which may be palpable. Obviously, if such callus lies near to bone or fibrous tissue, it will become adherent to it and the subsequent gliding of the tendon is seriously jeopardized or even completely prevented. Toward the end of the third week, the tendon callus begins to soften up about the tendon, while that part which lies between the tendon ends become more dense and organized, its cells and collagen fibers tend to line up in the direction of tendon pull. Toward the end of the third week, the union has become quite strong and will withstand a fair pull without rupturing. Indeed, it would seem at this phase of the healing process some motion is helpful and tends to lead to

strengthening of the union. The final phase of healing begins at this time and is known as maturation. At the start, motion and use must be restricted for a week or ten days and probably strenuous use and sudden forceful tensions are best avoided until the end of the fifth or sixth week after repair. Maturation lasts for many weeks or months until the site of union has become as strong as or stronger than the normal tendon. It is always possible to detect the site of union, or the tendon graft which has been put in, since the new tendon never regains entirely the glossy sheen of the normal tendon. Microscopically, however, little difference between them may be detected.

Relaxation of the sutured tendon is necessary to prevent separation of the tendon ends during the early stages of repair, since the union at this time is weak and easily separated. During the second ten days following suture, strenuous use will lead to separation while even mild motion without much force may lead to increase in the size of the tendon callus and its consequent firm adherence to the surrounding tissues. Hence, following tendon repair, the parts are splinted in relaxation for a period of three weeks (Fig 41), permitting no motion of any sort until the end of that time. In case of the flexor tendons, the wrist is held flexed at about 30 degrees and the involved fingers in what would approximate the position of function, i.e., slightly flexed, more so at the

Figure 39 Diagrammatic representation of the manner of healing of a tendon. A, First week—proliferation of fibrinous tissue and oblique consolidation of gap tissues and beginning stages in adaptation of surrounding tissues to subserve gliding function. From the fourth week on, and for many months thereafter, the union undergoes a process of maturation. L. Surg.

Figure 40 Diagrammatic representation of tensile strength of sutured tendons following suture. When first sutured, the tendons are held together by the sutures only. However, very soon the tendon ends

proliferation has started, and the line of union approached in tensile strength that equal to the holding power of sutures alone. From then on, a gradual increase in strength occurs and by the nineteenth to twenty-first day is sufficient to permit some active but guarded use. Thereafter, increase in strength, as a process of maturation, continues over a period of many months.

Figure 41. Following suture of the flexor tendons, the hand is splinted in flexion so as to relax the suture line for a period of three weeks.

Figure 42. Following suture of the extensor tendons, the hand is splinted in extension for three to four weeks.

metacarpophalangeal joints than at the interphalangeal joints. At the end of three weeks, the wrist is kept flexed on a splint and the fingers are provided with check reins which permit flexion but prevent more than just slight extension. This small splint and the check reins are worn for a week to ten days during which time the patient is permitted to flex the digits and mobilize them actively. After about ten days of this restricted motion, the splint is removed entirely and the patient is permitted and encouraged to use his hand in his daily life activities. Strenuous duties are, however, not permitted for another couple of weeks. When dressings and splints have been removed, the patient is instructed in "daily soaks." These are not just soaking of the hand in warm water, but consist in warm soapy hand washes, using a cloth or simply washing one hand against the other for four to five minutes, four to five times daily. Both hands are washed since it is the motion of the fingers and intrinsic muscles of the hand which act on the vessels to pump the blood through the tissues and upward into the forearm veins. It must be stressed to the patient that perfunctory fluttering of the fingers and waving them in the air is not accomplishing anything. The patient is told to feel the flexor muscles of his forearm and to make them hard by contracting them forcefully.

Splinting following repair of extensor tendons (Fig. 42) is, of course, just the opposite of that for flexor tendons. In this instance, the wrist is dorsiflexed about 40 degrees and the fingers are extended. However, one must

splint in 150 degrees of extension unless the tendon division has occurred on the digit itself, i.e., over the phalanges. In case of the thumb, the digit is abducted and usually extended fully.

Immobilization of the extensor tendons is carried out somewhat longer than is immobilization of the flexors—usually three and a half to four weeks for complete immobilization and then another week with restricted motion. Following this, the patient is fitted with a padded splint with straps which he wears at night for a few weeks. The night splint is necessary for the extensor tendons since the constant flexion, often strong, which occurs during sleep may lead to stretching of the site of union and loss of a certain amount of extension.

Rupture of the Extensor Pollicis Longus Tendon. Rupture of this tendon was described many years ago as drummer's palsy, since it was seen so frequently in drummers in the German army. After years of drumming, these men would suddenly lose the power of extension of a thumb. The condition would come on painlessly but completely and no amount of conservative therapy would cure it. It was assumed for some time that it was an isolated paralysis of the extensor pollicis longus muscle of unknown cause. However, when some bold surgeon cut down on one of the tendons, it was discovered that the condition was actually a rupture of the tendon in an area of attrition along that part of the tendon which moved back and forth over the lower end of the radius, obliquely transverse across the wrist and finally distally to the thumb. Age seems to be of some significance in the development of spontaneous rupture, since the circulation of the tendon becomes less as the tendon ages.

sion or hyperextension and correction is difficult. The finger joints, likewise, are seldom

Similar rupture of this tendon is seen infrequently following Colles' fracture. It comes on suddenly in the second or third week and is thought to be due to irritative damage to the tendon as it passes over the site of fracture. It is a condition inherent in the fracture and has nothing to do with the reduction or manipulation. It may occur in instances in which reduction is perfect and has been accomplished with little trauma.

The findings are perfectly typical of loss of function of the extensor pollicis longus tendon (Fig. 43). The thumb droops forward in flexion at the metacarpophalangeal and interphalangeal joints and the patient is unable to extend it. Although the extensor brevis and abductor longus are functioning, the great significance of the extensor pollicis longus in all motions having to do with extension and abduction is clearly revealed in this injury. When there is doubt as to the diagnosis, the crucial test is extension of the distal phalanx, which is not possible in loss of the extensor longus.

Treatment of the condition is operative. No amount of splinting will restore function. Suture of the tendon is seldom possible or feasible. The ends are degenerated and repair is impossible. It is quite possible to

insert a tendon graft between the distal stump at the base of the metacarpal, thread it through the proper tunnel and then attach it to the proximal stump. However, this is a formidable procedure. The proximal stump is difficult to find and requires an extensive dissection in the forearm. Besides these disadvantages, the tendon graft would have to run through a tortuous tunnel with rigid walls and stands a good chance of being stuck therein.

A procedure which fortunately works out well because of availability of tendons is that of tendon transference. There are two radial extensors to the wrist, either one of which can be detached and transferred to the distal stump of the extensor pollicis longus. In some patients, however, this transfer has been followed by a spastic condition of the thumb in which attempts at flexion are accompanied by extensor spasm. This was assumed to be due to differences in excursion of the two tendons, and such a difference does exist. The extensor pollicis longus has an excursion of 5.5 to 6.0 cm.; the extensor carpi radialis brevis and longus, 3.5 to 4.0 cm. Consequently, another double extensor supply has lately been utilized, namely, the extensor indicis proprius. Curiously

Figure 43. A, Isolated rupture of the extensor pollicis longus tendon occurs occasionally following Colles' fracture. It was at one time seen frequently in drummers in the German army and was shown to be due to attrition of the tendon due to repetitive trauma. B, The complex course of the extensor pollicis longus explains the liability of this tendon to damage at times of Colles' fracture and also illustrates the difficulties of suture and repair following injury. The close relationship of the extensor indicis proprius to the extensor pollicis longus makes tendon transfer a feasible solution to the problem (Kaplan, E. B.: *Functional and Surgical Anatomy of the Hand*. J. B. Lippincott Company).

enough, although this tendon has an excursion of 3.0 cm or less, it seems to function satisfactorily.

After-care for tendon transference consists in splinting of the thumb in the position of abduction and extension for three weeks, then application of a removable splint which the patient takes off for a few hours a day for the next two weeks and wears at night for another two weeks. Any vigorous use of the thumb is prohibited for at least six weeks.

Baseball Finger (Drop Phalangette; Mallet Finger). The insertion of the extensor tendon into the base of the distal phalanx of the finger is extremely thin and is frequently torn when the extended tip is forcibly flexed. This is seen especially in baseball players when a ball lands on the tip of an outstretched finger and flexes it acutely (Fig 44). One of two things may happen—the tendon tears across, usually at the level of the joint, or an avulsion fracture occurs with the bone of insertion fracturing with the pull of the tendon. It is wise, therefore, in these circumstances to secure x-ray films to determine if there has been a fracture.

The deformity resulting from the injury is quite typical and unmistakable. The distal phalanx drops forward in flexion and cannot be actively extended, producing a dropped finger tip. It can be pushed back into extension but drops down immediately to an angle of 125 degrees or less as soon as released. The finger flexes normally, but when the active flexion ceases, the finger comes back to about 125 degrees. This must not be confused with active extension, it is simply the angle which the tip assumes at rest.

Treatment of the condition varies with the pathologic condition present, with the probable extent of the damage and with the time elapsed since the injury. When there has been avulsion of the tendon with a chip of bone from the phalanx, healing will often occur satisfactorily following splinting of the finger in extension, with the distal phalanx in hyperextension. This must be maintained for at least five weeks and the patient will have to wear a splint at night for several weeks longer.

For rupture of the tendon without bone avulsion, splinting is likewise often successful, especially if the patient is seen quite early after the injury and if he wears the splint continuously for a period of five weeks and at night for a further two to three weeks.

Figure 44 Baseball, or mallet, finger is a characteristic deformity due to rupture or avulsion of the extensor insertion into the base of the distal phalanx.

The tendon heals quite rapidly; however, it is tissue-paper thin at the site of rupture and the thin callus stretches easily so that even though a full extension may be present early the tip will droop later. It is sometimes difficult to prevent a certain amount of dropped tip even under the best of conditions. Operative repair in the early case is of some advantage, since it permits the surgeon to remove bits of capsule and tendon from the joint cavity which may have fallen into it. The period of immobilization following operative repair must be just as long as after simple splinting.

When the condition is seen late, an open repair may be necessary since the gap between the torn ends of the tendon fills up quickly with callus and splinting in extension cannot be expected to shorten this callus. The open procedure consists in tendon shortening or, rather, callus shortening, since the distal stump is short and thin. The callus is divided obliquely in a longitudinal fashion and then, with the finger in maximum extension, the two flaps are overlapped and tacked together with a few fine sutures. The essential step is to maintain the hyperextension since the sutures themselves serve little function after the first day. In fact, the secret of all tendon repair is the maintenance of relaxation and, in this particular instance, the importance of this is markedly emphasized. At times, it may seem indicated to put a tendon graft into the digit to secure more stable union.

After-care following operation is the same as the treatment of the acute injury, namely, continuous uninterrupted extension of the finger for a minimum of five weeks and a

splint at night for a further two to three weeks.

Buttonhole Dislocation. This descriptive term applies actually to the typical deformity following the division of the central slip of the extensor, usually just distal to the proximal interphalangeal joint (Fig. 45). In order to understand the deformity produced by this division and to rationalize its treatment, it is necessary to understand the anatomic arrangement obtaining with regard to the insertion of the extensor tendons on the digits.

The common and proper extensors of the index, middle, ring and little fingers originate in the forearm and, after passing through their tunnels on the dorsum of the wrist, reach the region of the metacarpophalangeal joints. Here they pass over the joint capsule, attaching to it to greater or lesser extent. Certain of the fibers attach to the base of the proximal phalanx where they serve as extensors of the joint. The capsule and these tendon slips form what is known as the extensor cuff. Approaching the cuff from the sides, and between the metacarpal heads, are the

tendons of the lumbrical and interosseus muscles which form the so-called lateral slips of the extensor aponeurosis. These slips, however, become attached to the central slip or that portion of the extensor aponeurosis coming from the common extensor tendons, distal to the metacarpophalangeal joint, passing along the side of the proximal phalanx and proximal interphalangeal joint to reach the dorsum of the finger. These lateral slips come together just distal to the proximal interphalangeal joint and then proceed as a single band distally to insert in the base of the distal phalanx. The central slip in the meantime has inserted into the base of the middle phalanx where the majority of its fibers stop.

This arrangement accounts for the fact that the lumbrical muscles and interosseus muscles act as flexors of the metacarpophalangeal joint and extend the interphalangeal joints. It also accounts for the fact that the central slips coming from the common and proper extensors extend the metacarpophalangeal and proximal interphalangeal joints but do not extend the distal interphalangeal joint unless the whole extensor expansion is put under tension by flexion of the wrist and flexion of the metacarpophalangeal joints. When the central slip of the extensor aponeurosis has been divided, the proximal interphalangeal joint drops down into flexion and the extensor communis pulls upward or retracts. At the same time, the lateral slips become tense and hence they exert pull on the distal phalanx and draw this joint into extension. At the same time, with the central slip divided, the lateral slips tend to dislocate forward, thus accentuating the flexion of the proximal interphalangeal joint which then projects dorsally between the slips. A typical deformity is thus produced. The proximal interphalangeal joint tends to become more and more acutely flexed and the distal joint goes into more and more extension and eventually becomes hyperextended. This deformity is called buttonhole dislocation since the joint, while not actually dislocated, projects dorsally between the lateral slips of the extensor aponeurosis.

This deformity occurs usually from an open division of the central slip across the dorsum of the proximal interphalangeal joint. Repair of this injury entails repair of the divided tendon, which is not as simple as it sounds since the situation is usually not seen early and contracture has already occurred. It is usually necessary to bring the lateral slips forward as well as to repair the central

Figure 45. A, Division of the central slip of the extensor aponeurosis produces a typical deformity known as buttonhole dislocation. The proximal interphalangeal joint is flexed and the distal interphalangeal joint is hyperextended. B, Diagram adapted from Kaplan to show the mechanism of buttonhole dislocation (redrawn from Kaplan, E. B. Functional and Surgical Anatomy of the hand, J. B. Lippincott Company).

slip For this procedure, tendon grafts are often necessary.

It is sometimes possible in the early case to secure satisfactory healing by splinting of the proximal interphalangeal joint in extension with a splint which permits some flexion of the distal interphalangeal joint. If a patient is seen late, this same splinting should be carried out to correct the deformity before operation. In some instances, even when the patient is seen late, this splinting may correct the condition.

Rupture of the Flexor Tendons. Flexor tendons rarely rupture. In certain types of injuries, the tendon may pull out along with a digit, tearing through at the musculotendinous junction. Rarely, a flexor profundus will rupture through the insertion into the distal phalanx. When it does so, it will retract variable distances up the sheath, often restricted by the vincula. Symptoms are those one would expect from loss of the proper flexor of the distal phalanx. Repair usually entails a tendon graft since, except in early cases, it will be impossible to bring the stump distally and reinsert it into the distal phalanx.

Grease-Gun Injuries. These injuries are purely a product of the machine age, although similar lesions pathologically were produced in the early days of cosmetic surgery by the introduction of paraffin for the rounding out of contours and the building up of noses and breasts. Similar pathologic tumors were caused, in the old Russian and German armies, by recruits seeking to avoid military service by the injection of various oils to cause tumors. Occasionally the injection of medicaments in oil, especially if given subcutaneously, will lead to tumors (oleomas).

Grease from such guns, with small nozzle opening and very high pressure, may penetrate the tissues, leaving little or no mark of their entrance. The grease under great pressure is forced into the tissues, filling all spaces with an irritant foreign material. If the grease enters the tendon sheaths, they are completely filled.

The immediate reaction is a severe inflammatory process associated with moderate pain. Subsequently, the wound of entrance may open and a purulent greasy discharge develops. Later on, a hard, fibrotic sarcoma-like mass forms in all the involved tissues and may lead to complete disability of the part. The tumor tends to grow slowly and take over large areas. Although not malignant at the start, it may become so. When

first seen, efforts should be made to remove as much grease as possible by adequate incisions, which should be left open to drain grease which will still soak out on the dressings. If seen later, when tumor formation has occurred, extensive excision is often called for and various plastic procedures may be needed to reconstruct the hand.

BURNS

While the principles of care are the same wherever a burn may occur, there are certain special features in burns of the hand which require emphasis.

It cannot be stressed too strongly that, from the very start of care, it is important to place the hand in the position of function and maintain it on a splint under a compression dressing until healing has been secured. The hand goes so easily into a vicious position if great precautions are not taken to prevent it that this must be a constant care of the surgeon attending a patient with a burned hand. A compression dressing is of importance for, although this does not entirely prevent the formation of swelling and edema, it does tend to minimize it. Much of the stiffness of the hand which occurs after burns is due to the organization of the exudate which comes with burns. If this exudate can be reduced in amount and, if the hand can be kept in the position of function, much of the disability following burns will be avoided.

A good result following care of a burned hand depends on securing early healing. The

Many deep second degree burns of the hand become converted into third degree burns by infection. Hence, every means possible should be taken to prevent the development of infection.

Burns of the dorsum of the hand especially, even if not full thickness, tend to heal with thick keloid scars which contract and form an armor-like covering which seriously interferes with function.

Full-thickness burns of the hand should be excised early and the raw surface covered with split grafts. These grafts will seldom be the definitive cover for these areas, probably because it is not possible to carry out a complete excision in depth and in extent of the burn. However, they will secure early healing and will minimize deep scarring. Later on it will be possible to excise these areas and apply more suitable cover.

Dorsal burns of the hand, especially when the fingers are affected, tend to expose the tendons and the interphalangeal joints, especially the proximal joints. This unfortunate condition may result when the burn, originally perhaps deep second, becomes converted into third degree or full-thickness loss from infection. It is therefore especially important to get rid of slough or destroyed areas as early as possible and to secure healing.

Maintenance of the position of function is not as easy to accomplish as it may seem when deep burns and massive destruction are present. It is, however, not enough to keep the hand in the position of function. Unless the surgeon also secures early coverage, simply splinting the hand is of no avail, since the raw surfaces pile up granulations and the scar becomes thicker and more contractile.

Further care of the deep destructive burn with loss of tendons, joint fusions and severe contractures consists in the provision of adequate covering tissue, in securing the position of function and in providing as much motion to the hand as the contracture permits.

VON VOLKMANN'S ISCHEMIC CONTRACTURE

This crippling condition when fully developed is characterized by necrosis, followed by fibrous replacement of variable extent of the flexor muscles of the forearm and wrist, with subsequent contracture of the tendons leading to flexion deformity of the wrist and hand (Fig 46). Associated with it are varying degrees of nerve involvement, particularly of the median but also of the ulnar nerve, and general wasting of the extremity from the elbow down. It is most frequently seen following supracondylar fractures, particularly those treated in flexion with tight casts, but may occur without any of these etiologic factors. A similar muscular condition may occur in the small muscles of the hand alone, often due to constricting bandages and leading to a typical contracture deformity from shortening of the interossei.

The pathogenesis of the condition is not clear. In most instances it would appear that swelling due to hemorrhage and edema in an extremity which cannot expand, because of tightness of fascial compartments or tight dressings, or both, is the prime factor. However, in those instances in which tight dressings are not present, and in which the mechanical factor of compression does not obtain, it is thought that arterial damage

over the fracture site or arterial spasm is present to account for the necrosis due to lack of blood supply. Considerable experimental work has failed to explain the condition satisfactorily. Brooks was convinced that the condition was due to interference with the outflow of blood caused by venous obstruction and he produced some ingenious experiments to prove his point. Subsequent workers have not been able to reproduce his results.

The situation with regard to the nerves is not clear. In some instances, the median and ulnar paralysis recovers gradually while the patient is undergoing conservative treatment. In other cases, exploration of the forearm in patients in whom nerve recovery has failed to take place has shown the nerves to be reduced to scarred cords for a considerable area. In some patients, the median nerve at the elbow is actually divided or compressed by bone fragments or is constricted by scar involving the pronator teres. The nerve condition, however, is not the cause of the necrosis, but rather part of it or secondary to it.

The brachial artery, likewise, may be impinged on bony fragments at the elbow and its flow stopped. The significance of this in causing true von Volkmann's contracture is likewise not clear. Certainly, arterial blockage is more likely to lead to gangrene than to the condition of von Volkmann's contracture.

The significance of compression is real, as evidenced by the beneficial effects of release of compression by division of the cast and straightening of the elbow.

The onset of von Volkmann's contracture is ushered in by severe pain in the forearm and hand, usually after reduction of a supracondylar fracture at the elbow. The radial pulse disappears and the hand becomes swollen and blue. If the situation is recognized early, if tight dressings are removed and if the flexed elbow is straightened out, the initial symptoms may subside, the pulse return and the pain disappear. If, however, these symptoms are ignored, or if the patient is not under hourly surveillance, irreparable damage results. The pain will slowly subside after reaching a peak, the fingers gradually contract down into flexion and the swelling recedes. When the cast is finally removed, areas of necrosis of skin and subcutaneous tissues of the forearm will usually be found. When this process has cleared, the typical deformity will be present.

When fully developed, the deformity pro-

Figure 46. Von Volkmann's contracture is due to massive necrosis of the flexor muscles in the forearm, with variable degrees of median and ulnar nerve destruction. This produces the flexion contracture of wrist and fingers, adduction of thumb and pronation of the forearm, which are the unmistakable signs of this dread condition.

duces an unmistakable picture. The forearm is markedly wasted, especially the volar surface. The fingers are thin and atrophic and flexed at the interphalangeal joints. The wrist is held flexed and the thumb tightly adducted to the side of the hand. The fingers can usually be straightened if the wrist is flexed, but when one attempts to extend the wrist, the fingers flex tightly into the palm. The forearm is pronated and attempts to supinate it meet with resistance.

Sensation may be absent over the median and ulnar nerve distributions. Growth of the forearm and hand almost ceases and, since the condition is seen particularly in youngsters, it is not long before this difference in size is quite noticeable. The hand becomes an almost useless appendage. There may develop a modicum of flexion, but the range is limited and extension is restricted by the contracted flexor muscles.

Treatment depends upon the stage in which the condition is encountered. When the premonitory symptoms occur in the patient under

be taken to dressings at point where the radial pulse returns. It may be necessary to attempt some other means of controlling the fracture, but, at the moment,

the most serious problem is that of combating the threatened von Volkmann's contracture.

If these conservative measures fail, the surgeon must consider releasing tension under the forearm fascia, by wide splitting of the fascia, leaving it open, although the skin may usually be closed. At this time, opportunity should be taken to inspect the brachial artery which may be damaged or in spasm. The spasm may release spontaneously or infiltration of Novocain in the area may effect release. The median nerve should likewise be inspected at this time.

When the contracture has become established, the treatment in any case is long and tedious. Corrective tension-splinting should be started very early. This is designed to prevent or correct the flexion contracture by exerting constant but gentle pull of the fingers and wrist into extension, to hold or pull the thumb into abduction and extension and rotate the forearm into supination. Numerous ingenious splints have been devised to accomplish this end. None is perfect and all require constant watching and attention. The pressure must be accurately adjusted and inspection must be frequent lest the patient develop pressure areas under the straps and elastic bands.

Splinting and physical therapy, if started early and continued for a long time, may restore a hand to considerable function. However, it all depends upon the extent to which the muscles and nerves have been damaged. Obviously, if there are no living muscle fibers left in the flexor group, one cannot hope for return of function. If, however, some motion can be detected in them, there is a chance that with use and a determined patient a fair amount of function can be developed.

If it is not possible to bring the digits out into a functional position and there appears to be a fair amount of muscle present which is too short, the surgeon may consider some means of compensating for this discrepancy. Several possibilities present themselves, such as detaching the flexor group at its origin and advancing it an inch or so down the forearm. Another possibility is to shorten the forearm by cutting segments out of the radius and ulna. It has even been suggested to remove one row of carpal bones. The general principle is to shorten the forearm or lengthen the tendons so as to permit the fingers to be extended.

In those patients in whom sensory and motor recovery does not occur after a reasonable time, it is advisable to explore the median and ulnar nerves and to release them from their constriction. This may or may not be successful. When no motor function can be detected in the entire flexor group, the only remedy is to attempt transfer of functioning tendons into the nonfunctioning flexors. Usually the extensors of the wrist are functioning and may be utilized for this purpose.

DUPUYTREN'S CONTRACTURE

In 1831, Baron Dupuytren of the Hôtel Dieu in Paris had the opportunity to dissect a hand which was the seat of a peculiar contracture causing flexion deformities of the digits. Although the condition was known before this time, and, although it would appear that Sir Astley Cooper had previously pointed out the exact site of the trouble, Dupuytren's dissection and careful description were definite and precise and the condition has been known by his name ever since.

Dupuytren's contracture, as originally described, is a condition involving the palmar aponeurosis and its prolongations and connections, leading to the formation of hard fibrous nodules and bands in the palm, interdigital clefts and digits, and producing contractures of the skin and fingers (Fig. 47 and 48).

To understand Dupuytren's contracture, the anatomy of the fascia of the hand should be reviewed, particularly the palmar fascia (Fig. 49), which is the structure involved in the disease. Not only must one know the palmar fascia, but also the deep connections of this structure with the fibrous septa passing between the flexor tendons from the region of the metacarpophalangeal joints

Figure 47 Typical Dupuytren's contracture—flexion of the ring finger, moderate flexion of little and middle fingers and a hard, fibrous band beneath the palmar skin

Figure 48 The superficial palmar fascia

Figure 49. A cross section of the palm at the level of the metacarpophalangeal joints shows the relationship of the pretendinous bands of the palmar fascia to the underlying tendons. The perpendicular sheets from the undersurface of the fascia are shown passing deeply to either side of the tendons to become attached to the deep transverse metacarpal ligaments (Kanavel, A. B., Koch, S. L., and Mason, M. L.: *Surg., Gynec. & Obst.*, vol. 48).

distally, the prolongations of the fascia onto the digits and the various connections and relations of the digital fascial sheaths. Likewise, there must be an appreciation of the close association which exists between the palmar fascia and the overlying skin, especially in the middle third of the palm, i.e., in the region between the proximal and middle palmar creases and for a variable distance proximal and distal to these creases. Similar attachment of the skin may likewise exist over the volar surfaces of the proximal phalanges of the fingers. The relationship of the digital nerves to the fascia as they enter the fingers is of great significance, since their distortion by contracted fascia will lead to difficulties of dissection when operation is carried out.

The palmar fascia begins at the transverse carpal ligament, probably as the prolongation of the palmaris longus muscle, although there is no real agreement on this point. Starting as the apex of a fascial triangle, the tissue fans out distally into a central portion, flanked on either side by a lateral and medial sheet. The central portion makes up a fan with four ribs, the pretendinous bands, so-called because they lie over the underlying flexor tendons to the digits as they pass through the palm. They are not connected with the tendons in any way. When these bands are thick and contracted and are palpated through the skin, they feel like tendons and the uninitiated mistake them for

tendons. As these pretendinous bands approach the fingers, they separate like the ribs of a fan and the space between them is covered by a thinner layer of transverse fasciculi which holds them together. At the region just distal to the metacarpophalangeal joints, the fascia tends to thin out, the transverse fasciculi ending and leaving a fairly free space just proximal to the webs where the subcutaneous fat produces soft padlike areas. Just at the web, the transverse fasciculi again appear as thin definite bands, the natatory ligaments. The palmar fascia, as it passes onto the digits, then becomes continuous with the digital fascia which envelops the finger as a sheet and contains within two layers of it the digital nerves and vessels. When involved, it is this layer which draws the nerves and vessels out of their course, often to the opposite side of the finger. This fact is of great importance when the fascia is being dissected out.

The digital fascia is little in evidence in its normal state. However, when it is involved in disease, certain areas become thickened and appear as nodular masses on the volar surface or as lateral bands. These volar nodes and bands demonstrate the continuity of the fascia with the palmar fascia. The digital fascia is attached to the flexor tendon sheath in the region of the proximal interphalangeal joint. The lateral parts of the fascia, when involved as bands, are seen to be continuous with the

ons of the

fascia and to be attached to the proximal interphalangeal joint capsules.

One other anatomic fact is important when operative correction is undertaken. The skin of the palm is supplied by vessels which take origin from the common digital vessels in the palm and rise palmward between the tendons to perforate the fascia and reach the undersurface of the skin. Here they spread out for a variable distance to anastomose with other vessels from neighboring arteries. This anastomotic network, however, is not very well developed or extensive. The blood supply to the palmar skin, therefore, is easily jeopardized by the division of these vessels, especially so if the undersurface of the skin is badly contracted by fibrosis, such as occurs in Dupuytren's contracture. This jeopardy is further increased if, following removal of the fascia and closure of the incision, a large hematoma forms under the skin creating compression of the fine anastomotic vessels on its undersurface.

The etiology of the condition is not known. Dupuytren thought that repeated trauma was the cause. His coachman, who handled the whip, and his wine-handler, whose hands were constantly subjected to injury from hoisting wine barrels, go trooping through the pages of history. With the advent of the automobile, the emphasis was shifted from the whip to the gear shift and the brake. Nowadays, with automatic gear shift, we still see Dupuytren's contracture in laborer and nonlaborer alike. In other words, the cause of Dupuytren's contracture remains a mystery today, as it did a century and a quarter ago when Dupuytren first described it. Many studies have been made to attempt to correlate Dupuytren's contracture with rheumatism, with cervical arthritis, with diseases of the spinal cord and sympathetic nervous system, with diabetes, with repetitive trauma, but none has stood the test of mathematic

shown itself hereditary influence has been demonstrated in a good percentage of the patients and this, while not universal, has been more consistent than any other. The association with epilepsy, so clearly brought out by Skoog, is attractive and certainly there are many instances of this condition appearing in epileptic patients. From our observation, it can be said that Dupuytren's contracture is often seen in epileptic patients, but very rarely have we been requested to care for a patient with Dupuytren's contracture who gives a history of epilepsy. The same may be said

for age—the majority of patients with Dupuytren's contracture are fifty to sixty years of age, but it is seen in younger persons, though not so frequently. So far as sex is concerned, most of the patients are males, but it is not a disease of males alone and the studies of Stuart Gordon of Toronto seem to indicate that the figure of 10 to 15 per cent in females may be too low.

As far as trauma as an etiologic agent is concerned, this seems to have the strongest support. However, the evidence is equivocal and circumstantial. The history of trauma is by no means universally present, not even in an overwhelming majority of individuals afflicted. The hands obviously are the most subject to trauma of any part of the body, so that one would be hard put to find a patient who would not give a history of some sort of trauma to the hands. Usually the condition begins in one hand, often the right. The patient may give a definite history of an acute injury years before or of excessive use of the hand with repeated trauma to the palm. This seems to fit the condition quite well until several years later the same condition develops in the opposite hand or is discovered there by the examining surgeon. Nor does Dupuytren's contracture occur only in individuals who do manual labor. It is seen quite frequently in persons whose severest work is the use of pen and pencil and whose only palmar trauma consists in pressure of the steering wheel or golf club.

Heredity is thought to play a role in the occurrence of the condition. It is found not infrequently in a family for two or three or more generations. It must be admitted that heredity is by no means always implicated, although it is surprising how many patients will deny it initially, only to return later with the statement that upon inquiry they had discovered that some relative, usually but not always, on the father's side, had some sort of crippling condition of one or more fingers.

The gross pathologic state of the condition shows the pretendinous bands to be thickened and shortened (Fig. 50). Often, in the region over the metacarpophalangeal joints, thick nodules will be seen in the bands—1 to 2 cm. in diameter. Similar thick nodules will be found in the volar surfaces of the digits when these are involved. As these bands shorten, they pull the overlying skin into folds and dimples. These are, however, by no means simple skin folds, as the surgeon soon discovers on attempting to free the skin from the underlying fascia. The fascia will

prominent and a thickened hard cord may be felt to extend proximally and often distally, mistaken by the uninitiated for the tendon. Soon, as this band thickens and shortens, the proximal phalanx of the finger is drawn into flexion, at first, flexion is slight, but, as the condition progresses, the finger becomes more and more flexed, at both metacarpophalangeal and proximal interphalangeal joints. This may draw the finger down until the tip lies in the palm. In severe, neglected cases, it may actually dig into the palm. The distal interphalangeal joint, instead of going into flexion, tends to remain extended or even hyperextended, because of involvement of the dorsal expansion.

There are ordinarily few subjective symptoms other than the inconvenience caused by the contractures. Patients complain that it is difficult to shake hands, to hold a golf stick or grasp a hammer, or that they poke themselves in the eye while washing the face. Occasionally one will complain of vague discomfort, rarely of actual pain.

Examination reveals the contractures and thickening in the palm and digits. In the very early case, there may be only the nodule in the palm and the surgeon may be somewhat in doubt if he is dealing with an early Dupuytren's contracture. However, careful palpation will often reveal the thickening of the pretendinous band. It can often be more easily demonstrated if the fingers are passively hyperextended. When the contracture is alone, the prominent evidence

likewise, at this time, the skin over the transverse carpal ligament between the closely opposed bases of the thenar and hypothenar eminences will be drawn distally as a triangular fold. If the process is of long duration and marked contracture has taken place, there may be maceration in the skin folds and between the digits.

The treatment for Dupuytren's contracture consists in operative excision of the palmar fascia. It is preferable to remove the whole of the palmar plate, even if only certain segments are involved. The digits are not opened unless there is actual palpable involvement. Removal of the palmar portion of the fascia is carried out in a bloodless field, since it is imperative that the surgeon visualize the nerves, blood vessels and tendons at all times. The palmar portion of the aponeurosis can usually be removed through an incision made transversely across the palm at the level of the distal transverse crease. The skin is carefully raised from the under-

lying fascia by sharp dissection. Unless the condition has been present for a long time and the skin is completely adherent, it is usually possible to save the skin, which will live provided it has not been too badly traumatized, if the blood supply has not been too seriously damaged and if hematoma is prevented from forming beneath it after operation. As the skin is raised proximally, the surgeon looks for the perforating vessels which come up through the fascial plate to the undersurface of the skin. With care, many of these vessels can be saved. When the skin has been dissected free proximally as far as the distal border of the transverse carpal ligament, the medial and lateral attachments along the hypothenar and thenar eminences are divided and then one cuts across the origin of the fascia from the ligament. The fascial plate may then be drawn distally to about the region of the proximal palmar crease. Here the fascia sends down its vertical longitudinal sheets to either side of the underlying tendons. The nerves and blood vessels have been in view at all times up to now. From here on, special pains must be taken to visualize the neurovascular bundle. The surgeon identifies the nerve and divides the fascia only when both it and the nerve are under visual control. This visualization becomes increasingly difficult as the web spaces are approached and it is just here that the fascia may pull the nerve far out of position. If the digits are not involved, the excision of the fascia stops at, or just distal to, the proximal end of the digital tunnel.

If the digits are involved, it is necessary to enter them and remove the fascia. The first task, after entering the finger, is to identify the digital nerves on either side before making any attack whatever on the fascia itself.

The incisions made to remove the fascia are meticulously closed after bleeding points are controlled. This is ascertained by releasing the blood pressure cuff which has been securing the bloodless field. As soon as all bleeding points are secured and ligated, the cuff is again inflated and the incisions are closed. If it has been necessary to remove skin, the defect left by this excision is filled with a free full-thickness skin graft.

The most serious complication likely to follow this operation is the formation of a hematoma in the palm. This will lift up the already poorly vascularized palmar skin and necrosis is certain to follow. The postoperative course will be unduly prolonged and the

recovery poor. To avoid this complication, the palmar dressing is applied firmly with large amounts of resilient gauze. It is usually advantageous to hold this dressing firmly in the palm by means of silk sutures fastened to the skin on either side of the palm and tied over the dressings.

The hand is no longer dressed in complete extension following the operation. Complete extension of the fingers puts a great deal of tension on the palmar suture line and this may lead to necrosis. Full extension also prevents the skin from being pressed firmly into the palm so that hematoma formation is more likely to occur. Finally, the fingers, if held for some time in complete extension, tend to develop joint capsule changes so that, although the patient may be able to extend the digits, full flexion is seldom regained.

STENOSING TENOSYNOVITIS

The fibrous sheaths which hold the flexor tendons in position over the metacarpophalangeal joints and the sheath enclosing the abductor pollicis longus and extensor pollicis brevis alongside the styloid process of the radius may become thickened and inflamed (Fig. 52). When they do so, they constrict the tendons beneath them, interfering with their action. In the digits, the constriction may cause actual indentations on the tendons. When the patient attempts to flex the finger, it comes down to a certain degree of flexion where it appears to stick and then only with real effort and with pain can the patient complete the flexion. This release may occur suddenly, often with an audible snap, always with a palpable snap. For this reason, this condition is usually called "snapping finger." When an attempt is made to straighten the finger, the process is reversed, that is, the patient is unable to extend the finger actively but must assist it with the opposite hand. It is a troublesome condition which is a handicap and the patient hesitates to use the painful finger.

It may occur on one or several digits on one or both hands but is usually single, involving the middle or ring finger. When it occurs on the thumb, it seldom affects the fingers.

Snapping thumb appears both as a congenital and an acquired condition. It is seen in children at birth or is recognized shortly afterward, since the child refuses to use this digit. In adults, snapping thumb often appears to be an occupational injury, since it is seen not infrequently in persons who strike the base of the thumb frequently

Figure 52. Stenosing tenosynovitis occurs typically in two locations on the hand—in the fibrous sheaths of the flexor tendons over the metacarpophalangeal joints, where it causes snapping finger and snapping thumb, and over the radial styloid where it is called de Quervain's disease.

against some object or tool with which they are working.

Stenosing tenosynovitis over the radial styloid is known as de Quervain's disease. It affects usually only one hand, but may be bilateral, and is most often seen in females. It, too, would frequently appear to be due to trauma, usually to blows over the area, or to wringing actions of the wrist. Thus, it is occasionally seen in young mothers whose infants sit on the arm, resting against the lower end of the radius. It is thought by some that in these patients it may be due also to diaper wringing.

The pathologic picture of both snapping tendon and de Quervain's disease is quite similar. When the fibrous sheath is uncovered, it will be found to be thick, tight and constricted about the tendons. Since the patient is usually operated upon under local anesthesia, one can request him to move the affected digit and can actually see the tendon snap in and out beneath the constricted sheath. The tendon itself may present an actual constriction. Occurring in the index, middle, ring and little fingers, where there are actually three tendon slips, it sometimes appears that the block occurs when the two slips of the sublimis move up in the palm about the profundus, which lies between them. Occasionally there may seem to be an actual thickening or nodule in the profundus tendon. In rare cases, a tumor, such as a ganglion, may lie within the tendon and cause the trouble. When the thumb is involved, it is in the

volved, the surgeon more often finds a very definite constriction of the flexor pollicis longus tendon.

Seldom there is only an increase in the fluid content of the synovial sheath and only rarely is the synovial sheath thickened. In de Quervain's disease, the pathologic picture is quite similar except that actual tendon constriction leading to snapping is not seen, and there is usually a moderate inflammatory reaction of the synovial lining and not infrequently increase in the fluid content. Microscopically, the tissues show simply a chronic inflammatory process with fibrosis and moderate round cell infiltration.

The symptoms and findings in snapping tendon in the digits differ somewhat from those of de Quervain's disease. When the digits are involved, the patient usually complains of moderate pain which is referred to the proximal interphalangeal joint. This may persist for some time before actual blocking of tendon movement occurs and even when this happens the patient, and frequently his medical adviser, tend to localize the trouble in the proximal interphalangeal joint. By this time, however, palpation of the proximal end of the sheath in the palm will show that there is thickening and some tenderness here. If the surgeon palpates this region while the patient flexes or extends the finger, the tendons will be felt to snap back and forth beneath the thickened sheath. Watching the process of flexion and extension will show the temporary stoppage which occurs just before the finger finally "snaps" into full flexion or is brought back, often by use of the opposite hand, into complete extension.

In de Quervain's disease, or tenosynovitis over the radial styloid, the symptoms are somewhat different in that there is more pain, and interference with motion is due more to pain than to actual mechanical block. On examination, the radial styloid is more prominent than normal, in contrast to the unaffected side. X-ray examination will usually have been made and it will reveal no abnormality of the bone but will show the soft tissue swelling. Pain is especially noted when the thumb is adducted, thus interfering with grasp. A sign which is almost pathognomonic of the condition is based on the fact that adduction of the thumb with ulnar deviation of the wrist is extremely painful. The examiner grasps the hand with the thumb pressed into the palm. The wrist is then adducted toward the ulnar

side. This causes severe pain felt over the radial styloid.

Treatment of snapping tendon and de Quervain's disease consists in division of the fibrosed sheath. Usually it is best to excise the roof of the thick tunnel, although this is not absolutely necessary. Incisions for approach to the fibrosed sheath are made transversely and are therefore at right angles to the tendons, nerves and blood vessels. The operation may be easily done with the patient under local anesthesia, but must be done in a bloodless field. The incision in the palm lies at the level of or just proximal to the distal palmar crease. The sheath is uncovered, care being taken not to damage the neurovascular bundles which lie to either side. The sheath is then split longitudinally to permit free motion of the underlying tendons which may be tested by asking the patient to move the affected digit. The whole roof of the proximal half of the sheath may be excised without leading to functional disturbance. In the thumb, the approach is the same, however, the surgeon must be extremely cautious since the digital nerves lie to either side of the thumb, quite close to the surface, and with scarcely more than the tendons' breadth between them. They are quite easily injured if not visualized during operation.

In de Quervain's disease, the approach to the sheath or compartment is made transversely across the wrist at the level of the radial styloid. This incision lies directly across

Figure 53 In de Quervain's disease, adduction of the thumb and ulnar adduction of the wrist cause exquisite pain. The tunnel containing the extensor pollicis brevis and abductor pollicis longus may be divided into several compartments which must all be opened at the time of operation.

the sensory fibers of the radial nerve. For this reason, the surgeon should be very cautious after the skin has been excised. Dissection should be in a longitudinal direction and the nerves must be identified. The sheath is then exposed and divided longitudinally and the interior is inspected. There may be more than two tendons passing through this tunnel. In fact, one or both of the enclosed tendons (*extensor pollicis brevis* and *abductor pollicis longus*) may be represented by two or three slips each. The importance of this fact is that one or several of these slips may lie in separate tunnels in the wall of the main tunnel (Fig. 53) and, unless these tunnels are also opened, the pain will not be relieved. It is well to splint the involved digit for a week or ten days after operation to insure sound healing.

TUMORS

A great variety of tumors occur on the hand and their accessibility and ease of examination should make for early diagnosis and proper therapy. The vast majority are benign and are amenable to successful surgical removal. Malignant tumors comprise only about 10 per cent of all tumors of the hand and, of these, nearly 90 per cent are carcinoma, most of which arise as the result of irradiation dermatitis. Malignant tumors should be diagnosed or at least suspected early and the cure rate should be high.

The anatomy of the hand is such that removal of the superficial tumors frequently entails the necessity of skin replacement, since there is little laxity of cutaneous tissues, particularly on the digits and palmar surface. The deep tumors present their problems in demanding a careful anatomic dissection lest important nerves and tendons be damaged during removal of the tumor mass. Extensive and, particularly, neglected growths may require major reconstructive procedures and their treatment should not be attempted without adequate experience with this type of surgery.

Trauma appears to play a significant role in the development of carcinoma of the hand and may have certain medicolegal significance.

One-third of all tumors of the hand will be ganglia, one-third will be made up of four other types of tumors in approximately equal numbers, namely, xanthoma, epidermoid cyst, angioma and carcinoma arising from irradiation dermatitis. The remaining third may be divided into two approximately equal groups. One group, or one-sixth of the

whole, will be made up of carcinoma (not due to irradiation), lipoma, fibroma, neuroma and enchondroma in approximately equal numbers. The remaining sixth comprises the remainder of the tumors of the hand, some very rare, indeed. Among these are synovioma, glomus tumor, fibrosarcoma, giant cell tumors of bone, osteosarcoma, osteoma, Ewing's tumor, osteoid osteoma, lymphangioma, sweat gland carcinoma, myxoma, leiomyoma and metastatic tumors.

This classification is based on relative frequency of tumors of the hand and disregards tissue origin. It is customary, however, to group tumors according to the tissues from which they spring or in which they are considered to arise. Thus, there are tumors arising from the skin, from fibrous subcutaneous tissue, from fatty tissues, bones and joints, joint capsules, tendon sheaths and tendons, nerves, blood vessels, lymphatics, smooth and striated muscle. Some growths classified as tumors may very well not be tumors in the real sense of the word, e.g., the xanthoma, ganglion, angioma and glomus tumor. Tumors arising from nerves and fibrous tissue may be confused and their true status may frequently be in doubt.

Tumors Arising from the Skin. The common wart is of importance on the hand for several reasons. *Verruca vulgaris* is generally thought to be due to some type of virus infection and the vagaries of its appearance and disappearance under varied and most illogical treatments are well known. It is, however, often subjected to illogical types of treatment, either by the patient himself or a physician, and what has started out as a benign lesion may undergo malignant changes. The patient often keeps the wart trimmed down with his pocket knife or irritates it by picking it off with his fingernails. The wart may also be subjected to x-ray therapy which may or may not destroy it but often leaves in its place an area of skin damaged by irradiation, which, in time, may prove more serious than the original condition.

The treatment for warts on the hand is their removal. Many of them are removed by nonsurgical methods—cautery, escharotics, carbon dioxide snow and fulguration. Surgical excision with the patient under local anesthesia seems preferable even though other methods are often more successful. Certainly if the warts have failed to respond to other treatment or if they appear to be growing and are ulcerating, they should be excised. It is always comfortable

microscopic

section of such masses, since it is possible for carcinoma to develop in them. Excision must obviously be done carefully, as with all operations on the hand. The surgeon should be prepared to graft skin, particularly in case of the volar, digital and palmar warts, since closure of the defect may be difficult.

The *subungual wart* is especially a nuisance, since it forms an unsightly mass at the finger tip, partly under the edge of the nail, and is difficult to keep clean. Removal usually demands excision of part of the distal nail bed and not infrequently a tiny skin graft is needed. The surgeon is inclined to be timid and to leave part of the wart behind and the mass promptly regenerates.

Keratosis and hyperkeratotic lesions are frequently seen on the dorsum of the hand in older people, particularly those who have exposed the skin to wind, sun and weather. They present themselves as roughened, slightly raised light brown plaques, rough on the surface and not tender. They should be excised since they may be the forerunners of malignant disease.

Squamous papillomas may occur on the hand as well as elsewhere. They resemble soft warts, are quite benign and may be removed surgically under local anesthesia.

Epidermoid cyst, often referred to as *inclusion cyst*, occurs not infrequently on the hand, particularly on the palm and volar surfaces of the digits (Figs. 54 and 55). It is thought in some instances to be due to implantation of small bits of epithelium into the subcutaneous tissues by pricks of thorns or

other penetrating types of injury. Tumors of this nature have been produced experimentally in animals. These cysts differ from the sebaceous cyst in that they are derived from the epithelium only and not from the sebaceous glands. Hence they contain no sebaceous material and their wall is formed from flattened cutaneous epithelium in which the various epidermal layers may usually be identified. The contents of the cyst consist of desquamated epithelial cells and other cutaneous debris. They are harmless tumors but may occasionally become infected. They may be confused with ganglia and with xanthomas, particularly when the xanthoma is small and has only one lobule.

The treatment is, of course, surgical removal, usually under local anesthesia. These cysts show no tendency to recurrence.

Sebaceous cysts occur very rarely on the hand, when they do it is on the dorsum. They are treated, as similar cysts elsewhere, by complete removal.

Pigmented moles are rather infrequently seen on the hand. Since the hand is frequently traumatized and exposed, it would seem wise to excise these blemishes to forestall any possibility of their injury. Fairly wide and deep excision should be carried out. Under no circumstances should they be irradiated, fulgurated or cauterized. They should either be left strictly alone or excised widely.

An area of hyperkeratosis may occasionally be neglected in elderly people and develop into a *cutaneous horn*. This curious

Figure 54 Epidermoid cyst of digit.

Figure 55 Epidermoid cyst of the hand.

Figure 56 A, Carcinoma of the dorsum of the hand associated with exposure to sunlight. B, Carcinoma of the dorsum of the hand arising from a wart C, Carcinoma arising from area of chemical irritation

appendage is not malignant and may be removed easily by excision. Skin grafting may be necessary to compensate for the resultant defect.

Carcinoma. This is the most frequent malignant lesion to occur in the hand and accounts for 90 per cent of all cancer of the hand and for some 10 per cent of all tumors of the hand. Another interesting feature of carcinoma of the hand is the frequency with which some irritative factor can be discovered in the patient's history (Fig 56). In a fairly large series of hand carcinomas, irritation of some type or another was present in between 70 and 80 per cent of the patients. In only 20 to 30 per cent did it appear that the carcinoma arose from previously normal skin. Because of the frequency of some irritative factor, it is possible to group hand carcinomas into seven groups, depending upon the type of irritation—exposure to sun and weather, irradiation with x-rays and radium, chemical irritation, burn scars, internal medication, chronic infection and irritation of previously benign lesions. The 30 per cent or less of carcinomas of the hand arising from previously normal skin appear to be the most malignant of cutaneous carcinomas.

Hand cancer occurs with greater frequency in persons whose skin is exposed for long years to the vicissitudes of the sun and weather. A similar higher percentage of carcinoma of the skin of the face likewise is noted in sailors, farmers, ranchers and others who spend much time in the great outdoors.

It is not generally appreciated that irradi-

tion with x-rays and radium is so frequently the cause of carcinoma of the hand. In our experience, the majority of all cases of carcinoma of the hand are due to changes in the skin subsequent to exposure to x-rays or radium. In the overwhelming majority, if not all these instances, the exposure has been unnecessary or unwise.

Carcinoma most often results from exposure to small, frequently repeated doses or minute daily exposure over a long time. Thus, when x-rays were first introduced into clinical medicine, their dangerous potentialities were unknown and the older roentgenologists took few or no precautions to guard against the rays. These men—the roentgen ray martyrs—were seriously afflicted and many died of carcinoma after numerous operations on the hands and arms. Later, precautions were taken to prevent or minimize direct exposure. However, it was then realized that even minute exposure to infinitesimal amounts of x-radiation, if kept up day after day, would eventually cause a skin reaction which was persistent and which failed to clear with simple medication.

This skin reaction might not become manifest for several years after exposure had been initiated and it persisted even if the individual stopped exposing himself to irradiation. Not only this, but years later, often as much as twenty-five years, the original dermatitis would break down into areas of carcinoma.

At the onset of this type of chronic irradiation dermatitis, the skin becomes dry, often smooth, atrophic and then shiny, the hair might disappear or become quite sparse

on the backs of the hands, the nails rough and ridged (Fig. 57). The tiny cutaneous vessels in the area become apparent as telangiectases. This dry skin is easily traumatized and quite bothersome to the patient who treats it with various oils and greasy ointments. Soon, however, numerous areas of keratosis and roughening appear. Areas of skin, which at first appear normal, may begin to show changes of dermatitis. Possibly because of a minor injury or because of exposure to intense sunlight or other irradiation, an area of keratosis may break down into an ulcer. This ulcer may be exquisitely tender so that the patient hesitates to permit anyone to dress or examine it. Pain is more frequent and severe in the relatively acute ulcers than in the chronic ones. The development of an ulcer in chronic dermatitis usually, though not always, indicates malignant disease. In many instances, the malignant lesion develops "in situ," often in several areas of the skin, and, if numerous sections are taken from a segment of skin which has been excised in treatment of the dermatitis, one will usually find early changes in the epithelial cells in numerous areas which indicate early malignant change.

The therapy of irradiation carcinoma, therefore, must be considered in three phases: first, prophylaxis of irradiation dermatitis; second, prophylaxis of carcinoma in irradiation dermatitis, and third, treatment of irradiation carcinoma once it has developed.

With regard to the prophylaxis of irradiation dermatitis, it should go without saying that one should avoid needless exposure to irradiation from any source. The professional

roentgenologist and radiation specialist, of course, now take adequate precaution against the constantly repetitious exposure to which they were subjected in the old days. The nonprofessional, however, who uses x-rays especially in diagnosis, is not so careful and exposes himself to frequently repeated x-rays, at the same time not taking the precautions his professional brother takes. The dentist, likewise, is inclined to be thoughtless in exposing himself to irradiation while taking dental films of his patients. He, too, is becoming more cautious in this practice and has developed techniques which do not entail exposure to irradiation. Many surgeons expose themselves to irradiation while carrying out certain treatment or diagnostic procedures. For example, in the nailing of fractured hips, it is much simpler to carry this out under a fluoroscope and direct vision, but the orthopedic surgeon has learned the dangers of this procedure. Foreign bodies in the hand, if radiopaque, are easily seen in the fluoroscope and the temptation is great to search for them with forceps through a small skin incision. However, this has often led to serious acute radiation dermatitis both in the patient and the surgeon. Few surgeons now carry out this hazardous procedure. Radium laboratories frequently hire nurses to pack and handle radium and radium emanation. The hands of these girls are exposed day after day to radium and, after a few years of such exposure, the skin is irreparably damaged, although the evidence of it may not show up for many years.

But professional exposure is not the only cause of chronic irradiation dermatitis of the hands. One of the most frequent types of ex-

Figure 57. An "x-ray hand" in a dentist who held films in patients' mouths while taking exposures of the teeth.

posure is therapeutic, incurred in the treatment of various chronic recurrent skin diseases Eczema, ringworm and psoriasis are all often treated by irradiation. The evil of this treatment is that the dermatologic condition may clear up, either spontaneously or as a result of x-rays, only to recur. The patient returns for more treatment. If it is refused by his first physician, the patient frequently seeks help elsewhere and often does not inform the second practitioner of the previous x-ray treatment. Such a performance may be repeated several times until the patient has received a very large dose of x-rays delivered over a period of years. Since the rays used are those which especially affect the skin, i.e., are not deeply penetrating, the damage produced is quite serious. Irradiation for the treatment of pruritus is seldom used on the hands, although we have seen one patient whose fingers were irradiated while he held his scrotum out of the way during irradiation therapy for pruritus ani. Carcinoma may eventually develop in these subjects years later, although the incidence is slightly lower than in the professional group.

The carcinoma which develops is almost always of a squamous cell type and occurs not just in one spot, but in many. Numerous theories have been promulgated as to the mechanism by which this irritant gives rise to carcinoma, especially so many years following its discontinuance. One theory long held has been that the effect the irradiation has upon the circulation of the skin leads to chronic oxygen deprivation and that this eventually leads to nutritional disturbances which end in carcinoma. Another theory, somewhat similar in nature, has likewise to do with the effect of the irradiation on the vascular system. Dermatitis and telangiectatic vessels occur about the periphery of areas of irradiation. From time to time, these vessels thrombose and the thrombus lying beneath the thin skin forms a dark black speck, known as a "coal spot." The theory is that this coal spot or spots signify areas of tissue irritation and devitalization and that they stimulate the epithelium to repeated efforts at regeneration. Eventually, from such irritative stimulation, carcinoma develops.

These theories seem somewhat unfounded and are not borne out by careful studies of microscopic material. True enough, the arterioles of the irradiated skin are markedly narrowed by endarteritis and by fibrosis about them and there is no question but that the

skin is poorly nourished above them, but this is no proof that the poor nourishment in itself causes carcinoma. The overlying skin, situated as it is on densely fibrous corium, is easily traumatized, is constantly subjected to mechanical irritants and lacks protection by the natural skin oils which have been suppressed by the partial or complete destruction of the oil glands. Therefore, this irritative factor, rather than just the circulatory one, could easily be as responsible for carcinoma. This same factor may well be at work in the production of burn scar carcinoma.

As for coal spots, if they are a cause, they must only rarely be implicated. In many sections studied by Teloh, Mason and Wheelock, coal spots were by no means a constant or even frequent occurrence. Carcinoma, on the other hand, has been quite frequent and seldom is found in the vicinity of coal spots. It has seemed that the rays must have produced some deep changes in the actual cutaneous cells. These changes, probably in the

over a period of years show the results of the process. It is possible to follow these changes in the skin cells from normal cellular structure, and minor variations in polarity and arrangement, to complete disorganization and carcinoma. These changes are seen not just in one area, but in many areas of the same specimen.

The treatment of this type of carcinoma may be considered separately from carcinoma arising from apparently normal skin, since the prognosis, if the lesion is properly treated at the start, is very good and since prophylactic measures may be taken both to prevent the development of the dermatitis and to head off the occurrence of carcinoma in skin already affected by dermatitis. Likewise, skin, and I

been delay in treatment and invasive carcinoma with lymph node involvement is present, a 25 per cent mortality can be anticipated.

It is wise practice to excise the whole of the involved skin and to replace it at once with grafts. It is not always possible to determine accurately the true limits of the skin involvement at the first observation. An apparently adequate excision may prove later to have been incomplete, since skin which at first appears perfectly normal may later show evidences of dermatitis at the borders of the

grafts. Why this is so is difficult to explain. The gross appearance of the skin suggests no trouble; however, there must be significant basic changes in the cells which are latent but which inexorably manifest themselves as time goes on. For this reason, persons who have such lesions should be examined periodically and new manifestations treated. The surgeon will often be surprised when the pathologist reports areas of carcinoma in situ in what appears to be only moderately involved skin.

When carcinoma is present it is treated, as is cutaneous carcinoma elsewhere, by wide excision. If it is attacked early, there will very probably be no deep invasion, since the dense fibrosis of corium and blockage of lymphatics tend to hold the process localized. However, once these barriers have been passed, x-ray and radium carcinoma metastasize, as do other squamous cell lesions. Fortunately, the great majority are of low-grade malignancy. However, the roll of roentgen ray martyrs stands as evidence of the malignant possibilities. Lymph node invasion may well occur and is present in about 50 per cent of the

such dissections do not appear necessary. With deeply invasive carcinoma, in which amputations are needed to effect removal of the local lesion, lymph node removal is advisable regardless of the findings.

Chemical irritation has long been recognized as leading to the development of carcinoma of the skin of the hands. Among the chemical irritants used commercially, of particular importance are coal tar and its derivatives, aniline, oils and greases, paint and coal soot. These are important only when the hands are constantly exposed to them over long periods. Certain industries are particularly hazardous in this respect, this has been recognized and measures are taken to avoid or minimize exposure. The liability aspects of the exposure cannot be ignored.

It is well known that burn scars of long duration, especially those of deep third degree burns with marked keloid formation, may break down into carcinoma. The thin epithelium overlying the dense scar beneath is frequently traumatized, breaks down easily into ulcers, cracks in usage and is frequently infected. Many years, often as many as sixty, may elapse between the burn and its breakdown into carcinoma.

Internal medication may be responsible for carcinoma of the hands. Fortunately the use

of Fowler's solution has been very much curtailed, since this medication used over a period of years often tended to lead to arsenical keratosis which eventually broke down into squamous cell carcinoma. The lesions occur especially on the palms and soles but may be found wherever there is squamous epithelium and have been seen in the larynx. The condition is especially treacherous, since not one but multiple carcinomas develop on many regions of the body and continue to do so over a long time, until metastases and a fatal outcome occur.

Chronic infection may be associated with carcinoma of the hand. At one time, areas of cutaneous tuberculosis were irradiated and these occasionally developed carcinoma in association with the tuberculous lesion. One occasionally sees chronic osteomyelitic sinuses on the hand, down which epithelium has grown and in which carcinoma has developed.

Irritation of previously benign lesions may be responsible for carcinoma of the hand. The ordinary wart if irritated sufficiently by picking and shaving it off or by overdoses of irradiation may occasionally break down into carcinoma. Several of the most extensive carcinomas of the hand which we have seen have been of this origin.

Carcinoma of the hand is almost always on the dorsal surface. Why the dorsal skin should more frequently develop carcinoma is not known, although it is tempting to speculate on the possibility of greater exposure of this area to various types of irradiation—solar, x-ray and radium. Certainly the palm is more subject to mechanical trauma than is the dorsum and, if mechanical trauma were a factor, here is where carcinoma should occur. Possibly the histologic difference between palmar and dorsal skin is the real reason.

If recognized early for what it is, the lesion is seldom found to be invasive, although it has the same malignant, locally invasive potentialities and tendency to lymphatic spread as do any of the cutaneous carcinomas. Wide excision, if there is no deep extension, beyond the skin, is frequently sufficient in the very early case. When invasion has occurred, more extensive procedures are called for and often partial amputations of a metacarpal and its digit will suffice. The extensive lesions involving wide areas of the palm or dorsum, however, will require amputation of the hand.

Dissection of the nodes draining the hand should be carried out in all patients in whom these nodes are enlarged or deep invasion has taken place. Whether or not routine axillary

and epitrochlear dissection should be carried out in every patient rests on the judgment of the surgeon. Axillary and epitrochlear dissection is not necessary in patients with superficial lesions without deep invasion. However, in all in whom there is deep invasion or palpable nodes, dissection should be carried out. In the latter group, about 50 per cent will have evidence of involvement of the nodes.

Melanoma. The melanoma of the hand is most often seen involving the nail bed—the melanotic whitlow of Hutchinson (Fig. 58). It was first clearly described by Hutchinson who pointed out that these lesions are most often treated for some time as chronic paronychia. He also pointed out that these lesions show a pigmented border even if their central portions do not show any pigment. Their apparent innocuousness in the early stages may be misleading and the lesion may go toward deep invasion when its surface appears quite innocent. Nothing should be done to irritate the area. Biopsies are out of the question unless the surgeon is prepared to carry out at once the initial surgery. In the nail-bed melanoma, amputation of the digit should be performed. The generally accepted course of action is then to carry out an axillary and epitrochlear dissection some four to six weeks later. This procedure has the authority of time-honored acceptance. Whether it is logical or the best treatment has not been determined. On grounds of analogy and logic, dissection starting at the axilla and working down along the supposed line of the lymphatics would seem more reasonable. It does not appear that the terrifically mutilating

forequarter amputations have offered much better prospects in regard to prognosis than have less extensive procedures.

Tumors of Fibrous Tissues. *Fibroma.* Fibromas occur in many locations in the hand. They are usually subcutaneous and produce superficial masses which are frequently diagnosed as neurofibromas, implantation cysts or early xanthomas. They may occasionally be pedunculated and hang from the skin by a thin pedicle. The early nodules of Dupuytren's contracture are usually diagnosed by the uninitiated as fibroma of the palm, and only as the fascial bands become more evident is the true identity suspected. Deep fibromas are seen occasionally in or on the tendons where they may cause symptoms of blockage due to mechanical interference with gliding. The fibroma is quite benign and does not recur after removal. However, a peculiar fibroma does develop on the hand which does recur and usually is more extensive at each operative procedure. The microscopic appearance of this recurring fibroma may suggest nothing unusual. After several postexcisional recurrences, however, its structure may change somewhat. This type of tumor probably should be included in the sarcomas.

Sarcomas (Figs. 59 and 60) There are many varieties of sarcomas of the hand. Many of them probably take their origin from nerve sheaths and are neurofibrosarcomas. They may, however, arise from any of the soft mesodermal tissues and vary from hard fibrous tumors to cellular masses containing only slight amounts of stroma. They may begin as tiny nodules in the lower layers of the skin or subcutaneous tissues but can arise deeply from any fibrous tissue as hard, usually painless, masses. They become fixed early to surrounding tissues and may cause pain. They may grow slowly for months or even years before their malignant nature becomes apparent. On the other hand, some of them develop very rapidly, become invasive and lead to early metastases and death. They may be composed of round cells, spindle cells or a mixture of the two and present a varying amount of stroma.

There is a variety which, while not peculiar to the hand, appears as a recurring fibroma that involves the overlying skin. This tumor is usually excised quite easily and apparently well beyond its limits. The defect left by the excision will often require a skin graft. Several months or even longer afterward, following an apparent cure, the tumor reappears in or along the border of the previous excision.

Figure 58 Hutchinson's melanotic whitlow (melanoma of the nail bed). (Hutchinson's original sketch.)

A second, and often a third or fourth excision, each wider than the preceding, will fail to lead to a cure. Careful study of microscopic sections may show nothing incompatible with

scopie characteristics will become more com-

patible with a diagnosis of sarcoma. Despite this, however, distant metastases are seldom encountered.

Lipoma. Lipoma is a fairly frequent tumor of the hand, where it forms a rather typical soft mass (Fig. 61). It is most often seen as a subcutaneous mass on the dorsum. Occasionally it is lobulated, particularly if crossed by tendons or other dense structures. The

Figure 59 Fibrosarcoma.

Figure 60. Malignant xanthosarcoma.

Figure 61. Lipoma

superficial lipoma may be mistaken for an epidermoid cyst or xanthoma, however, the characteristic consistency is usually a definite clue to its nature. These tumors are said to become hard when the hand is plunged into cold water. Deep lipomas may arise within muscle bellies, about nerves, on or about tendons and within tendon sheaths. The intramuscular ones are very difficult to diagnose because of their location. They are said to become malignant occasionally. One variety of lipoma, known as an arborescent lipoma, occurs within the tendon sheaths where it spreads throughout the involved sheath and produces a picture quite similar to that seen in chronic tenosynovitis. Its removal entails an extensive dissection. It may be confused preoperatively with a tuberculous or other type of chronic tenosynovitis,

with xanthoma of the tendon sheath or with villonodular tenosynovitis.

The prognosis for lipoma is good as far as recurrence or malignancy is concerned. In rare instances, a liposarcoma may occur.

Tumors Arising from Joint Capsules and Tendon Sheaths. This interesting group of tumors should probably be called synovial tumors except that the name *synovioma* carries with it the connotation of malignancy. King has studied these tumors more thoroughly than anyone else and has come to the conclusion that they are derived from cells destined to form the joint membranes, capsules and ligaments. They are, in fact, true tumors of synovial cell origin and should be known as *synoviomias*.

The most frequent of these tumors is the *ganglion* (Figs. 62 and 63). It is also one of the most frequent of all tumors, but it is at the same time one of the most obscure. It is held by many to be due to trauma and is said to occur especially in persons who subject their hands to frequently repeated motions, such as pianists, typists, violinists or others whose work entails use of the fingers and wrist for long periods of finely coordinated activity. Clinical observation does not seem to bear this out, since this tumor is seen in persons with all types of occupations. There was at one time, especially among French observers, an inclination to ascribe the condition to tuberculosis. However, it seems likely that neither tuberculosis nor trauma is the real etiologic agent. Still another theory of its origin, and this was taught

Figure 62. Ganglia of the hand—dorsal-carpal and volar ca

for many years, was that it represented a hereditary tumor. It was a tiny tumor which was sought for the stalk when removing the tumor. The joint capsule is always opened when a ganglion is removed, but this is done because the tumor originates from those tissues which form its base and consequently removal entails excision of a portion of the joint capsule. Actual communication of the cystic cavity with joint space, however, cannot be demonstrated.

When ganglia are studied microscopically, they are found to be made up of a basal tissue which is fibrous joint capsule or tendon sheath containing cellular areas within which may often be seen tiny cystic spaces. The cystic mass is continuous with this and consists of a thin-walled unilocular or multilocular cyst. It would appear that the large cysts come about by the enlargement and coalescence of the smaller cysts which originate in the basal tissue. It would appear also that the recurrence of ganglia is due to the fact that the basal tissue has been left behind in removal. This concept of origin likewise explains the frequent recurrence which follows simple rupture or aspiration.

Ganglia occur in a number of typical locations on the hand. Most frequent are the ones seen on the dorsal surface, the so-called dorsal carpal ganglia, which take origin from the joint capsule at the base of the second metacarpal and which present themselves on the wrist between the tendons of the common

digital extensors and the radial extensors. Another favorite dorsal extension is in the anatomic snuff box where they originate from the joint capsule at the base of the thumb and from adjacent tendon sheaths. A volar-carpal ganglion is seen on the wrist at the radial side in connection with the joint capsule at the base of the thumb and the fibrous sheath tissue about the radial-carpal flexor. These latter two ganglia are in intimate association with the radial artery as it winds through the snuff box to the interval between the bases of the first and second metacarpals. The vessel is liable to injury during excision of the ganglia and must be visualized at all times.

Ganglia are also seen to arise from the fibrous tendon sheath of the flexor tendons over the proximal phalanges of the fingers, usually the index, middle and ring fingers, just distal to the proximal digital crease (Fig. 63). Here they are thought by the uninitiated to be sesamoid bones, although it should be realized that sesamoid bones lie over the joints which are considerably more proximal.

Occasionally cystic structures resembling ganglia are found within the substance of tendons and they may be so located as to cause the phenomenon of snapping tendon.

The symptoms of ganglia are mainly due to the presence of a hard mass in the tissues which causes either a lumpy cosmetic blemish or pain when the mass is pressed against underlying tissues. At times, the development of the dorsal-carpal ganglion may be heralded by pain and tenderness at the base of the second metacarpal which may be present for weeks or months before the actual tumor appears. The recurrence of a ganglion after removal may be predicted by similar pain and tenderness.

Treatment of ganglion is surgical excision. Often excision of a ganglion is one of the first elective operations turned over to the tyro. However, it is not the simple and easy procedure it would seem to be. The difficulty does not lie in removing the cyst intact, although this is not at all easy, but in removing the basal tissue from which the ganglion springs. This tissue is difficult to distinguish from the normal joint capsule and only the presence of tiny cysts within it gives evidence of its identity. The ganglion should be followed down to its base and then a generous segment of capsular tissue should be excised with the ganglion taking origin from its surface. It is imperative, of course, that the procedure be carried out in a bloodless field. Local infiltration anesthesia usually suffices, although there are certain advantages to re-

Figure 63 Volar digital ganglion

moval with the patient under general or conduction anesthesia so as to avoid the obscuration of tissue detail by infiltration with fluid. The volar-digital ganglia (Fig. 63) which sit like pearls on the tendon sheath are excised in toto with the underlying square of tendon sheath. There is no clearer demonstration of the fact that ganglia are not herniations of tendon sheath than these tiny tumors.

Only too frequently the surgeon approaches ganglion through a longitudinal incision. This almost invariably leads to keloid scar over the dorsum of the wrist, to an unsightly scar on the volar surface and to a contracted scar on the finger. A transverse incision is always indicated. The incisions which run transversely across the lines of nerves, blood vessels and tendons must be made with great care to avoid injury to these structures, this is greatly facilitated by operating within a bloodless field. Following operation, the wrist or finger is splinted in a functional position for about ten days to permit healing.

Other methods of treatment yield a high percentage of recurrences. Crushing the tumor by directing a heavy blow upon it with a book may sometimes effect a cure, although the surgeon who employs this treatment is not likely to know the final results. The procedure is quite painful. Injection or aspiration and injection likewise are unsatisfactory. The experience of others in the treatment with hydrocortisone seems to show that this method is also unsatisfactory.

The *mucous cyst* (Fig. 64) which occurs on the dorsum of the distal phalanges at or near the sides of the base of the nail resembles a ganglion in appearance and in the gelatinous character of its contents. As King has pointed out, however, it is the result of mucoid changes in the subcutaneous tissue and does not originate from the joint capsule. The location over the base of the nail often leads to a depressed deformity of the nail. It recurs very promptly after removal, unless the overlying skin and cyst are excised together. This would seem to indicate that these tumors

Figure 64. Mucous cyst of finger with compression of the nail bed

ance in the instance of the isolated tumors and their exact nature is somewhat of a mystery. They are probably synovial tumors arising from the joint capsule.

These tumors are numerous. Numerous sections from various areas of a single tumor can a composite picture be made of them. Study of a single section will not give a true picture of the histologic structure. The tumor is made up of four elemental areas intermixed in varying proportions from tumor to tumor. Foreign-body type giant cells are a striking characteristic. These have led many to diagnose the tumor as a giant cell sarcoma. Intermixed with the giant cells is a stroma of spindle-shaped epithelioid cells. There are areas of variable size and shape made up of foamy cells with small nuclei and bubbly cytoplasm filled with cholesterol. Dissolved in the cholesterol is xanthine, which gives the tumor its yellow color, the cholesterol itself is colorless. Scattered throughout the tumor are hemosiderin deposits which some believe to represent hemorrhages indicative of trauma. In many of the tumors, peculiar spaces are found containing no blood cells, which have been thought to represent a tendency on the part of the tumor to form joint spaces and, hence, to indicate its derivation from synovial cells.

The tumor is benign and is amenable to local removal. This must, however, be very

Xanthomas, or giant cell xanthomatous tumors, occur as isolated tumor masses on the hand in contrast to the multiple xanthomatous processes which are seen in association with metabolic disturbance as multiple infiltration processes involving many tendons. There does not appear to be any cholesterol disturb-

thorough since the recurrence rate is quite high because the tumor takes origin from deeper tissues and the superficial mass may be only the surface manifestation of a long stalk which passes into the tendon sheath of a digit. If the stalk is not removed, the tumor re-forms. In other words, recurrences are not true recurrences, but simply growth of the portion of the tumor mass which has been left behind. In rare instances, following several removals, the tumor may assume malignant characteristics.

Xanthomas occur particularly on the digits (Fig. 65) where they may be confused with epidermoid cysts. These latter are usually unilobular, in contrast to xanthomas which are usually multilobular. Either may be mistaken for the other. Xanthomas do not involve the overlying skin, but are firmly attached in the depths and, hence, are not movable. They are occasionally seen in the palm or the wrist, where they assume the characteristics of villonodular synovitis. Few symptoms are caused except for cosmetic blemish or interference with use because of actual size and location.

Treatment is surgical removal. This must be carried out in a bloodless field, since every trace of the tumor must be removed to insure against recurrence. The digital nerves and vessels will be found coursing across the tumor mass, usually in a deep groove which separates one lobule from another. Unless particular pains are taken, the nerve and its associated vessel will be divided. Great care must also be taken to follow the tumor throughout its entire course and not be content with removing simply the large lobulated more superficial mass. A tail of the tumor will often be found to enter the tendon sheath and to run for a variable distance in it. This may be the origin of the tumor and must be removed. When the tumor presents itself at the wrist, it may be very extensive and involve the whole of the radial or ulnar bursa, or both, and require

as extensive a dissection as does tuberculous tenosynovitis. Here also one may occasionally find the tumor to have invaded the carpal bones.

The prognosis for xanthoma is good as far as malignancy and metastases are concerned, but the recurrence rate tends to be high unless special care is taken in the primary removal. In occasional instances the tumor may be so extensive on a digit as to replace almost entirely large areas of the digital fatty tissue and to compromise the blood supply so seriously that a finger may have to be amputated.

Synovioma. The tumors previously described are probably of synovial origin and should be classed as synoviomas. However, the term "synovioma" has become attached to a particular malignant variety of these tumors which fortunately is rarely seen on the hand. These lesions occur near the joints as painless, slow-growing, rather indefinite masses suggestive of a rheumatic nodule. They form encapsulated or diffuse masses, often butter-yellow in color. They may be solid or fleshy and often are not easily distinguishable from the surrounding tissues. They appear to spring from the joint capsule and in early stages do not involve bone. Following simple removal, prompt recurrence is to be suspected and metastasis may be anticipated if amputation of the digit is not soon carried out.

Blood Vessel Tumors. All of the varieties of vascular tumors met with elsewhere on the body occur on the hand and forearm. Whether or not they are true tumors is often to be questioned. Reid, from an extensive experience with many such tumors, concluded that most, if not all of them, represented some form of arteriovenous communication. It would seem logical to ascribe many of them to arrests in development of segments of the vascular tree. Study of the numerous contributions made by Sabin re-

Figure 65. Xanthoma.

garding the growth of the blood vessels gives one a picture of the various phases of growth, in many of which the vessels resemble the vascular tumors as we know them. The only malignant blood vessel tumor resembles the angioblastic phase of vascular development. Other blood vessel tumors suggest certainly the stage of capillary plexus formation; some, the retiform stage; and still others, arrest in the stage of stem formation. The diffuse arteriovenous aneurysms with multiple arteriovenous communications would certainly seem to represent arrests in intermediate stages of vascular tree development.

While arrest in development of blood vessels may represent the origin of the tumors, their continued growth may be a manifestation of the effects of arteriovenous communications and the effect of the abnormal circulation upon neighboring vessels. A specific blood vessel tumor may not always be of a certain type but may contain various mixtures of capillary and cavernous and vessel types of angioma.

The *capillary* or telangiectatic type of angioma is present familiarly as the port-wine stain or strawberry mark and has usually been manifest since the birth of the patient. It is usually elevated and soft, of bright color and nonpulsatile. It may occupy only the under layers of the skin, but there may be cavernous spaces beneath it. Occasionally it will disappear during the first year of life, but one cannot count on this. From a small beginning, the tumor may grow, extending over larger and larger areas until its eradication presents a very difficult problem indeed. Hence early removal seems indicated if the mass is of any size, and especially if it shows any tendency to growth. It may be necessary to replace the skin area excised with skin grafts if primary closure cannot be accomplished otherwise.

The *cavernous angiomas* are occasionally seen on the hand, particularly in the palm, where they seem to take over the venous elements of the circulation (Fig. 66). When uncovered, there are discovered large thin-walled venous lakes which extend up and down about nerves and tendons, into muscles and not infrequently from palm to dorsum. Very extensive involvement is almost the rule and, although the arteries are not involved per se, it is often impossible to remove the angioma without damaging the normal vessels. Hence, a staged operation is frequently required.

In not a few instances these cavernous

Figure 66 Venous angioma.

Figure 67 Arteriovenous aneurysm (congenital) involving the vessels of the middle finger.

lakes involve the bones, usually of one or two digits, a fact which is indicated by x-ray examination.

The *congenital arteriovenous aneurysms*, as they occur on the hand, frequently affect the vessels of one area, e.g., one or two digits (Fig. 67). They are characterized by extensive pulsating vascular tumors, enlargement of the involved digits or of the whole hand, and venous dilatation over the hand and forearm. The arteriovenous communications in these instances are multiple, thus contrasting with the traumatic arteriovenous aneurysm and making for considerable difficulty in care. The tiny vessels in the skin become dilated, the s... es thin ov r...

them and furious hemorrhage may occur following a trivial injury.

Treatment of the angiomas consists in surgical eradication. Although the capillary type is sensitive to irradiation, this must be given in such destructive doses to effect cure that the skin is left badly involved with irradiation dermatitis. When irradiation has been carried out, subsequent excision of the skin followed by grafting is often required. Such therapy seems contraindicated in youngsters since the epiphyseal plates may be damaged and serious growth disturbances result. Injection of sclerosing agents, although advised in the older literature, is seldom practiced today.

Capillary angiomas may be excised and satisfactory results obtained. The need for skin replacement at the time of excision will depend upon the size of the area removed. Cavernous angioma may, likewise, be excised, although it presents a more difficult problem than does the capillary type. As intimated above, the tumor may be so extensive that complete removal may be impossible and the surgeon must be content with partial excision of the most troublesome area. At times the procedure must be staged for fear of compromising the blood supply to one or more digits, if excision of the tumor involves the blood supply too seriously. These tumors only rarely develop arteriovenous communications, hence, partial excision may be successful.

Congenital arteriovenous aneurysms present one of the most difficult problems in surgery of the hand. Theoretically one should be able to approach and ligate the arteriovenous communication. Practically, this is seldom possible, except in a limited sense. The communications are multiple, often affecting vessels over a large area, on both volar and dorsal surfaces, and one usually finds that after supposedly adequate excision and ligation the tumor promptly grows again, often to a greater proportion than previously. If the vessels of a single digit are involved, amputation of that digit is indicated. Unfortunately, the process is seldom confined to one finger. The surgeon may offer some chance of cure, or at least of amelioration, by local attack on the tumor, plus ligation in stages of the blood vessels to the hand, allowing sufficient time between ligations to permit collateral circulation to develop.

Telangiectatic granuloma (pyogenic granuloma, Fig. 68) may or may not be a true tumor. It is known for a long time as false

Figure 68. Telangiectatic or pyogenic granuloma.

botryomycosis since it resembled a tumor mass developing in horses following castration and was thought to be due to a fungus infection. While it is now known that it is not due to a fungus, its true nature is still subject to controversy. It is most frequently called a pyogenic granuloma and the implication is that it is an infectious granuloma. It appears as a small mushroom-like growth, frequently located on or near the finger tip, but may be in any location on the hand. The stalk of the growth pushes out through a small opening in the skin which forms a thin collar about it. Microscopic study of the mass shows it to be made up of myriads of tiny capillary vessels, resembling very much a capillary angioma. Some think it is, in fact, an angioma which has burst through the skin. It often disappears after x-ray therapy, occasionally even when it is treated by compression. It is quite amenable to simple excision with closure of the defect. This seems to be the preferable treatment. The tumor does not recur after removal.

Glomus tumor. This tumor originates from the neuromyoarterial glomus, a structure associated with the autonomic nervous system and having to do with the heat-regulating system. The glomus is found only in warm-blooded animals and is especially developed in the feet of ducks. Glomera are essentially arteriovenous communications made up of fine arterioles connecting directly with venules forming the canals of Sucquet-Hoyer. The vessels are surrounded by cells resembling epithelioid cells, which are thought by many to be modified smooth muscle cells. No nerve cells are found in the glomus; however, there are many myelinated and nonmyelinated nerve fibrils in

Figure 69 Subungual glomus tumor Previous to operation it showed up as a dark purplish-red patch under the nail. The inset is a photograph of the tumor after excision.

it and these give evidence of its close association with the neurovegetative system. Glomera are found scattered all over the body and tumors arising from them have been reported in bone and other deeper structures. They are especially abundant in the palmar skin and in the nail bed (Fig 69). Hence, the vast majority of glomus tumors are reported as occurring on the hand, although these lesions have been reported in practically every region.

The tumor is frequently very small (5 mm. or less in diameter) but may attain sizable proportions, measuring up to 1 inch in diameter. Multiple tumors have been reported.

Glomus tumors give rise to a rather typical pathognomonic chain of symptoms. Starting insidiously, they develop into tiny painful nodules or painful areas which may not be palpable as nodules. If they occur in the nail bed, they may be visible as reddish or purplish tumors, a few millimeters in diameter, which push up but do not perforate the overlying nail. They are visible at times, invisible at others, and are more painful at times than at others. Sometimes they are especially painful when cold, in other instances when warm. They are always painful to touch and may be so exquisitely tender that the patient protects the part by placing his hand in his pocket. They often give rise to paroxysmal attacks of pain which radiate up the forearm and arm or even into the

neck. In a few of the patients, Horner's syndrome has been observed. The patient usually presents himself with a long history of an undiagnosed painful spot which has made life generally miserable.

Diagnosis is usually suggested by the history and the findings of a tender, subcutaneous or subungual nodule. The tumor under the nail may be visible and the nail itself may be pushed up and rounded by the underlying mass. An x-ray examination of the finger tip may reveal a depression in the distal phalanx due to the pressure of the tumor. Similar tender spots may be caused by other tumors, such as leiomyomas and neuromas, but these are rare and none gives the typical history of the glomus tumor.

Treatment consists in simple shelling out of the tumor. Because of the pain and apprehension on the patient's part, operation may often have to be accomplished under a general anesthetic. A bloodless field is essential since the tumor may suddenly constrict and what was a pink or red tumor mass may become invisible. This is especially liable to occur when the patient is under local anesthesia. Recurrence is rare unless the tumor is missed. These tumors do not become malignant.

Lymphangiomas. Lymphangiomas are extremely rare. They are seen as congenital lesions leading to enlargement of parts or all of the hand, forearm and arm. They may produce a type of gigantism. Excision is usually difficult because of their extent.

Bone Tumors. Enchondroma. Except for enchondromas, tumors of the bones of the hand are rare. Enchondroma is, however, not at all infrequent. It is seen particularly in the shafts of the metacarpals and proximal phalanges but never in the carpus. It may be multiple and both hands should always be x-rayed when a suggestive bony swelling is present. Occasionally the surgeon will find multiple tumors of both hands, but this is rare in our experience.

Enchondromas develop as slowly growing, hard tumor masses in the tubular bones, usually near the head of a metacarpal or base of a proximal phalanx (Fig 70). Occasionally the patient will complain of dull pain, but more frequently there are no symptoms until a trivial injury leads to a fracture which prompts an x-ray examination which discloses the tumor. Curiously enough, there is seldom gross displacement of the fracture, probably because the injury has been so trivial or because the solid tumor helps support the bone. The x-ray shows a well-

defined vesicular area of rarefaction within the shaft of bone which has expanded and thinned out the cortex but does not perforate it. The picture may resemble very closely that of a giant cell tumor. However, the giant cell tumor is more like a soap bubble in appearance and, in addition, is of extreme rarity in the bones of the hand.

Treatment consists in unroofing of the tumor and thorough curettage of its granular, pearly white contents. If the patient presents himself with a fracture, the bone should be splinted and allowed to heal before the tumor is attacked. Healing of the fracture can be anticipated to take place satisfactorily.

At operation, the surgeon should expose the thinnest portion of the involved shaft and, after stripping back the periosteum, carefully remove the protruding cortex to give adequate access to the underlying tumor mass. The remainder of the shaft is undisturbed since it preserves continuity. The pearly white rather dry granular tumor is then scooped out with a small curet. A surprising amount of material will be removed and great care must be taken to secure all of it. Only the cortical shell should remain. It was at one time advised to fill the defect with bone chips; however, this does not seem to be necessary. The stripped periosteum is allowed to drop back as well as it will and the soft tissues are closed. The cavity soon fills with a clot and the bone re-forms over it satisfactorily so that in time a practically normal shaft is present. The tumor will not

recur if it is adequately removed. It is not malignant.

Exostoses. These tumors appear infrequently on the hand, usually in the region of tendon insertions, and are occasionally multiple. They are larger on palpation than the x-ray with

tilagu velop in the nail bed as Dupuytren's exostoses. They push up and erode through the nail, leading to a granulomatous lesion. These tumors are not malignant and respond to simple local removal.

Osteoid osteoma. This tumor was first separated as a definite entity by Jaffe, in 1940. It is seen with moderate frequency on the hand as indicated by the report of Carroll, who collected the records of a number of cases from the literature and, with his own cases, studied a series of twenty-eight of these tumors in the bones of the hand.

Osteoid osteomas are easily confused with other rarefying bone lesions, such as osteomyelitis, bone abscess and syphilis, and must be differentiated from them as well as from osteochondritis dissecans, xanthoma or even bone callus. The tumor appears roentgenologically as a small translucent area in the bone, either in spongy bone or the cortex, surrounded by an area of increased density or sclerosis. Pathologically it is made up of a center of osteoid tissue surrounded by sclerosed bone.

The clinical picture should be quite sug-

Figure 70. Enchondroma. The fracture led to x-ray examination which revealed the tumor.

gestive of the nature of the condition. The most prominent feature is pain—chronic, nagging in character, rather than severe, and increasing especially at night. However, the pain responds to mild sedation with aspirin. Study of the x-ray film, with these facts in mind, makes the diagnosis certain.

Moberg has shown that the tumor runs a natural course over a period of several years, and eventually cures itself.

Treatment consists in removal of the tumor. Great care must be taken to remove the nidus or center of osteoid tissue since, if any of this remains, recurrence is certain.

Giant cell tumors. These are quite rarely seen on the hand. When they occur on the upper extremity they are usually seen in the radius near the wrist. They have, however, been reported in the metacarpals near the epiphysis. They are slow-growing tumors. Their presence is characterized by boring pain, usually severe and worse at night. They may appear a great deal like enchondroma on x-ray examination but usually appear more like soap bubbles. The severe pain would tend to differentiate them from enchondroma which is painless.

Treatment of the giant cell tumor consists in its complete removal, which may be more difficult and more extensive than the procedure required for enchondroma. Frequently a segment of bone must be excised and a bone graft inserted although, occasionally, thorough curettage of the currant jelly-like contents may suffice.

Bone cysts, myxomas, osteomas, fibromas, hemangiomas and **Ewing's tumors** may occur in the bones of the hand. **Aneurysmal bone cyst** is rare in the bones of the hand. Only four or five have been reported. They resemble giant cell tumor and enchondroma on roentgen examination. Only microscopic study will determine the diagnosis. **Bone sarcomas** are also seen on the hand, but with extreme rarity, only five cases have been reported. Treatment consists in amputation of the hand.

Tumors of Nerve. Tumors of the peripheral nerves, as they occur on the hand, are actually tumors of the sheath elements. They are nodular, diffuse, a spindle-shaped enlargement of the nerve area or a plexiform thickening of all the nerves of an area—often of the entire hand—as in von Recklinghausen's disease.

The nodular types of neuromas, neurinomas or neurofibromas (Fig. 71) are usually subcutaneous nodules, single or occasionally multiple, in the subcutaneous tis-

Figure 71. Fibro-neuroma of the hand.

ues, in connection with subcutaneous sensory nerves. They are derived from the connective tissue elements of the nerve sheath and present a typical histologic picture. Their removal occasions no disturbance in nerve function.

The fusiform neuromas develop along the course of the major nerves of the hand, usually the median, less often the ulnar nerve, and may extend over large distances of the trunk. We have seen several which involved the median nerve from a point several inches above the transverse carpal ligament down into the palm and along the terminal rami of the nerve to the base of the digits. Seddon claims that it is possible to strip the nerve fibers proper from the surface of the tumor, about which they lie thinly spread out like the ribs of an umbrella. This has not been our experience with this tumor. In those which we have attempted to dissect free of nerve fibers, there has been such an interwoven complex of nerve fibers and tumor that separation has proved impossible. However, the surgeon should always make this attempt before deciding to sacrifice the whole nerve trunk. The tumors are benign, but one must always suspect multiple occurrence in other parts of the body. Many of these may well be manifestations of von Recklinghausen's disease.

Von Recklinghausen's disease may involve the hand as it does other areas of the body. The significance lies in the fact that appropi-

mately 15 per cent of these tumors become malignant.

Plexiform neuroma. This condition is characterized by diffuse thickening of a nerve or group of nerves over a more or less extensive area. A single finger may be involved or several digits or even the whole hand. The thickening involves not only the main nerve trunk, but the fine terminal twigs and even the skin. Associated with this is general thickening of the skin and subcutaneous tissues; the fingers become thick, soft and long. Grotesque enlargement may take place. When it is marked, it is known as elephantiasis neuromatosa. It would be impossible in many instances to remove all involved tissue without complete sacrifice of parts of the hand. However, it is usually possible to improve the condition from a cosmetic standpoint by partial excision and skin grafts.

Neurosarcoma or neurofibrosarcoma. This tumor may appear as a nodular mass which grows back slowly after apparently adequate excision. The tumor in such instances may give all the appearance of being benign, even on microscopic section, and only its prompt reappearance gives a clue as to its identity. Often its course may extend over many years; eventually amputation of the extremity may be required. On the other hand, some of the neurosarcomas are extremely malignant, metastasizing early and leading to death in twelve to eighteen months. As with any sarcoma, the initial operation is the most important. It should be radical and extensive.

Metastatic tumors. The hand is occasionally the site of a metastatic tumor, usually lodging in the bone. A fair number of such cases have been reported. In rare instances, they may be the only manifestation of the primary tumor. The source is usually the lungs, prostate or testes.

CONGENITAL DEFORMITIES

Although congenital deformities of the hand tend to fall generally into certain patterns, these are only roughly definite compartments and there is not the general pattern of deformity such as is seen, for example, in harelip and cleft palate. Except in a general way, no two cases are exactly alike and, except for such conditions as syndactylism, it is not possible to devise standard operative procedures, such as those that are employed for harelip. Many and various theories have been put forth in explanation of the origin of congenital deformities, most

writers on the subject hark back to our prehistoric ancestors and to analogies with closely related present-day animal relatives to account for the various and curious malformations which occur. External influences and intrauterine accidents have been blamed. However, in most instances it would seem that actual changes in the germ plasm, often of an inherited nature, are to blame. Experiments with irradiation indicate that this modality might lead to gonadal damage and the latter may cause the development of inheritable deformities in the offspring.

Despite difficulties in classifying these deformities, better understanding is gained if one attempts to place them in certain groups, depending on certain general characteristics. Kanavel, who made an exhaustive study of congenital deformities, concluded that deformities could be grouped into those showing hypoplasia and aplasia, disorientation of tissue and hyperplasia. Further, he noted that malformations have a predilection for certain parts of the hand and forearm, e.g., radial and ulnar defects or combined radial and ulnar.

Kanaval was led to believe, on the basis of anatomic and functional studies and from certain evidence based on comparative anatomy and embryology, that the hand and forearm may be divided into "ulnar and radial divisions, separated by a fibrous partition attached to the middle metacarpal bone." The vascular and nerve supplies likewise suggest a close relation of the little, ring and middle fingers to the ulnar division, and a less close association of the index finger. The thumb is radial alone. Functionally, the thumb acts alone, the three ulnar digits together and the index finger in association with the ulnar digits. The fourth and fifth digits are frequently involved together and not infrequently the middle finger is involved with them. The index finger is seldom involved with the other digits, while the thumb is usually involved alone, occasionally with the index finger. In congenital absence of the ulna, the thumb and index are usually preserved, while in lobster-claw hand the middle finger is usually the one absent while the thumb, the index, ring and little fingers are preserved.

In a study of congenital deformities of the hand, the surgeon is inclined to think only of the configuration of the bones, as evidenced by x-ray examinations, and the gross morphologic changes, as evidenced by examination of the hand. One sees absence of

Figure 72 Congenital amputation This was long thought to be due to amniotic bands and adhesions but is now recognized to be due to defects in the germ plasma (Kanavel, A B Arch Surg, vol 25).

bones, bones reduced in size, fused to each other or actually duplicated. On examination of the hand, the fusion of digits, webbing and rudimentary or extra digits are easily seen and recorded. What is not so often considered is the fact that these changes affect the whole fabric of the forearm and hand and may even be evidenced in tissues of the cord. There may be absence not only of the bones, but of nerves and tendons as well. Fusion may affect the deep soft tissues as well as the hard tissues and skin. Attempts to correct these deformities operatively must not be approached as simple problems of bone and skin surgery; attention to the nerve, vascular and tendon supply is equally significant. It must be remembered also that, although certain types of deformities may be discussed as entities, they are seldom present alone. Thus, syndactylism, or fusion of the fingers, is frequently combined with fusion or absence of joints in the digits, with shortening or absence of digits, with absence of a phalanx in a digit or even with an accessory digit. It will lead to less confusion, however, if the various elements of deformity are discussed separately, keeping in mind always that such elements are seldom, if ever, the only feature of the deformity.

Congenital Amputations (Fig. 72) Amputations of digits, hand or arm and congenital constrictions involving these areas were for a long time thought to be due to bands of amniotic adhesions, actually constricting the part. This theory has been abandoned and these deformities are now thought to be due to actual factors in the germ plasma or to the effect of noxious factors, such as irradiation, on the developing embryo.

Figure 73. Congenital absence of the radius (Kanavel, A. B : Arch. Surg., vol 25).

When there is absence of a part, surgery can do little about it. Constricting bands, however, can often be corrected or helped. Thus, deep constricting bands may seem almost ready to pinch off a digit at its base and it would hardly seem possible that there is space for blood vessels to enter. Such bands may often be opened up, usually by a Z-plasty, and considerable improvement in appearance and function can be secured.

Hypoplasia and Aplasia. The group of deformities classed as hypoplastic and aplastic, while numerous and varied, have in common the element of tissue destruction ascribed to injury to the germinal anlage, or to damage to the growing embryo. Parts of the extremity may vary in evidence of this destructive factor from simple diminution in size to complete absence or loss. In about 50 per cent of cases of congenital deformities of the hand, the most serious defects fall into this group. The severity varies from such simple anomalies as shortness of a digit to its complete absence, from diminution in size of the hand to complete loss, from shortness of arm and forearm to their absence with the hand coming directly off the shoulder, to entire absence of the whole upper extremity. Nor are those anomalies single, they are often multiple and are associated with other less severe defects due to disorientation of tissue. The hypoplastic and aplastic deformities show marked hereditary tendency to development of similar anomalies in succeeding generations.

Congenital absence of the radius (Fig. 73) is bilateral in almost one-half of reported instances, the radius may be completely or partially absent. If it is partially absent, the upper end may be missing with a more or less rudimentary diaphysis; the lower end may be missing with varying amounts of diaphysis, or the diaphysis may be absent with upper and lower . . . The ulna is . . .

dial side or may rarely be double. Other deformities of the hand may be present, such as absence or atypical forms of the carpal bones, absence of the first metacarpal and absence of, or rudimentary, thumb. The other digits are usually normal. The elbow may be ankylosed. The muscles and nerves of the forearm may be disoriented, atrophic, fibrotic and contracted. The hand is deviated to the radial side, thus producing the radiopalmar clubhand, and may be small, but is usually potentially functional.

Treatment consists in correcting the radial deviation by division of the shortened soft tissue or, in favorable cases, by appropriate splinting and then holding the hand in proper position by replacement of the absent radius by a bone graft. It is occasionally necessary to fix the hand in the position of function by fusion at the wrist. If a bone graft is used, it should be fixed against bone at each end; otherwise, it will undergo resorption.

Absence of the ulna occurs much less frequently than does absence of the radius, probably in the ratio of about 1 to 5. It is a complementary picture to that of radial absence in that the forearm is short, the radius is curved and there is ulnar deviation of the hand. The elbow, however, is usually dislocated and there are more likely to be deformities and destruction of the digits and carpal bones. The loss of digits often makes these hands less functional than does the radial type of deformity. The little, ring and middle fingers are the ones most usually absent. Loss, atrophy and fibrosis of muscles, nerves and vessels usually accompany the deformity in varying degrees. The defect is frequently bilateral. If the hand has not taken part in the process, function is good. If, however, the hand is involved, the functional loss is often very great.

Hypoplasia affecting the hand produces a multiplicity of deformities which do not follow any definite pattern, such as the absence of radius or ulna does in the case of the forearm. The involvement may start at the wrist and the whole hand may be implicated. Only the medial digits may take part in the condition or the thumb bud may be the most affected. Individual bones may be shortened or lost. There is seldom hypoplasia alone, usually more than one extremity is affected and a hereditary tendency is very frequently noted.

Hypoplasia of the elements which make up the middle finger produces a striking picture quite out of proportion to the general

importance and, because of its redness, lobster-claw hand has been accorded a prominent, easily-remembered spot among the congenital deformities of the hand. In this condition, the middle finger with all or most of its metacarpals is missing and the hand is cleft down the center into two halves, each bearing two digits, presumably the ring and little fingers to the ulnar side and the thumb and index finger to the radial side (Fig. 74). Since this condition is thought to resemble the foot of certain ancient mammals and since certain living mammals have cleft feet, the lobster-claw hand has been thought to be due to reversion of the human hand to ancestral human type. However, this evidence is not especially convincing and does not explain the other types of hypoplasia of the hand and the numerous associated deformities which usually are found with this an-

to

cosmetic position. It must be remembered by the surgeon, however, that attempts to restore cosmetic appearance should not interfere with the use of the hand which the patient already has or may develop. The deformed hand is the only hand the patient has known and he learns to use it remarkably well despite its bizarre appearance. In some cleft hands, it may be possible to unite the two halves of the hand after removal of remnants of the third metacarpal and to cor-

rect the syndactylism which obtains follow-

ever, the patient himself, left to his own resources, will usually secure a most functional member from a seemingly hopeless situation.

Hypoplasia and aplasia of elements of the hand and wrist are many and varied. There may be shortening of digits, due to short metacarpals or short or absent phalanges, in various combinations. There may be flexion deformities and deviations of the digits, occasionally with disorientation of epiphyses. The triphalangeal thumb is thought by some to be an atavistic affair, by others to be a duplication of the index finger with absence of the thumb. The origin of the biphangeal thumb is thought by some to represent absorption or disappearance of the metacarpal with the present metacarpal being actually the proximal phalanx.

Fusion of Hand and Arm Elements. Fusion of the various parts of the hand, wrist and forearm may vary from simple webbing of the digits to actual fusion of bones in whole or part in all degrees. In the forearm, the picture of radioulnar synostosis is a fairly definite entity (Fig. 75). The union usually occurs at the proximal end of the bones and is often associated with anterior dislocation of the head of the radius. The forearm is usually in pronation. There is often little functional disturbance due to this lesion in itself, supination being carried out by movement of the shoulder. If the disability is severe, some motion may often be secured by osteotomy of the radius below the point of union.

Syndactylism. This is a fairly common condition, often part of other congenital de-

Figure 76. Syndactylism.

formities of the hand. It consists in the fusion of two or more digits (Fig. 76). The fusion may be complete from base to tip or may extend only a short distance down the web space. There may be only fusion or lack of separation of skin or, from this relatively simple fusion, there may be many degrees, ranging from fusion of distal phalanges on up to complete fusion of all joints of the digit. The soft tissues may likewise partake of this fusion, so that tendon, nerves and vessels may be reduced to only a single set between the fused bones. Any group of fingers may be involved, although the most frequent are the ring and middle fingers, less often fusion of other digits, including the thumb and the index finger.

Treatment of syndactylism has undergone many phases. The separation of fused fingers has intrigued surgeons for well over a century and many ingenious procedures have been proposed and carried out. Several factors are to be considered in the indications for operation and in the technique for carrying it out. As to whether operation is indicated at all, it must be remembered that, as far as use is concerned, the patient uses the hand usually quite well despite the uncosmetic and unusual anatomy. In some subjects, the webbing may be so severe and the distortion of the digits so grotesque as to render the hand useless. Again the surgeon must study each hand most carefully to learn as much as possible about nerve and tendon involvement in the process and the condition of the bones and joints. When it would appear that only one tendon serves two fused digits, the wisdom of separating them, ex-

cept for cosmetic reasons, would seem questionable. The age at which separation is indicated is important. Parents bring their children in soon after birth and the request for surgery is often quite urgent. However, it must be remembered that these operations usually require skin grafting and splinting and much after-care; that, in the tiny child, splinting is most difficult; that the little hand can be immobilized only with difficulty, and

it is best to delay operation until the child has reached the age of four or five years, or even older.

Separation of the fingers is a plastic procedure based on a few definite principles. The first lesson the surgeon must learn is that it is seldom if ever possible to fashion flaps of skin from the webs to cover the defects left by separation of digits. The many ingenious flaps devised in the past look beautiful and most logical on paper. In practice, they never work. There is never enough skin to cover the raw surfaces and suture lines under tension always spread and lead to raw surfaces which heal with scar and subsequent contracture.

Occasionally, in a young child in whom digital distortion is occurring, early operation is justified to release digits which are being pulled into deviation, are being pulled down to the level of shorter digits or in which the tips of the fingers and thumb are fused. In the early operation, grafts must be used and since they do not keep pace with the growth of the hand, they must be replaced later.

In all other instances, the surgeon must start out by realizing that a free full-thickness skin graft will be required. A tongue or flap of skin should be fashioned from the web, either anteriorly or posteriorly, to fill the web space between the digits. This tongue of tissue is brought forward or dorsally and forms the base of the web. After it has been formed, the remainder of the web is divided in a wavy line and the digits are separated. This procedure leaves triangular defects on either side which are covered with free full-thickness grafts.

An alternate procedure is to excise the whole of the web and fill it with a free full-thickness skin graft shaped somewhat butterfly fashion. Care is taken that the lines of suture on the digits are wavy or zigzag, not straight, otherwise, contractile scars will develop.

Polydactylism or Duplication of Digits.

This condition is often symmetrical and usually has a hereditary history; it is frequently associated with deformities of the feet. It ranges in manifestation from simple dichotomy of a digit to a so-called mirror hand. The digits most often involved are the little finger, the middle and ring fingers, the thumb or the index finger, in that order of frequency.

In the case of the little finger, the extra digit may be represented by a tiny, flabby nubbin of skin and subcutaneous tissue or there may be complete separation of two complete digits. In the case of the middle and ring fingers, the situation is usually complicated by syndactylism (Fig. 77), the polydactylism being unsuspected until x-ray films are taken showing duplication of parts of the phalanges. Hyperphalangism, or polydactylism, of the thumb is interesting from the speculative standpoint as to origin, since the thumb is the only digit coming from the radial bulb. Various degrees of polydactylism of the thumb are seen; even as many as three thumbs on one hand have been recorded. There may be associated syndactylism, triphalangeal thumbs (Fig. 78) and extra metacarpals.

Double major bulbs produce the so-called mirror hand. In this condition there may be two ulnar elements with absence of the radial element. The sets of fingers are set at an angle to each other in such a way that they appear to be the mirror image of each other.

Treatment of polydactylism in its various forms may be simple or quite complex. The tiny, flabby nubbins not infrequently seen in the newborn may be snipped off without any qualm, however, when the more serious deformities are met with, the problem becomes one of determining the muscle and tendon attachments of the apparently acces-

Figure 77 Polydactylism (Kanavel, A B: Arch. Surg., vol. 25).

Figure 78 Triphalangeal thumb (modified from Muller Die angeborenen Fehlbildungen der menschlichen Hand, Thieme.).

sory digits. It may be wise in some instances to leave the hand alone, since function is more important than cosmetic appearance. Tendon transference may come into consideration. Bifid digits may often be improved in appearance if such an operation does not destroy function. Tendon transference has been described by Bilhaut-Cloquet for the bifid thumb.

Hypertrophy. Hypertrophy of a digit is rare and may be due to bone growth or to neurofibromatosis. When bone growth is the cause, treatment is not indicated except for cosmetic reasons. If neurofibromatosis is present, the soft excess may be removed.

Arachnodactylism (Spider Fingers). This is seen as a definite entity in association with certain endocrine disturbances.

Multiple Cartilaginous Exostoses. These are occasionally found as congenital lesions on the hand as on other parts of the skeleton.

RECONSTRUCTIVE SURGERY

The problems which are encountered by the surgeon who carries out reconstructive surgery of the hand are many and varied. These range from the correction of scar contractures through nerve and tendon reconstruction, bone replacement, tendon transferences and digital reconstruction and transference.

The surgeon who undertakes this work must have first of all a concept of the func-

Figure 79. The hand possesses three basic functions: sensation (A), grasp (B) and pinch (C). Without sensation, a hand must be under constant surveillance of the eye. Grasp and pinch, even if limited, give considerable function to a hand, provided sensation is present.

tions (Fig. 79) of the hand and an appreciation of the basic motions. He must be able to visualize the anatomic structure of the part and have the diagnostic acumen to detect the basic loss and to recognize the potentialities of what is left. He must be able to plan a series of procedures, often requiring months or even years of effort and several stages, to restore even minimal use to a hand. He must appreciate that function and not cosmetic appearance is the end result to be secured.

It must be remembered that only in a certain percentage of cases is a single element of difficulty present; frequently more than one problem is present and these must usually be solved individually.

The sine qua non for any reconstructive surgery of the hand is intact, healthy, pliable skin. As the result of burns, crushing wounds, infection and other causes, the skin may be lost or seriously damaged, so that when the patient presents himself for care there are serious contracted scars which interfere with the use of the part. Burn scars on the dorsum may pile up keloid tissue and prevent proper flexion of the digits. A similar scar between the thumb and second metacarpal may draw the thumb into extreme adduction. Scars on the volar surface may hold one or more or all digits in acute flexion.

These scars may be the only element leading to disability; the structures beneath them may be undamaged or relatively so. In such cases it will only be necessary to correct the cutaneous scar by some type of skin replacement to restore the hand to use (Fig. 80).

If, however, along with the damage to the skin there

dons and bones, the skin replacement must be such that the surgeon can subsequently lift it up along one side and carry out needed surgical repairs beneath it. In such instances, a free graft will not be satisfactory and a pedunculated flap of skin with subcutaneous fat beneath it and carrying its own blood supply will be necessary.

Also, if the excision of scar contracture of the skin entails uncovering of bones, joints, nerves and tendons, it is usually necessary to apply a pedunculated flap to replace the skin excised. Determination of whether or not such a flap will be needed often requires very critical judgment and the surgeon must occasionally be prepared to use whichever seems indicated at the time of operation.

At times the functional loss may be due to loss or division of tendons and/or nerves (Fig. 81). Here, the first problem is to determine the extent of the damage; that is, a diagnosis of the tendons and nerves involved must be made. The second problem will be to determine just how repair may be carried out.

Attention has been called to the fact that, when deep repair must be undertaken, the covering tissues must be supple and there must be adequate subcutaneous fatty tissues through which to work. Therefore, the first job will be to assure oneself that the skin through which surgery must be carried out is satisfactory. This may require, therefore, that before any nerve and tendon repair can be carried out a skin flap will have to be applied to the part.

Again, the joints which are to be moved by the newly repaired tendons must be mobile. Mobilization of joints may in itself require long periods of splinting, physical therapy and open operation before the tendon repair can be undertaken.

Lastly, some decision must be reached as to the type of repair, i.e., tendon suture, ten-

don graft or tendon transference. The first problem is that of nerve and tendon division in the palm. The problem is not simple, but there are probably fewer factors to be considered than, for instance, in division of the digits. If the patient is seen quite early and there has been no infection and no unsuccessful attempts were made at repair at the time of injury, the factor to be considered is the amount of tendon retraction. Under ideal circumstances, retraction in a few weeks will not have been very great and the surgeon can feel assured that in all probability a suture of all tendons can be carried out, certainly of the profundus tendons, and that the nerves may likewise be repaired. The important factor is the amount of retraction which the proximal stumps have undergone. In the early case, this will be minimal.

If, on the other hand, the tendon injury occurred six months or a year previously, the forearm muscles will have retracted a good deal and, under such circumstances, it is quite likely that tendon grafts will be needed.

Another factor is introduced when one comes to consider repair of tendons in the digits. Whether immediate repair was either not carried out or was attempted and failed, there is only one answer to the problem and that is the introduction of a tendon graft. There is only one possible exception to this rule, which does not often obtain, and that is profundus tendon division alone. If division has occurred close to the distal joint, the amount of tendon retraction may be so minimal that a suture may occasionally be feasible. Usually, however, the proximal retraction will be so great that a tendon graft will be required.

Division of the flexor pollicis longus may or may not demand a tendon graft. The proximal stump frequently "snaps" up into the lower forearm, becomes bulbous and short-

Figure 80. Scar contractures involving only the skin may be corrected by complete excision and replacement with a free full-thickness skin graft.

Figure 81. Deep scars involving tendons, particularly when nerve and tendon repairs are required, must be replaced by a pedunculated flap to furnish suitable coverage for subsequent surgery.

ened and its distal end may degenerate and become friable and necrotic

Division of the flexor tendons in the wrist and lower forearm, unless immediately repaired, presents one of the most unfortunate situations to correct. The median nerve is always divided and often the ulnar nerve also. A perfectly useless hand results which is not only without motion, but also without sensation. The forearm muscles retract with alarming rapidity; the hand assumes a position which is difficult to prevent, even with splinting, and the most careful of repairs can promise but mediocre improvement. It is for this reason that primary suture of nerves and tendons should be undertaken in these patients whenever possible.

Secondary repair of the nerves and tendons above the wrist will eventually require tendon grafts; not infrequently five grafts will be necessary, one for each profundus tendon and for the flexor pollicis longus

Division of tendons over the dorsum of the wrist presents a similar problem in that the proximal tendon stumps in synovial sheaths retract a good distance up the forearm and, within a short time, it is not possible to carry out suture. Tendon grafts are often required.

"The tendency to retraction is usually least

sum of the wrist is so irregular that suture within it would be certain to end in failure. Therefore, a neighboring tendon stump,

either the extensor carpi radialis brevis or, preferably, the extensor indicis proprius is used.

Division over the dorsum of the metacarpus may usually be repaired by suture unless there has been actual loss of tendon substance. The paratendon through which the tendons pass in this portion of their course tends to prevent too great retraction.

Injuries of tendons over the dorsum of the fingers present complex problems varying from phalanx to phalanx. Division over the dorsum of the metacarpophalangeal joint is usually amenable to suture even when seen late. The attachment of tendon to joint capsule prevents too great separation and the gap between the divided capsule and tendon ends fills with tendon callus. It is usually possible to dissect out this callus, freshen up the tendon ends and capsule and carry out satisfactory suture.

Tendon transferences are frequently required when paralytic conditions of one type or another cannot be remedied by nerve repair. The most common condition met with requiring transferences is in patients having median and radial paralyses. In median nerve paralysis, the short muscles of the thumb may fail to recover after median nerve suture. This makes it impossible for the patient to rotate the thumb about into the position of function or apposition for grasping. The thumb lies back against the side of the hand and can grasp only against the side of the index finger. It is advantageous in this condition to transfer a tendon, frequently the sublimis flexor of the ring finger, from the lower forearm subcutaneously across the thenar eminence to the thumb in the region of the metacarpophalangeal joint. This tendon will then pull the thumb out in abduction and apposition to face the other digits (Fig. 82).

In radial nerve paralysis, in which for some reason or other repair of the nerve is not possible, it is customary to transfer one or both of the carpal flexors onto the dorsum of the wrist and insert it or them into the common digital extensors and into the extensor of the thumb

One other transference which is occasionally carried out is valuable in ulnar paralysis in which, despite nerve repair or when repair is not possible, the interossei fail to regenerate. In this situation, the sublimis tendons of two fingers are divided at their insertions and slips are led around the sides of the finger to be inserted into the lateral slips of the extensor expansion. If transference is

successful, these slips will extend the interphalangeal joints.

Many other tendon transfers are practiced. In most instances, individual indications obtain in each case and the surgeon must determine what motions are most important and which motors are present to make those motions possible.

Problems with regard to the bony framework of the hand likewise occur. If they are present, they take precedence over every other repair except that of the skin which must be satisfactory to permit deep repairs on the bones. Correction of malunions, consolidation of nonunions and bone replacement by bone graft may be needed to restore satisfactory framework.

It may occasionally be obvious that active motion can never be secured in certain joints, and that it would be better to fuse them in a functional position. Thus, it may be indicated to swing the thumb around into a position of abduction and apposition to face the pads of the other digits and fix it there by means of a bone block between the first and second metacarpals. Occasionally the interphalangeal joints may be so badly damaged that active motion is not likely to be restored. In these instances, it may seem wise to fuse them by one means

or another in a slightly flexed position, thus permitting the digits to be flexed as a whole at the metacarpophalangeal joints.

The surgeon must have some conception of the basic functions of the hand before he can intelligently carry out any sort of reconstructive surgery. He must start out with the concept that the hand is fundamentally a grasping and sensory organ. From these two simplest mechanisms of the hand, the functions are built up gradually, becoming more and more complex until the fully developed and trained human hand guided by a trained intelligence is reached. Following the function of grasping will come another simple function—that of pinching. These three functions, grasp, pinch and feeling, should be the minimum which the surgeon should strive to restore. However, this does not mean to imply that finer and more complicated actions should not be restored if the possibility exists. Thus, it may be possible to restore the individual flexion and extension of the digits by various tendon transferences or tendon grafts. Abduction and adduction of the fingers, so necessary in certain fine movements, may be partially or completely restored by certain operative procedures.

The loss of the thumb, which renders grasp impossible, is very serious and many procedures have been devised to compensate for this disability. In some patients it may be possible to restore grasp, provided the metacarpal and a bit of the proximal phalanx are left, by deepening the cleft between the first and second metacarpals. This will render the thumb remnants more mobile and will often make a most satisfactory buttress against which the fingers can grasp objects. In instances in which a fair remnant of the thumb is left and the index finger is gone, the cleft may be further deepened by removal of the second metacarpal.

If there is no thumb remnant left, or if what little is left is too small to be serviceable, various procedures have been carried out to build up a new thumb. These have consisted essentially in the formation of a tubular graft of skin into which a bone or rib cartilage graft is inserted to give stability. While these thumbs occasionally function fairly well, often they do not. They are usually without sensation and are immobile, ugly appendages which patients would be glad to be rid of.

In a few instances, surgeons have successfully reported the grafting of a toe to the hand to replace a lost thumb. The procedure

Figure 82 Rotation of the thumb may often be secured by transfer of a tendon, usually the sublimis flexor of the ring finger, to the region of the metacarpophalangeal joint. The transferred tendon is led through a fascial loop about the flexor carpi ulnaris or may simply be passed beneath the flexor carpi ulnaris so that the line of pull is from the region of the pisiform bone. This is a very valuable procedure when the motor function of the median nerve has not returned and the small muscles of the thenar eminence are paralyzed.

would be applicable only in youngsters who could withstand the long period of awkward and tiring immobilization necessary for such a graft to take. Likewise, the tissues must be young and well vascularized to withstand such procedures.

A more ingenious procedure described by Hilgenfeldt, and later popularized by Littler. This consists in transferring another digit of the same hand to the location of the thumb. To be successful, it is necessary that some of the base of the metacarpal be present into which the metacarpal of the transferred digit is fixed. The digit to be transferred is isolated along with its nerve, vascular supply and flexor tendons intact, and set onto the thumb metacarpal. A number of such successful cases have been reported.

Before procedures of this sort are to be carried out, the surgeon must make sure that the patient will benefit from them and that he cannot carry on satisfactorily without a new thumb. Hilgenfeldt has advised that patients be permitted to carry on for about a year with the hand before the operation is performed. Many times the patient will decide against the procedure.

While there is no doubt that the thumb is a most valuable digit, there may be some question as to the exalted position it has been given. Certainly the surgeon must make every effort to save all length possible and to restore to every possible function whatever remnants there are of the thumb. However, when this digit is irretrievably gone, there is some question as to whether its loss is as great a handicap as we have been prone to think. Hilgenfeldt has given some good advice concerning replacement of the thumb. He has counseled waiting a year or at least a number of months before making the decision. During this time, the patient attempts to get along with the hand, carries on his work and the general acts of daily life. If, at the end of that time, the thumb loss is still a serious handicap, operative restoration is undertaken. It is often surprising to see how well a patient can get along without a thumb. Many functions of the hand, awkward at first, are easily carried out and adequate substitute motions are developed.

If there is a good thumb on the opposite hand, the indications to restore the thumb are much less urgent than in instances in which the thumb has been lost bilaterally.

Age and occupation of the individual should be taken into account, as well as those other factors which the surgeon must con-

sider, when starting off on a long series of operations or a course of treatments which will require the fullest cooperation of a willing and honest patient. Many patients are reduced to dependent loafers by apparently justifiable attempts to restore a moderate increase in function to an already fairly useful hand.

Finally, one must always keep in mind the surgical risk itself. There is always the possibility that the transferred digit may not survive—not great, to be sure, with skilled operative technique—but, if gangrene does develop, the patient will not be just without a thumb, but also without another digit. If this has been a normally functioning finger, the tragedy is great.

The surgeon who carries out reconstructive surgery of the hand must be skilled in peripheral nerve repair, since it is part and parcel of hand surgery.

THE FOOT

By WILLIAM A. LARMON, M.D.

WILLIAM ALEXANDER LARMON, born in California, received his collegiate and medical education at Northwestern University, where he is now an Assistant Professor of Orthopedic Surgery. Dr. Larmen has been responsible for writing and producing a series of teaching color motion pictures for the Veterans Administration on the principles of the treatment of fractures. His teaching abilities are reflected in his contribution to this volume.

The surgeon must be mindful of the complex relationships of the foot to the rest of the body. The foot is the connecting link with our terrestrial environment, balancing the body in the upright posture and propelling it about. Proper function of the foot depends upon the integrity of the musculoskeletal and nervous systems for balance and movement, the circulatory system for nourishment and the skin and subcutaneous tissues for protection and covering. Pathologic changes in any of these systems may affect the foot and alter or limit our ability to stand, walk or run.

FUNCTIONAL ANATOMY

Motion and Positions of the Foot. To treat successfully pathologic conditions of the foot, the surgeon must understand the normal anatomy and physiology of the lower extremity.

Movements and positions of the foot are traditionally described with the foot off the ground and unencumbered. When the dorsum of the foot is brought toward the anterior surface of the leg, the movement is dorsiflexion and the position of the foot is termed calcaneus. The opposite movement is plantar flexion and the foot is in the equinus position. These motions take place at the tibiotalar joint. When the heel is in-

clined toward the midline of the body, it is inverted and in varus position. The opposite is eversion and valgus position. This motion takes place in the joint between the talus and the os calcis or subtalar joint. When the forefoot is brought toward the midline of the body, it is adducted. The opposite movement and position place the forefoot in abduction. These motions take place in the calcaneocuboid and talonavicular joints as well as in the joints of the other tarsal bones.

The subtalar, calcaneocuboid and talonavicular joints work as a unit producing supination of the foot when the plantar aspect is directed toward the body midline. Pronation of the foot is found when the sole of the foot is directed away from the midplane of the body. Varus and valgus positions of the foot are synonymous with supination and pronation.

When the toes are brought toward the plantar surface of the foot, they are flexed, and when in the opposite position, they are extended.

The cardinal positions of the foot are calcaneus, equinus, varus and valgus. Various combinations of these terms describe the positional deformities that occur in the foot. Thus, talipes equinovarus points out the abnormal position of clubfoot.

The Arches of the Foot. The act of stand-

Figure 1. The center of gravity of the body is located at the second sacral vertebrae (A) Weight of the body falls between the feet at the level of the navicular bone CW. When standing the body sways forward periodically. Contraction of the triceps surae (A) pulls the tibia posteriorly on the foot to maintain balance. Ligamentous strain in the foot is relieved by shifting body weight from one foot to the other frequently (C) walking is line a. The axis of medial and lateral balance is line b (redrawn from Morton, D. J. *The Human Foot*. Columbia University Press)

ing demands stability and balance in the structures of the foot and walking and running require mobile, elastic, shock-absorbing properties. The architecture of the foot fulfills all of these functional requirements.

The hind foot, composed of the talus and the massive os calcis, is adapted to support body weight. The midtarsal bones, the meta-

tarsal bones and the phalanges are more mobile and are adapted to the function of balance and propulsion.

The medial and lateral halves of the foot are also designed for special purposes (Fig 1B) The os calcis, cuboid and fourth and fifth metatarsal bones with their phalanges form a stable platform in contact with the

ground. The medial half of the foot, composed of the talus, navicular, cuneiform bones, and the first, second and third metatarsal bones and phalanges form an arched, elastic and mobile structure necessary for balance and propulsion.

The arches of the foot have been likened to a stone bridge, the fit and shape of the bones of the foot maintaining a rigid arch. Such is not the case (Fig. 2A). The medial longitudinal arch is composed of bones with curved articulations which in no way resemble the keystone shape of the stones in a bridge. These curved joints, held together and supported by strong ligaments, tendons and muscles, provide elasticity and mobility necessary for the function of the foot. The longitudinal arch of the foot is more accurately described as a bow or spring. The plantar structures composed of fascia, ligaments, tendons and muscles are the bow strings.

The transverse arch of the foot exists at the metatarsal cuneiform joints but gradually flattens as the heads of the metatarsal bones are approached (Fig. 2B-D). All of the metatarsal heads in the normal foot make equal contact with the ground when weight is borne and no true arch exists at this point. The transverse arch is stable at the metatarsal cuneiform joints as these

bones more nearly resemble the keystones of the stone bridge. The configuration of these joints provides stability.

The Ligaments. The bones in the foot are joined by ligaments which are thickened areas in the joint capsules. In addition to the ligaments of the individual joints, there are two major ligaments and the plantar aponeurosis which act as bow strings to aid in maintaining the arches (Fig. 3A). One of these—the calcaneonavicular ligament—arises near the sustentaculum tali on the calcaneus and inserts into the plantar aspect of the navicular bone. This ligament passes under the head of the talus as a sling, providing support but not restricting motion of the talonavicular joint. It prevents the talus from excessive plantar flexion at the mid-tarsal joints, thus preserving the longitudinal arch.

The second important ligament is the long plantar, arising near the tuberosities of the calcaneus and inserting into the cuboid and the base of the metatarsal bones (Fig. 3B). This ligament supports the midportion of the longitudinal arch, approximating the metatarsal bases to the calcaneus, and is a second string in the bow.

The third structure—the plantar aponeurosis—arises at the tuberosities of the os calcis and inserts into the toes on the plantar as-

Figure 2 A, The longitudinal arch of the foot is made up of bones with curved articular surfaces adapted for complex movements. Ligaments must maintain the relationships of these surfaces to preserve the arch. B, The transverse arch is well defined at the base of the metatarsal bones. The articulations are wedge shaped and stable. C, The transverse arch flattens in the midmetatarsal area. D, No arch is present at the head of the metatarsal bone. Body weight is borne by all of the metatarsal bones. When one bone becomes prominent in the sole of the foot, more weight is borne by the involved bone and pressure symptoms occur.

Figure 3 A, The plantar aponeurosis aids in support of the longitudinal arch. B, The long plantar and the calcaneonavicular ligaments support the midpart of the arch. The calcaneonavicular ligament acts as a sling under the head of the talus. The pulley-like arrangement of the tendons on the plantar aspect of the foot running beneath the malleolus produces active support for the arch. C and D, The heads of the metatarsal bones act as a pulley for the plantar aponeurosis when the toes are dorsiflexed. This shortens distance between the metatarsal heads and the condyles of the os calcis and raises the arch. This mechanism supports the arch at the point of "push-off" in walking (C and D redrawn from Hicks, J. H. *J. Anat.*, vol 152).

pect (Fig. 3C, D). When the toes are extended, the plantar aponeurosis, passing over the rounded metatarsal heads, tightens. This mechanism shortens the plantar aponeurosis, approximating the metatarsal heads toward the heel, maintaining the longitudinal arch. This action can be likened to the mechanics of the windlass. The toes are the handle and the metatarsal heads the drum of the windlass, the plantar fascia is the rope pulled over the drum, shortening the distance between metatarsal heads and the heel, raising the longitudinal arch. This takes place when most needed at the point of push-off in walking when maximum strain is thrown on the arch of the foot.

The Muscles. The intrinsic muscles of the foot lend active support to the ligaments in standing and walking. They are arranged to aid in supporting the elastic arches (Fig. 3C and D). Medially the abductor hallucis, arising on the os calcis and inserting into the great toe, adds another string to the bow. The central muscle group, composed of the quadratus plantae, flexor brevis of the toes and the lumbricales, maintains the central portion of the arch.

The long muscles arising in the leg provide the motor power for the gross move-

ments of the foot necessary for balance and locomotion.

The triceps surae, or calf group of muscles, composed of the gastrocnemius and soleus muscles, is the prime lifter of the body in walking, through plantar flexion of the foot at the subtalar joint. In addition to this action, this muscle group inverts the heel at the subtalar joint in plantar flexion (Fig. 4A). This inverting action is prevented by the balanced action of the peroneus longus muscle which contracts synchronously in walking (Fig. 4B). The pulley action of the peroneus longus tendon, passing from the lateral side of the foot at the cuboid bone to the base of the first metatarsal bone, everts the foot in plantar flexion. It also depresses the distal end of the first metatarsal against the ground in walking and standing, thus elevating the arches of the foot and aiding in propulsion.

The dorsiflexors of the foot are the strong tibialis anticus and the weaker extensor digitorum longus. The tibialis anticus inserting into the medial aspect of the foot inverts and supinates the foot, elevating the arch, while the extensor digitorum longus, passing lateral to the axis of balance of the foot, tends to evert the foot in dorsiflexion (Fig. 5).

The tibialis posterior, passing beneath the pulley of the medial malleolus and inserting into the plantar aspect of the navicular bone, inverts the foot and adducts the fore-foot. The peroneus brevis, passing beneath the lateral malleolus and inserting into the base of the fifth metatarsal, balances this action of the tibialis posterior and produces

eversion of the foot and abduction of the forefoot.

The action of these muscles can be likened to three sets of reins attached to a bridle in providing medial and lateral stability for the foot. The triceps surae and peroneus longus balance each other in plantar flexion. The tibialis posterior and peroneus brevis balance

Figure 4 A, The triceps surae muscles produce plantar flexion and inversion, equinovarus position. B, The peroneus longus counteracts the inversion by the triceps surae in plantar flexion. C and D, Acting alone it everts the foot in plantar flexion, valgus position and depresses the distal end of the first metatarsal bone, raising the arch and fixing the bone to the ground in walking during the push-off phase.

Figure 5 A, B, C, The tibialis anticus dorsiflexes and inverts the foot and elevates the first metatarsal bone, calcaneovalgus position. D and E, The extensor digitorum longus is a weak dorsiflexor of the foot as well as the toes. The tendons pass lateral to the axis of balance of the foot and produce eversion of the foot in dorsiflexion, calcaneovalgus position. The two muscles balance each other in pure dorsiflexion of the foot.

the foot in neutral position and the tibialis anticus and the extensor digitorum longus balance in dorsiflexion.

Any disturbance in the function of these muscles and tendons will result in foot imbalance and produce static and dynamic deformities and disturbances in walking.

Standing and Balancing. When we stand in the normal position, the feet are moderately separated with the toes pointing outward. In this position the body weight is equally divided between the feet. The center of gravity of the body may be assumed to be at the center of the second sacral vertebra (Fig. 1A and B). A plumb line dropped from the center of gravity falls midway between the feet at the level of the navicular bone. Thus, the body is supported by two pillars with the center of gravity falling between them. These two pillars are supported on the lever arms of the foot which extend forward of this center of gravity as the forefoot and backward as the heel. Thus, stability is insured through these lever arms forward, backward and from side to side.

Balance is maintained by a minimum expenditure of muscle power. The muscles contract periodically to correct swaying of the body, but the majority of the time they are at rest (Fig. 1A). There is a rhythmic forward sway of the body which is counteracted by periodic contraction of the triceps surae muscles and the toe flexors. This forces the forefoot lever against the ground. Since the foot is fixed to the ground, the effect of this force is to pull the tibia backward, bringing the center of gravity back to the normal position. The act of balancing can be clarified if we consider the foot as fixed to the ground. The muscles then act on the leg to maintain its position over the foot. Attempts to plantar flex the foot pull the tibia backward. When one attempts dorsiflexion, the tibia is pulled forward. Inversion force pulls the leg medially and eversion force on the foot pulls the leg laterally.

While this balancing is taking place, the weight passing through the feet is supported by the ligaments. However, these ligaments are not strained because we shift position frequently (Fig. 1C). It has been found that the standing person shifts his position about every 30 seconds from one foot to the other and forward and backward on both feet. Seldom does a person stand still for a full minute. This economy of muscle power and shifting of body weight to various ligaments

accounts for our ability to stand for long periods without fatigue.

Weight transmission through the feet while standing has been determined by many investigators. When the center of gravity falls opposite the navicular bone, equal weight is supported by the forefoot and heel. The heel bears half of the body weight; the metatarsal bones bear the other half. The division of weight through the metatarsal heads, however, is not equal. The first metatarsal bone supports one-third of the weight borne by the forefoot and the lateral four metatarsal bones share equally the remaining two-thirds. Thus it is apparent that there is no transverse arch on weight bearing at the level of the metatarsal heads. Any disturbance in transmission of this load through these structures will produce static problems in the foot. The typical callus on the plantar aspect of the foot over the distal end of a metatarsal bone signifies the disturbance in weight bearing and indicates overloading of that metatarsal.

This distribution of weight in the long axis of the foot has been termed the *axis of leverage* by Morton (Fig. 1B). However, in balancing, the functional axis of the foot falls between the second and third metatarsal bones, each half bearing equal weight. This has been termed the *axis of balance*.

Walking. The act of walking is accomplished by shifting the center of gravity of the body forward. This is accomplished by inclining the body forward and propelling it upward by plantar flexion of the foot (Fig. 6). Gravity pulls the center of gravity forward and downward. The forward-swinging opposite leg and foot catch the falling body. The momentum of body weight carries the trunk over the leg. The process is then repeated; the center of gravity is raised and propelled forward as the triceps surae contracts, forcing the foot into plantar flexion. Thus, muscle contractions raise the center of gravity and incline it forward, gravity then supplies the acceleration necessary to carry the body over the advanced leg. This mechanism conserves muscle power. The muscles in the leg and foot act only for short periods in the swing and stance phase of walking; gravity supplies part of the force necessary for locomotion.

Other muscles in the leg and foot contract briefly at various phases of the step. Following the forward propulsive force of the triceps surae and toe flexor muscles, the quadriceps muscle group contracts briefly to

straighten the knee (Fig. 7). As the leg swings forward, the hamstring muscles contract for a short period just before the leg is completely extended. This action of the hamstring muscles prevents the leg from snapping into extension at the knee. The dorsiflexor muscles contract as the heel strikes the ground to prevent the foot from sudden plantar flexion. These various muscle contractions supply no forward propulsion but control the forward-swinging leg and make for a smooth rhythmic gait.

Disturbances of the muscle control of the leg and foot in the swing and stance phase of walking produce dynamic changes in the foot, a source of limping and abnormal strain.

The joints of the foot and leg not only are concerned with the up-and-down oscillations of the body but take part in other actions. Because of the configuration of the hip and knee joints, the femur internally rotates at the hip and the tibia at the knee as the lower extremity swings forward and the knee is extended. As the heel strikes the ground and weight is borne on the foot, the tibia and femur externally rotate. Since the foot is fixed to the ground, the external rotation of these bones is taken up in the subtalar joint. This produces torque to the foot similar to that applied in skating, aiding in forward propulsion.

When there are disturbances in the alignment of these joints, normal function is compromised and abnormal strains are imposed on the ligaments and joint surfaces.

The weight borne by the foot during the stance phase passes through the center of the talus to the os calcis as the heel strikes the ground. As the body swings over the foot, the weight progresses into the midtarsal region. A part of this is transmitted to the navicular and cuneiform bones to the first two metatarsal bones and part through the cuboid and lateral three metatarsal bones. The weight with the foot flat to the ground is thus divided between the medial and lateral halves of the foot along the axis of balance between the second and third metatarsals (Fig. 1B). As the push-off phase of the step is reached, the weight of the body is transferred to the leverage axis of the foot between the first and second metatarsal bones. Strong plantar flexion of the great toe at this point adds further forward propulsive force.

Abnormalities of this weight-bearing transmission through the foot will produce abnormal strains on bones, joints, ligaments, tendons and muscles and abnormal pressure

on the protecting covering of skin and subcutaneous tissue.

DISEASES OF THE FOOT

Diseases of the foot may be classified as congenital and acquired. Congenital deformities include skeletal defects, absent or supernumerary parts, defects in muscles and tendons, defective joints, circulatory and lymphatic system defects and defects of the nervous system producing abnormalities of the leg and foot.

Acquired defects include postural strains, static and dynamic deformities, diseases of the nervous system producing paralysis or spasticity of muscles, circulatory diseases, tumors, infections, injuries and generalized systemic disease.

CONGENITAL DISEASES OF THE FOOT

Congenital Talipes Equinovarus. Congenital defects of the foot are many and varied. Some of them have a tendency to transmission to succeeding generations.

Congenital talipes equinovarus, or clubfoot, is a serious deformity occurring once in every 700 to 1000 births (Fig. 8). The defect in varying degrees encompasses 75 per cent of the congenital anomalies of the foot. Frequently it is bilateral and is found twice as often in boys as in girls.

Clubfoot is a combination of three distinct deformities in the foot and ankle. The forefoot is adducted and supinated, the heel inverted and the foot is in equinus at the ankle. The degree of deformity varies from a mild flexible one to a severe, rigid defect. There is *no bone deformity at birth*, but the relationship of the joints is abnormal. The metatarsal bones are adducted at the metatarsal-tarsal joints. The first metatarsal bone may be shorter than normal. The cuboid and navicular bone shift medialward, producing widening laterally at the calcaneocuboid joint. The navicular bone lies on the medial surface of the head and neck of the talus.

The normal relationship of the talus and

Figure 8. Talipes equinovarus or clubfoot in in-

the calcaneus is disturbed. When viewed from above, the long axis of the talus is directed forward and medially while the axis of the calcaneus is directed forward and laterally (Fig. 9). The intersection of these axes forms a V with the opening forward. The clubfoot heel is inverted and the os calcis appears to lie directly under the talus with their long axes parallel.

The soft tissues are contracted on the medial and plantar aspect of the foot, accompanying the varus deformity.

The calf muscles are short, holding the foot in equinus position, and the insertion of the Achilles tendon appears to lie more medially on the os calcis.

The etiology of clubfoot is not clear. Several theories are applied to explain the deformity. Arrest or anomalous development of the germ plasm concerned with develop-

ment of the foot in the first trimester of pregnancy may explain the defect in some instances.

During fetal development, the limb bud first is in the equinovarus position, but gradually the limb rotates to the normal position. Failure of rotation may account for clubfoot.

Biopsy material has shown degenerative changes in the muscles and there may be anomalous insertion of the tendons in the foot.

In infancy, since the deformity is produced by soft tissue contractures, stretching of these structures is begun as soon as possible, often within the first week of birth, and continued until complete overcorrection is obtained.

Three definite steps are followed to correct the deformity. Adduction and supination of the forefoot are gently changed into ab-

Figure 9 A, Relationship of bones in the normal foot B, Abnormal position of bones in clubfoot. The adduction of the forefoot is marked. The talus lies directly over the os calcis in the anteroposterior view and the foot is plantar flexed at the ankle.

Figure 10 A, Corrective clubfoot cast extends above the bent knee and holds the foot in abduction and eversion. B, Correction of equinus by dorsiflexion is started only after adduction of the forefoot and varus of the heel have been fully corrected

duction and pronation. The inverted heel is everted and the equinus is corrected by dorsiflexion of the foot.

The overcorrection must be maintained until the affected muscles recover, which often may require many months.

There is frequently a tendency for recurrence of the deformity and the child must be observed until growth is completed and any recurrence treated immediately

To correct the deformity, the foot is gently stretched manually by the surgeon and a well-padded cast applied from the toes to above the flexed knee with the forefoot abducted (Fig. 10A and B). The cast is changed every two weeks. When full abduction of the forefoot is obtained, the heel is gradually everted. Dorsiflexion of the foot must not be attempted until this has been accomplished.

Failure to fully correct the adduction of the forefoot, the talonavicular joint and the inverted heel before dorsiflexing the foot will result in a rocker-bottom foot. The foot dorsiflexes through the midtarsal joints, the talus and calcaneus remain in equinus. This deformity may be as disabling as clubfoot. When this occurs, the entire procedure must be started over.

When clubfoot is fully corrected, the surgeon should be able to approximate the lit-

Figure 11 The test for full correction of equinovarus deformity approximates the fifth toe to the anterolateral aspect of the leg

tle toe to the lateral side of the leg (Fig. 11).

Following cast treatment, to maintain the correct position, the baby wears prewalker clubfoot shoes and a Denis Browne splint until walking is begun.

When the foot is rigid or treatment is started late, wedged casts may be necessary (Fig. 12). Occasionally soft tissue contractures on the medial side of the foot are released surgically. The capsules are

incised to allow correction of the forefoot adduction and heel inversion. Excessive stripping of the structures from the bone is avoided, as the scar tissue which forms is inelastic and may cause recurrence.

The Achilles tendon may be lengthened when there is persistent equinus in order to prevent a flat-top talus. The talus held in prolonged equinus develops a flat tibial articular surface which blocks dorsiflexion. However, some weakness of the leg results from lengthening of the Achilles tendon and the procedure should be reserved for resistant clubfoot which fail to respond to stretching.

When the peroneal muscles function poorly or do not develop, even a well-corrected clubfoot will recur. When the child walks, the peroneal muscles fail to contract and the foot swings into inversion. Transferring the tibialis anticus to the cuboid bone tends to balance the foot and prevent the deformity.

Older children who have not been treated or who have been allowed to develop recurrent clubfoot may have abnormally shaped bones in the foot. If wedged casts fail to correct the deformity, resection of the deformed bones may be necessary. This is most conveniently done by removing appropriate wedges of bone from the subtalar, talonavicular

and calcaneocuboid joints and fixing these joints in the proper position by arthrodesis (Fig. 13). The operation must not be done before the age of ten years as disturbance of growth of the foot follows.

Congenital Metatarsus Varus or Adductus. Two types of congenital metatarsus varus are found in the newborn. The first type exhibits adduction and inversion of the metatarsal bones with the heel in the valgus position. This foot deformity is rigid and difficult to correct and recurrence is the rule. Fortunately the condition is rare.

The second type is flexible, the forefoot is adducted and the heel is in neutral or slight varus position (Fig. 14A and B). This type has been increasing in frequency in recent years. Fortunately this deformity is easily corrected and recurrence is uncommon. The forefoot is adducted and inverted and the longitudinal arch is higher than normal through the action of the tibialis anticus muscle. The lateral aspect of the foot at the base of the fifth metatarsal bone is prominent. The hind foot is normal and the foot can be readily dorsiflexed.

In mild deformities, stretching the forefoot in abduction and eversion is done by the mother each time the baby's diaper is changed. This may be the only treatment

Figure 12 A, Recurrent and resistant clubfeet may require wedged casts to correct the deformity. B, A wedge of plaster is removed laterally to allow gradual stretching of the adducted forefoot. C, The wedge closed and the forefoot abducted. D, The heel viewed posteriorly is forced into eversion by removing a wedge of plaster laterally just above the subtalar joint. E, The wedge closed and the heel everted. F, The equinus deformity is corrected by removing a plaster wedge from the cast at the level of the ankle joint. Figure 13 A, Bony deformity of clubfoot demands resection of bone to place the foot in the normal position. Arthrodesis of the talonavicular and calcaneocuboid joints is done to prevent recurrence of the adduction deformity (redrawn from Speed, J. S., and Smith, H.: *Campbell's Operative Orthopaedics*, 2nd ed C. V. Mosby Company).

B, A wedge of bone is removed from the subtalar joint to place the heel in slight eversion. C and D, The corrected foot.

Figure 14. A, Metatarsus varus deformity. B, The deformity is increased and perpetuated if the infant sleeps with the legs internally rotated.

necessary. Prewalker clubfoot shoes attached to the Denis Browne splint in external rotation may correct more severe deformity. Occasionally casts are used as in the first part of the correction for clubfoot.

Untreated, the deformity may persist and increase in severity. Older children who fail to respond to use of a wedged cast require osteotomy of the base of the metatarsal bones (Fig. 15A and B). Following union of the bones, outflare shoes are worn for several months.

Congenital Calcaneovalgus. The congenital calcaneovalgus foot is the direct opposite

of talipes equinovarus. The etiology is thought to be abnormal intrauterine position of the foot.

The bones of the foot are normal. The foot is in dorsiflexion, the heel points downward in valgus position and the forefoot is abducted and dorsiflexed. The fifth toe may be easily approximated to the anterolateral aspect of the leg. Usually the foot is quite flexible and may be partially plantar flexed and inverted without difficulty.

The deformity is easily corrected by repeated gentle stretching and there is little tendency toward recurrence. The mother is

A

B

Figure 15 A, X-rays of bilateral metatarsus varus. B, Healing after osteotomy near the base of the metatarsal bones correcting the varus deformities

instructed to stretch the foot in plantar flexion, inversion and adduction each time the baby's diaper is changed. Denis Browne splints may be used if the deformity is resistant to stretching. The feet are internally rotated and inverted by the splint. Rarely is cast correction indicated.

When the child begins to walk, the foot may tend to assume a valgus position on weight bearing. The child should be fitted with a $\frac{1}{4}$ inch inner heel wedge on the shoe during this period.

Syndactyly of Toes. Syndactyly may occur in two or more toes. The deformity tends to be a familial one. The toes may be webbed completely or partially from the base to the tip. The soft tissues only may be affected or the deformity may have a bony bridge between the phalanges. Little if any functional disability results from the defect. Separation of the toes by surgery is seldom necessary as the foot functions well and shoe-fitting problems are unusual.

If, for cosmetic reasons, the toes are separated surgically, x-rays must first be made to determine the degree of bone involvement. When the bones are joined near the epiphysal plates of the phalanges, the operation should be deferred until spontaneous closure of the epiphyses has taken place. If the operation is done too early, unilateral closure of a portion of the epiphysal plate will cause angulation and deformity of the toes with growth.

Polydactyly. Polydactylism in the foot is characterized by the presence of supernumerary toes. The deformity is usually familial. The extra digit may be completely formed, normal in appearance and function, or it may be misshapen, rudimentary and functionless. Reduplication of a part of the toe, such as the distal phalanx, is a variation of the deformity. Shoe-fitting problems are frequently encountered, demanding amputation of the extra toe or plastic reconstruction of reduplicated phalanges. Amputation of a complete toe can be done at any age; however, resection of portions of duplicate phalanges must not interfere with the epi-

Figure 16. Reduplication of the distal phalanx of the great toe. The epiphysis is involved in the defect.

Figure 17. Agnasia, syndactyly and deformity of the toes. Congenital constriction band is present in the right forefoot.

Figure 18. Os trigonum. Thin cortex about the entire bone differentiates it from fracture of the posterior talus.

physical plate. X-rays should be taken to determine the degree of bone deformity and involvement of the epiphysis (Fig. 16).

Agnasia. Agnasia of part or all of the foot may result from faulty limb bud development and be the source of profound disability. The forefoot is most frequently the site of deformity. Parts of toes and metatarsals may be absent. Abnormal insertion of tendons and absence of bones may produce considerable distortion of the foot (Fig. 17). Occasionally tendon transference, plastic operations or stabilization of the joints of the foot is necessary to correct deformity.

Macroductyly. Occasionally a foot is encountered which exhibits one or more giant toes. The overgrowth of the part may be due to vascular or neurotropic lesions or to some defect in the growth capacity of the toe. Amputation of the toe or reduction of the size of the toe by plastic surgical procedures is usually necessary to permit the wearing of matched shoes.

Accessory Bones of the Foot. Accessory bones of the foot occur in many locations, but most do not produce symptoms and are found incidental to x-ray examination of the foot. The recognition of these bones as accessory bones and not fractures is of medicolegal import. The accessory bone has a complete cortex surrounding the bone while the recent fracture has an absence of cortex at the fracture line.

The most common accessory bones in the foot are the os trigonum, found near the posterior aspect of the talus, and the os vesalianum, at the base of the fifth metatarsal bone

(Fig. 18). These bones do not produce symptoms or weaken the foot but are often confused with fractures.

The accessory navicular bone located at the medial aspect of the parent bone produces a prominent mass. A bursa and painful callus may form over the medial aspect of the foot at this site from shoe pressure. The longitudinal arch of the foot may be weak and flat because the tibialis posterior tendon is abnormally inserted.

Symptoms are usually pain and swelling of the bursa over the bony prominence and fatigue and aching in the midtarsal region because of faulty support for the longitudinal arch.

When the symptoms cannot be relieved by supports to the arch of the foot, surgical correction of the deformity is necessary. The accessory navicular bone is removed and the tibialis posterior tendon is inserted under the navicular bone.

Pes Planus or Flatfoot. Pes planus may be acquired or occur as a result of a congenital deformity (Fig. 19A-C). Flatfoot associated with congenital calcaneovalgus deformity and the accessory navicular bone has been described. Other congenital defects may be etiologic factors in the development of flatfoot. Hypermobility flatfoot with a short tendo achilles and coalition of the tarsal bones producing peroneal spastic flatfoot are examples. Pes planus may be acquired as a result of excessive strain in the obese with weak ligaments, neurologic lesions affecting the muscles and ligaments,

trauma or infection producing bone, joint or muscle abnormalities, and disease of muscle.

Not all flatfeet are painful. Like the shape of noses, the height of the arches of the foot varies and may follow familial patterns. The small child beginning to walk may appear to have no arch at all. A fat pad occupies the plantar area at this age and may obscure the arch which is readily revealed when weight-bearing x-rays are taken.

Pain develops in flatfeet when the ligaments are subjected to abnormal strain. Con-

tinued use leads to synovitis of the joints of the foot and later traumatic arthritis. In the growing child, the tarsal bones develop abnormal shapes. The patient suffering from painful flatfoot rotates the foot and leg externally while walking. In this position, the anterior lever of the foot is shortened; the push-off is from the medial side of the first metatarsal head and great toe. The stride is shortened, producing a shuffling gait.

The calcaneus is in valgus position at the subtalar joint. The talus points more medialward and the head of the bone tips down-

Figure 19 A, Pes planus. Flat medial arch with abduction of the forefoot B, Complete flattening of the longitudinal arch C, Valgus position of the heels

e 20. Abduction of the forefoot with separation of the anterior relationship of the talus and os calcis—adult flatfoot.

ward. The longitudinal arch is flattened by angulation plantarward at the talonavicular or cuneiform-navicular joints, or at both joints. These bones rotate medialward and down, carrying the base of the metatarsal toward the plantar surface of the foot. The metatarsal bones abduct and the joints on the medial aspect of the foot open and compress on the lateral side (Fig 20). The calcaneonavicular and long plantar ligaments are stretched and relaxed.

Short Triceps Suræ Muscles. When the tendo achillis and triceps suræ muscles are short, dorsiflexion of the foot is limited and increased strain is placed on the anterior lever arm of the foot. If the supporting ligaments stretch with weight bearing, the longitudinal arch flattens. The talus and calcaneus remain in equinus and the forefoot dorsiflexes through the midtarsal joints. The condition may occur as congenital shortening of the muscle group or secondary to the contractures of spastic paralysis or other neuromuscular afflictions.

Treatment is directed toward lengthening the tendo achillis and calf muscles and supporting the arch in the normal position until the muscles and ligaments recover. The triceps suræ muscles in the child are stretched with wedged casts. The foot must be inverted and the forefoot adducted during this procedure to prevent further stretching of the medial plantar ligaments and increasing the deformity.

When the calf muscles cannot be stretched, the Achilles tendon or the musculotendinous junction can be lengthened surgically. The foot and leg are immobilized in a plaster cast with the foot inverted and dorsiflexed for three to six weeks. A supporting shoe with an extended rigid counter, Thomas heel and medial heel wedge is used postoperatively to support the repositioned arch.

Hypermobile Flatfoot. Hypermobile flatfoot with short tendo achillis occurs secondary to a congenital defect in the relationship of the talus to the os calcis. Characteristically, the foot is flat only on weight bearing, assuming a normal appearing arch when weight is removed. A history is obtained usually of asymptomatic flatfeet during childhood followed by aching, easily fatigued feet in adolescence or early adult life. Occasionally pain develops in childhood. Symptoms vary in intensity.

The primary etiologic factor is inadequate support for the head and neck of the talus by the os calcis. The triceps suræ muscles are short, but this finding is secondary to the

Figure 21. A, The normal relationship of the bones is shown for comparison. B, Relationship of the talus to the os calcis in hypermobile flatfeet. The talus is displaced medially and the long axis of the bones diverges anteriorly. The head and neck of the talus project farther forward and the sustentaculum tali is narrow, offering less support for the talus. (Redrawn by permission from *Hypermobile Flat Foot with Short Tendo Achilles*, by R. I. Harris and T. Beath, *J. Bone & Joint Surg.*, vol. 30-A, pp. 116-140, Jan., 1948.)

bone anomaly. The head and neck of the talus are displaced medially and the bone forms a more divergent angle with the long axis of the calcaneus (Fig. 21). The talus appears to project farther forward on the os calcis and the sustentaculum tali is underdeveloped, slanting and more posterior on the calcaneus than normal. This lack of bony support under the head of the talus allows it to plantar flex. Coupled with this defect, the midtarsal joints are more mobile than normal, allowing the forefoot to abduct and dorsiflex to a greater degree. The calcaneus assumes a valgus position on weight bearing and, since the calf muscles are short, the forefoot dorsiflexes and abducts to produce the flat foot.

Treatment is directed toward support for the talus and relieving the pull of the short triceps suræ. Since the degree of anatomic abnormality and the severity of symptoms vary, so does the treatment. In childhood it may be necessary only to support the foot with adequate shoes and arch supports. A heel lift may be used to lessen the pull of the calf muscles. This same treatment may continue into adult life if the condition is mild and the symptoms easily controlled.

When the symptoms are due to an anatomic deficit

are severe, the subtalar and midtarsal bones must be stabilized by arthrodesis in the correct weight-bearing position. This may be accomplished by triple arthrodesis after growth of the foot is complete (Figs. 22 and 23).

Peroneal Spastic Flatfoot. Peroneal spastic flatfoot is a painful rigid foot associated with spasm and contracture of the peroneal muscles. It is due to congenital coalition of the tarsal bones. Complete or partial bony

bridges form between one or more tarsal bones. This coalition of tarsal bones limits motion between the involved bones. Since the subtalar, talonavicular and calcaneocuboid joints act as a unit, limitation of motion in any joint throws additional strain on the remaining mobile ones. This strain eventually produces irritation in the joints and ligaments. The irritation, in turn, produces reflex spasm of the peroneal muscles which forces the foot into eversion. As the irritation

Figure 22 A and B, Triple arthrodesis of the subtalar, talonavicular and calcaneocuboid joint is performed to correct and stabilize the hypermobile flatfoot when the major angulation is at the talonavicular joint. The procedure may be used in any type of flatfoot. C, A wedge of bone is removed from the subtalar joint with the base medial to correct the valgus of the heel.

Figure 23 A and B, The forefoot abduction is corrected by removing a wedge of bone with the base medial, stabilizing the talonavicular and calcaneocuboid joints.

OL Miller operation for flat foot

FIGURE 24 A Painful flatfoot with the major plantar angulation at the naviculocuneiform joint is stabilized

continues with weight bearing, pain develops in the midtarsal and subtalar joint areas, often beneath the lateral malleolus.

The patient cannot voluntarily invert the foot and attempts by the surgeon to do this produce immediate pain and the peroneal muscles involuntarily contract. A similar clinical picture may occur when irritation and limitation of motion are present in the damaged subtalar joint following fracture of the articular surface of the os calcis.

The most frequent coalition is between the anterior os calcis and the navicular bone. The bones fuse by either a complete or partial bridge of bone at the medial anterior portion of the os calcis and the lateral inferior portion of the navicular bone. This bridge of

bone limits inversion and eversion in the subtalar joint. Routine anteroposterior and lateral x-ray views fail to reveal the abnormality. Oblique x-ray views are necessary to show the coalition.

Other bony or cartilaginous bridges form between the os calcis and talus. One may occur posteriorly through the os trigonum, the other in the region of the sustentaculum tali. The latter can only be visualized by special x-ray technique. To obtain the x-ray, the patient is placed on the x-ray table with the knees flexed. The x-ray beam is directed from the posterior downward and forward between 35 and 45 degrees to correspond to the angulation of the articular surface of the sustentaculum.

The calcaneus may coalesce with the cuboid bone through a bridge of bone through the os peroneum. Other fusions of bone take place between the cuboid and navicular bones and the talus and navicular bone. Rarely, massive fusion of several tarsal bones is found.

Injury may precipitate the original pain in the ligaments followed by the syndrome of peroneal spastic flatfoot.

Treatment is directed toward relief of irritation and muscle spasm. Rest, elevation and heat are prescribed, followed by gentle manipulation of the foot to the inverted position. The foot and leg are immobilized in a plaster cast with the foot inverted for six weeks. Weight bearing in a walking cast is resumed at the end of three weeks. If the symptoms subside, the patient is fitted with an orthopedic shoe to support the longitudinal arch and hold the heel slightly inverted.

Recurrence of the symptoms and deformity is the rule and surgical correction is often necessary. Arthrodesis of the tarsal joints eliminates motion and the irritation which produces the peroneal muscle spasm. Following this procedure, inversion and eversion of the foot are lost, but the foot is stable in the proper weight-bearing position and is painless.

Triple arthrodesis of the subtalar, calcaneocuboid and talonavicular joints is useful in correcting flatfoot deformities which do not respond to conservative supportive measures (Figs. 22 and 23). The operation is indicated in peroneal spastic flatfoot, hypermobile flatfoot, arthritic flatfeet and in flatfeet when the main deformity occurs at the talonavicular joint.

Some flatfeet exhibit the primary plantar angulation at the navicular-cuneiform joint. Children or young adults with symptomatic flatfeet that do not respond to conservative measures may require correction and fusion of this joint with the first metatarsal-cuneiform joint (Fig. 24). Following the operation, the foot is immobilized in inversion and plantar flexion to raise the arch until arthrodesis occurs.

Congenital Vertical Talus. The deformity of congenital vertical talus produces a rigid rocker-bottom foot. The longitudinal arch is nonexistent or reversed. Although the etiology is considered congenital, the high incidence of this deformity associated with arthrogyposis suggests a definite relationship to this disease.

The forefoot is dorsiflexed, the heel is in equinus and deep creases may be present

over the anterior ankle. Eversion of the heel and abduction of the forefoot are not present at birth, but develop later. Rigidity of the foot is a characteristic finding. The posterior os calcis does not touch the ground when standing. The first metatarsal is dorsiflexed and a flexion deformity may be present at the metatarsal-phalangeal joint of the great toe. The calcaneus is narrow and beak shaped anteriorly and the talus resembles an hourglass. The navicular bone dislocates dorsally and laterally and articulates with the talus at the neck of the bone.

The disability is profound. Shoes are difficult to fit and pain develops in the foot. The rigidity of the foot defeats conservative corrective measures. Triple arthrodesis at an appropriate age may place the foot in a better weight-bearing position, but the result is never perfect.

Talipes Cavus. Pes cavus, or clawfoot, is the opposite deformity of flatfoot. The longitudinal arch is higher than normal. Usually the hind foot is near normal; the os calcis may be slightly inverted. The high arch is due to plantar flexion of the forefoot through the tarsal and metatarsal joints (Fig. 25). Mild deformities may not affect the toes and are asymptomatic. With more severe deformity, the toes become flexed at the interphalangeal joints and hyperextended or dorsally dislocated at the metatarsal-phalangeal joints. The plantar fascia becomes shortened and the metatarsal heads are prominent in the ball of the foot. Calluses develop over the metatarsal heads and corns appear over the proximal interphalangeal joints of the toes. The foot may be in moderate equinus

Figure 25 The arch is elevated in the cavus foot. The dorsum of the foot is prominent. The deformity is primarily due to plantar flexion of the forefoot with the heel in the normal position. In this case, the toes are contracted into the clawfoot deformity.

Figure 26. A, The high arch of the foot.

a wedge of bone through the foot—the talonavicular, calcaneocuboid, and cuboid joints. When the wedge defect is closed, it lowers the longitudinal arch.

position associated with contracted calf muscles.

The deformity may be idiopathic or secondary to diseases of the nervous system or muscles. It frequently follows poliomyelitis, myelodysplasia, spina bifida and muscular dystrophy. The intrinsic muscles of the foot are ineffective.

Imbalance of the joints of the toes creates an imbalance. The unopposed long extensor muscles produce hyperextension at the metatarsal-phalangeal joints and the long flexor muscles promote flexion of the interphalangeal joints.

Conservative treatment in the mild condition consists in elevation of the depressed heads of the metatarsal bones and stretching of the tight plantar structures. This may be done with a transverse metatarsal bar placed on the sole of the shoe just proximal to the metatarsal heads. A similar method may be used in which a metatarsal arch support is placed in the shoe. This raises the metatarsal heads and relieves pressure on the plantar calluses by transferring the weight more proximally in the foot. The elevation of the metatarsal bones tends to straighten the contracted toes.

When more severe deformity is found, operative correction may be necessary to relieve the symptoms. Since the plantar aponeurosis is short, it may be lengthened by section of the attachment to the os calcis. The foot is stretched and immobilized in the corrected position in a plaster cast for three weeks. When the toes are in the claw position, the metatarsal heads are depressed and the toes do not function. Arthrodesis of the interphalangeal joints so they are straight permits the long flexor muscles of the toes to act at the metatarsal-phalangeal joints,

holding the toes in proper weight-bearing position.

If the plantar

is

arc

In addition to arthrodesis of the toe joints, the extensor tendons of the toes are resected with the dorsal joint capsules. The dorsally dislocated toes can then be reduced. The extensor digitorum longus tendons are transferred and inserted into the neck of the metatarsal bones. This aids in elevating the distal metatarsal bones, reducing the forefoot drop and prominent metatarsal heads.

Wedge resection of the navicular-cuneiform joints and the cuboid bone

is a procedure in which a wedge of bone that is removed is dorsal (Fig. 26). When the osteotomy site is closed and the base of the metatarsal bones is displaced plantarward, the longitudinal arch is lowered. This is feasible only when the relationship in the hind foot is normal. If the heel is inverted and the forefoot adducted, triple arthrodesis with removal of appropriate wedges of bone from the subtalar, talonavicular and calcaneocuboid joints is necessary to correct the deformity. These operations on bone should be deferred until the foot is well developed. Before the age of ten, the ossification of the bones is incomplete and growth of the foot is retarded or arrested when the operation is done. The operative procedures on the soft tissues can be done before this time and may help prevent more serious deformity.

AFFLICTIONS OF THE FOREFOOT AND TOES

Hallux Valgus and Bunion. One of the most common and distressing deformities of the forefoot and toes is the bunion and bun-

ion (Fig. 27). The great toe points laterally, producing a prominence on the medial aspect of the head of the first metatarsal bone. Shoes create pressure on the bony prominence and a painful bursa develops. When the deformity is pronounced, the great toe overlaps or underlaps the second toe forcing this toe dorsally or plantarward. The second toe may dislocate (Fig. 28A and B).

The cause is usually an abnormal varus angulation of the first metatarsal bone. Occasionally the condition occurs with metatarsus latus or splayfoot which produces a similar angulation of the first metatarsal bone. The space between the distal end of the first

and second metatarsal bones and toes is exaggerated. The adductor of the great toe deviates the toe laterally and the extensor hallucis longus tendon subluxates laterally. The flexor hallucis brevis with the lateral sesamoid bone and the flexor hallucis longus become similarly displaced. The abductor hallucis subluxates plantarward and the corrective influence of the muscle is lost. The tendons in the laterally displaced position increase the angulation of the great toe. The condition is usually slowly progressive.

When the deformity is mild and inflammation of the bursa periodic, a wide shoe made of soft kidskin is worn to minimize pressure on the bursa. The longitudinal arch of the foot and first metatarsal bone is supported with pads or a corrective shoe. To prevent increasing splayfoot, the metatarsal arch is elevated with a pad.

Since the deformity is progressive, the metatarsal head becomes more prominent. The inflamed bursa stimulates the bone and an exostosis forms medially beneath the bursa and joint capsule. Osteoarthritis is prone to develop in the metatarsal-phalangeal joint. The push-off action of the great toe is lost as the deformity progresses.

Surgical treatment is indicated when conservative measures fail. Numerous operations have been devised to relieve the distress of bunions. The objective is to correct the valgus position of the great toe, remove the prominence of the head of the metatarsal bone and correct the deforming pull of the muscles.

The metatarsus primus varus or metatarsus latus can be corrected in young people to prevent recurrence. The presence of osteoarthritis in the joint demands remodeling of the joint surfaces.

Three general types of operative procedures are available to the surgeon. The choice

Figure 27. Hallux valgus and bunion. The great toe is deviated laterally, the first metatarsal bone is angulated medially. The prominent medial aspect of the head of the metatarsal bone is the site of a painful bursa.

Figure 28. A, Severe hallux valgus with plantar flexion forces the small toes dorsally. B, The second toe is dislocated dorsally at the metatarsal-phalangeal joint.

SILVER'S TECHNIQUE

KELLER'S OPERATION

LAPIDUS PROCEDURE

Figure 29. Upper A, Mild hallux valgus may be corrected by Silver's technique B, The joint capsule is removed C, The joint capsule is removed D and the lateral joint capsule is shortened

Center The Keller operation is used when the deformity is pronounced or the metatarsal-phalangeal joint is arthritic A, The exostosis is removed from the metatarsal head and the proximal third of the phalanx of the great toe is resected B, The toe corrects easily and a painless pseudarthrosis forms The toe is shortened but functions well. (Redrawn from Keller, W L. New York M J, vol 95)

Lower The Lapidus procedure corrects the metatarsus varus and hallux valgus A, The exostosis is removed from the metatarsal head The cuneiform-metatarsal joint is resected to correct the metatarsus varus B, The adductor tendon is resected from the proximal phalanx and sutured to the first metatarsal C, The deformity is corrected and the base of the first metatarsal bone is stabilized to the cuneiform bone and the second metatarsal bone to prevent recurrence (Redrawn from Lapidus, P W.: Operative Correction of the Metatarsus Varus Primus in Hallux Valgus, Surg Gynec & Obst, vol 58)

of operation depends upon the patient's age, circulation, degree of deformity and the presence or absence of arthritis in the joint. Mild deformities require only removal of the exostosis and the prominent bone (Fig. 29). Correction of the toe is obtained by shortening the medial joint capsule and, in some cases, sectioning the lateral joint capsule and adductor tendon. When the deformity is greater, the adductor tendon may be reinserted into the metatarsal bone to remove the deforming influence and to help correct the metatarsus primus varus. The abductor tendon may be repositioned over the medial aspect of the joint.

If osteoarthritis is found, arthroplasty or remodeling of the joint must be done in order to prevent pain and stiffness (Fig. 29). This is most simply done by excision of the proximal third of the proximal phalanx of the great toe. The malposition of the toe is easily corrected as relaxation of soft tissues follows removal of the segment of bone. Pseudoarthrosis develops at the metatarsophalangeal joint which is pain free and mobile.

Young adults or older patients who have excessive metatarsus varus may require more extensive surgery to correct the deformity and to prevent its recurrence (Fig. 29). Adequate circulation of the foot is a prerequisite. The objective is to correct the metatarsus varus as well as the hallux valgus. Osteotomy or wedge resection, at or near the base of the first metatarsal bone, is performed and the bone realigned. Arthrodesis of the first metatarsal base to the second as well as the metatarsal-cuneiform joint may be necessary to maintain the position.

Metatarsus latus, or splayfoot, may be corrected by a similar procedure combined with the creation of a plantar sling of tendon from the fifth to the first metatarsal heads, pulling the metatarsal bones together.

Hallux Rigidus or Hallux Nonextensus. Hallux rigidus, as the name implies, is characterized by painful limitation of extension at the great toe joint.

The etiology is not always clear, however, an exostosis of the

use of a stiff-soled shoe to prevent dorsiflexion force on the toe and removal of pressure on the bursa when it is present.

The dorsal exostosis may be removed surgically and the proximal third of the phalanx of the toe resected. Following surgery, the patient must be taught to walk with the foot pointing forward to lessen arch strain.

Digitus Quinti Varus or Bunionette. Varus position of the fifth toe with bunion formation is less common than hallux valgus. The bursa forms over an exostosis or prominence of the head of the fifth metatarsal bone on the lateral aspect of the foot. The little toe may exhibit little or marked varus deformity angulating toward the medial side of the foot. It may overlap the fourth toe or lie beneath it.

Conservative treatment is designed, as for hallux valgus, to lessen pressure on the bursa and to straighten the fifth toe. Stretching the shoe over the bursa and placing a felt pad between the fourth and fifth toes often is all that is necessary to relieve the symptoms.

Resection of the exostosis combined with shortening or reefing the lateral capsule of the metatarsal-phalangeal joint straightens the toe and removes the irritating prominence. When the fifth toe is in extreme varus position over or underlapping the fourth toe, osteotomy of the base of the first phalanx will correct the position of the toe.

When the fifth toe is held in dorsiflexion and varus by a contracted extensor digiti quinti longus tendon, the tendon is sectioned at the ankle. The tendon is withdrawn through a second incision at the base of the toe. A tunnel is created by blunt dissection medially and plantarward about the base of the phalanx and the tendon passed through the tunnel and terminated laterally. It is sutured into the abductor tendon and muscle of the fifth toe, converting the tendon to a flexor abductor pulling the toe down and out.

Hammer Toe. Hammer toes are similar in appearance to claw toes, but lack the extreme hyperextension of the metatarsal-phalangeal joints. The proximal interphalangeal joint is flexed and the distal joint flexed or extended.

Symptoms are produced when the toe rubs in the shoe. A callus is formed over the plantar pad of the distal phalanx and a corn is found over the dorsum of the flexed interphalangeal joint. Shoes with a boxlike toe may give the toes room and relieve the pressure symptoms. Padding beneath the metatarsals may tend to straighten the toes when they are flexible.

Straightening the toes by resection or ar-

and osteoarthritis frequently accompanies this change. A bursa may develop over the dorsum of the joint. The foot is turned outward when walking to avoid dorsiflexion of the toe. A callus may form on the plantar aspect of the interphalangeal joint secondary to hyperextension of this joint.

Conservative measures are limited to the

Figure 30 A, The medial and lateral plantar nerves join between the third and fourth metatarsal bones. The common digital nerve of the third and fourth toes. B, the metatarsal bones. C, metatarsal bones. The entire mass is excised.

throdosis of the proximal interphalangeal joint produces a comfortable foot, eliminating the points of pressure and friction.

Plantar Callosities and Prominent Metatarsal Heads. The heads of the metatarsal bones may be depressed into the sole of the foot by a variety of abnormalities. The involved bone then carries more weight. Friction and pressure lead to hyperkeratotic skin changes. Pain on weight bearing is the usual complaint.

Treatment is directed toward correction of associated foot deformity and redistribution of weight through the metatarsal bones. Transverse metatarsal bars and arch supports elevate the metatarsal bone and relieve the abnormal pressure. With relief of excessive pressure, the callus disappears.

Plantar warts, thought to be virus infections, may be found in the callus. These lesions may disappear when excessive pressure is relieved. Some plantar warts, however, are persistent or recurrent. Salicylic acid adhesive plaster is applied to the area for forty-eight hours. The callus and wart may be carefully trimmed after the skin softens.

X-ray therapy supervised by a roentgenologist is warranted when plantar warts do not respond to the above treatment. Care must be exercised to prevent excessive radiation.

Occasionally pressure of a prominent metatarsal head cannot be relieved with arch supports. After the other associated defects in the foot are corrected, one or two metatarsal heads, with the exception of the first, may be resected without weakening the foot. Removal of the head of the first metatarsal bone produces a serious defect in the weight-bearing mechanism of the foot.

Interdigital Neuroma. Neuroma of the common digital branch of the plantar nerves produces characteristic symptoms which have been called Morton's toe (Fig 30A). Lancinating pain in the region of the third and fourth toes and metatarsal bones occurs periodically while walking. Pain may radiate to the anterior surface of the leg and the toes may be drawn into the claw position. Relief is obtained by removing the shoe and massaging the foot.

Examination may reveal normal appear-

ing foot or the common forefoot deformities may accompany the condition (Fig. 30B). Pressure exerted by the examining finger between the base of the third and fourth toes will often reproduce the typical attack of pain. Occasionally a firm tender mass can be palpated between the metatarsal bones. The sensation of pain and temperature is usually diminished on the adjacent surfaces of the toes.

The medial and lateral branches of the plantar nerve form an arch in the forefoot joining at the fourth common digital nerve. Traction or pressure on the nerve at this fixed point is thought to be the etiologic factor producing the neuroma. Inflammatory reaction about the nerve stimulates the formation of fibrous tissue in the nerve, forming the tumor mass. Occasionally a small bursa filled with clear yellow fluid surrounds the neuroma.

During the early stages of the syndrome, symptoms may be relieved by a transverse metatarsal bar on the sole of the shoe to minimize pressure on the third and fourth metatarsal bones. If the symptoms recur or persist, the area about the tumor is injected with local anesthetic and 25 mg. of compound F.

Symptoms which have been present sev-

eral months and do not improve with conservative measures usually require excision of the tumor. This is done through a web-splitting incision between the toes (Fig. 30C). Identification of the tumor mass just proximal to the bifurcation of the proper digital nerves is easily accomplished by blunt dissection. The common digital nerve is sectioned proximal to the mass and the tumor removed.

The same lesion is found less frequently in the other toes but may occur in any of the digital nerves.

Ingrowing Toenails. Ingrowing toenails (Fig. 31) develop secondary to injury, infection or pressure. The edge of the nail cuts into the adjacent soft tissue, injuring the skin. Bacteria invade the area and an abscess or chronic granuloma results. Periodic recurrent episodes of pain and swelling occur as the nail grows. Injury to the nail bed or a fungus infection may deform the nail or pressure of the shoe on the soft tissues about the nail margin can produce the condition.

During the acute infection, the principles of rest, heat and the establishment of adequate drainage are applied. The offending portion of the nail is removed and the nail margin packed away from the skin with cotton. Packing with cotton is continued to form a gutter through which the nail may grow without pressure on the skin. Frequent changes of cotton, application of fungicides and removal of keratotic skin are carried out until the nail has grown past the distal skin margin of the toe. The toenail is then trimmed straight across.

Recurrent episodes of infection are treated by resection of the margin of the nail and destroying the nail bed from which it grows (Fig. 32).

Clavus or Corns of the Toes. Pressure and friction by shoes on the toes produces localized keratotic lesions in the skin called clavus or corns. The lesions occur typically at the flexed interphalangeal joint with claw-toe

Figure 31. The ingrowing toenail is abnormally curved, predisposing to encroachment on the soft tissues at the margin of the nail.

Figure 32. Resection of ingrowing toenail. A, Eponychium incised and reflected to expose the base of the toenail. B, Wedge-shaped resection of the nail and toenail bed. C, The eponychium is closed and the remainder of the wound packed with petrolatum gauze.

deformities. The lateral dorsal surface of the fifth toe is the most frequent site. When pressure and friction are excessive, a small, painful bursa develops beneath the layer of keratotic skin. Eliminating pressure with a soft leather, low-heel shoe with adequate room for the toes may relieve the symptoms. The toes can be straightened if they are clawed. The corn over the lateral aspect of the fifth toe is due to prominence of the lateral condyle of the proximal phalanx. Excision of the bony prominence along with the bursa is usually successful.

HIND FOOT PROBLEMS

Afflictions of the hind foot involve primarily the heel and adjacent structures. Bursitis of the os calcis on the plantar aspect and Achilles tendon posteriorly is a frequent source of pain in the heel. Spurs about the origin of the plantar aponeurosis were at one time thought to be a source of pain. Removal of these spurs seldom gave relief and the procedure is now done infrequently.

Symptoms of bursitis in the plantar surface of the os calcis are localized to that area. Tenderness to pressure and weight bearing is confined to the condyles of the os calcis over which the bursa forms. *Plantar fasciitis producing similar symptoms is more diffuse and follows the course of the plantar aponeurosis into the foot.*

Bursitis about the attachment of the Achilles tendon may be deep or superficial. The deep bursa is located between the upper margin of the os calcis and the tendon. The superficial one lies between the subcutaneous tissue and the insertion of the Achilles tendon. Irritation of these bursae results from pressure of the shoe coupled with a prominent posterior border of the os calcis. Hyperkeratotic skin forms over the protruding bone or bursae. Cracks or blisters in this skin lead

to infection. Reduction of pressure at the inflamed bursa is necessary to bring about relief of symptoms. On the plantar surface, sponge rubber pads are placed in the heel of the shoe to cushion the bursa. Posteriorly, felt pads are placed on each side of the heel to relieve pressure on the Achilles tendon insertion. It is sometimes necessary to cut out the counter of the shoe.

Injection of local anesthetic and compound F into the bursae frequently relieves the inflammation. Surgery is seldom necessary. Excision of the plantar bursa of the os calcis is often followed by the formation of painful scar tissue. Resection of the prominence of bone about the Achilles tendon insertion narrows the os calcis and relieves the pressure.

PARALYTIC DEFORMITIES

Poliomyelitis and other neuromuscular afflictions are the etiologic factors in many disabling deformities of the foot. Since these diseases frequently occur in childhood during the growth period, muscle imbalance and contractures produce profound changes in the foot. Growth disturbance in the paralyzed leg may result in unequal leg length and foot size.

Obviously, countless combinations and grades of muscle weakness and paralysis can take place following poliomyelitis. The major deformities, however, follow the pattern of the cardinal positions of the foot—equinus, calcaneus, varus or valgus (Fig. 33). Combined deformities are usual. The high arch, or cavus, or flatfoot may accompany these deformities. Frequently cavus and equinus or cavus and calcaneus deformities are combined. Pes planus and valgus or cavus and varus occur in combination.

These deformities result from muscle imbalance. The development of deformity follows a pattern. First, dynamic muscle imbal-

Figure 33 A, Equinus position of the foot B, Calcaneus position of the foot C, Varus position of the foot. D, Valgus position of the foot.

ance appears which is exaggerated by use of the part. Static deformities appear accompanied by contractures. Alteration of bone configuration occurs with growth. These changes lead eventually to fixed deformity.

The deformities of the foot may be classified according to the loss of power in the major groups, dorsiflexors, evertors, invertors, intrinsic, and plantar flexor muscles.

As in all paralytic disorders, prevention of deformity by preventing contractures and developing maximum muscle power in the remaining muscle fibers is essential to rehabilitation. Physical medical measures consisting of active exercise, stretching of contracted muscles, supporting braces and corrective shoes are aids in the prevention of deformity. However, when gross muscle imbalance is present, deformities will develop in the growing child and to a lesser degree in the adult. Restoration of muscle balance and power is necessary to correct the deformity and provide maximum function. Often it is impossible to obtain sufficient power from other muscles to effectively substitute for those paralyzed. Stabilization of foot joints to provide a firm, stable base for walking and standing is then necessary. When deformities are established, the deformity must first be corrected, then the foot balanced and stabilized. This may demand stretching of contractures with wedged casts, surgical length-

ening of soft tissues or resection of deformed bones to re-establish proper weight bearing.

Paralysis of Dorsiflexor Muscles. When all of the dorsiflexors of the foot are functionless, i.e., the tibialis anticus and long toe extensors, the foot assumes the equinus position because of the unopposed power of the tri-

Figure 34 Drop-foot brace for paralysis of the dorsiflexors of the foot.

Paralysis of tibialis anticus

Figure 35. A and B, Paralysis of the tibialis anticus muscle with the remaining muscles balanced often produces equinus deformity by contracture of the calf muscles. The extensor longus tendons of the toes produce claw toes and equinus deformity may occur C, To convert the long extensor muscles of the toes to dorsiflexors of the foot, the Achilles tendon is lengthened or stretched. The extensor hallucis longus is transferred to the first metatarsal and the extensor digitorum longus to the base of the middle metatarsal bones or

Figure 36 A, Paralysis of the peroneus longus and brevis allows the tibialis anticus (B) to invert the foot and elevate the first metatarsal bone B, Triple arthrodesis to stabilize the foot is combined with (C) transference of the tibialis anticus to the middle of the tarsal region

Figure 37 A, Paralysis of the invertors—the tibialis anticus and posticus—produces valgus deformity by the action of the peroneal and toe extensor muscles B, Stabilization of the foot by triple arthrodesis, followed by (C) transfer of the peroneal muscles to the middle tarsal region

ceps surae. If the peronei and tibialis posticus are normal, the foot is usually balanced medially and laterally. If the calf muscle group is regularly stretched in walking, fixed equinus may not occur and little deformity is present. In walking, it is necessary to raise the leg higher to clear the ground when swinging the planter flexed foot forward. A lightweight footdrop brace may be all that is necessary to provide a practically normal gait (Fig. 34). If the calf muscle group has been allowed to contract so that a fixed equinus

position of the foot is present, the muscle may be stretched with wedged casts, forcing the foot into dorsiflexion. In exceptional instances it may be necessary to lengthen the Achilles tendon, however, this should be avoided if possible as inevitably some weakness of plantar flexion and push-off in walking results (Fig. 35).

Paralysis of the Evertor Muscles. When paralysis of the peroneus longus and brevis muscles occurs, the primary evertors are lost except for the rather weak evertor action of

the long extensors of the toes. The peroneus longus acts as a depressor of the first metatarsal bone as well as an evertor. The unopposed dorsiflexor inverter action of the tibialis anticus elevates the first metatarsal and inverts the foot. The tibialis posterior inverts and adducts the forefoot. The weak action of the long toe extensors acting as evertors is insufficient to overcome this tendency and the foot gradually assumes the position of varus of the heel, adduction of the forefoot and elevation of the first metatarsal. The great toe flexes in an attempt to contact the floor. With growth, the bones adapt to this position and the deformity becomes fixed (Fig. 36A).

The foot may be balanced by transferring the tibialis anticus tendon from the normal insertion on the cuneiform first metatarsal to a more lateral position on the dorsum of the foot in the middle or lateral cuneiform or the second or third metatarsal. The strong inverter action is thus eliminated and, when done early, may be all that is required. If deformity of the bones and marked contraction of the soft tissue on the medial side of the foot are present wedge resection of the bone with triple arthrodesis of the talonavicular, calcaneocuboid joints and the subtalar joints may be necessary, reshaping the foot to a normal weight-bearing position (Fig. 36B and C).

Paralysis of the Inverter Muscles. Paralysis of the tibialis anticus and posticus mus-

cles allows overaction of the peroneals, forcing the foot into valgus or eversion (Fig. 37A) with complete loss of the longitudinal arch and a completely flat foot with an everted heel (Fig. 33D). If the calf muscle is allowed to contract, an equinovalgus deformity develops. If the long extensor tendons of the toes are lost, dorsiflexion of the foot is lost as well. The peroneus longus and brevis may be transferred to the dorsum of the foot to remove the deforming evertor action and to produce dorsiflexion of the foot (Fig. 37B and C). Since medial and lateral stability is lost, triple arthrodesis is necessary to stabilize the foot or to correct fixed deformity. If the foot is in equinus, this must first be corrected by wedged casts or Achilles tendon lengthening.

Paralysis of the tibialis anticus with normal posterior tibial and peroneals and strong long toe extensors may result in a cavovarus deformity. In this instance, the tibialis posterior may prevent the valgus deformity of the heel. The peroneus longus depresses the first metatarsal and the extensor hallucis longus forces the toe into cock-up position, further depressing the first metatarsal. A paradoxical situation arises; dorsiflexion of the foot causes the foot to evert through the action of the long extensors of the toes. However, on weight bearing the fixed depression of the first metatarsal head forces the foot into varus position.

Transferring the long extensor of the great

Figure 33. Prolonged equinus position of the foot either secondary to paralysis or clubfoot produces a flat tibiotalar articulation. This deformity of the bone prevents dorsiflexion.

Figure 36 A, Paralysis of the peroneus longus and brevis allows the tibialis anticus (B) to invert the foot and elevate the first metatarsal bone. B, Triple arthrodesis to stabilize the foot is combined with (C) transference of the tibialis anticus to the middle of the tarsal region.

Figure 37 A, Paralysis of the invertors—the tibialis anticus and posticus—produces valgus deformity by the action of the peroneal and toe extensor muscles. B, Stabilization of the foot by triple arthrodesis, followed by (C) transfer of the peroneal muscles to the middle tarsal region.

ceps surae. If the peronei and tibialis posticus are normal, the foot is usually balanced medially and laterally. If the calf muscle group is regularly stretched in walking, fixed equinus may not occur and little deformity is present. In walking, it is necessary to raise the leg higher to clear the ground when swinging the planter flexed foot forward. A lightweight footdrop brace may be all that is necessary to provide a practically normal gait (Fig. 34). If the calf muscle group has been allowed to contract so that a fixed equinus

position of the foot is present, the muscle may be stretched with wedged casts, forcing the foot into dorsiflexion. In exceptional instances it may be necessary to lengthen the Achilles tendon; however, this should be avoided if possible as inevitably some weakness of plantar flexion and push-off in walking results (Fig. 35).

Paralysis of the Evertor Muscles. When paralysis of the peroneus longus and brevis muscles occurs, the primary evertors are lost except for the rather weak evertor action of

the long extensors of the toes. The peroneus longus acts as a depressor of the first metatarsal bone as well as an evertor. The unopposed dorsiflexor invertor action of the tibialis anticus elevates the first metatarsal and inverts the foot. The tibialis posterior inverts and adducts the forefoot. The weak action of the long toe extensors acting as evertors is insufficient to overcome this tendency and the foot gradually assumes the position of varus of the heel, adduction of the forefoot and elevation of the first metatarsal. The great toe flexes in an attempt to contact the floor. With growth, the bones adapt to this position and the deformity becomes fixed (Fig. 36A).

The foot may be balanced by transferring the tibialis anticus tendon from the normal insertion on the cuneiform first metatarsal to a more lateral position on the dorsum of the foot in the middle or lateral cuneiform or the second or third metatarsal. The strong invertor action is thus eliminated and, when done early, may be all that is required. If deformity of the bones and marked contracture of the soft tissue on the medial side of the foot are present wedge resection of the bone with triple arthrodesis of the talonavicular, calcaneocuboid joints and the subtalar joints may be necessary, reshaping the foot to a normal weight-bearing position (Fig. 36B and C).

Paralysis of the Invertor Muscles. Paralysis of the tibialis anticus and posticus mus-

cles allows overaction of the peroneals, forcing the foot into valgus or eversion (Fig. 37A) with complete loss of the longitudinal arch and a completely flat foot with an everted heel (Fig. 33D). If the calf muscle is allowed to contract, an equinovalgus deformity develops. If the long extensor tendons of the toes are lost, dorsiflexion of the foot is lost as well. The peroneus longus and brevis may be transferred to the dorsum of the foot to remove the deforming evertor action and to produce dorsiflexion of the foot (Fig. 37B and C). Since medial and lateral stability is lost, triple arthrodesis is necessary to stabilize the foot or to correct fixed deformity. If the foot is in equinus, this must first be corrected by wedged casts or Achilles tendon lengthening.

Paralysis of the tibialis anticus with normal posterior tibial and peroneals and strong long toe extensors may result in a cavovarus deformity. In this instance, the tibialis posterior may prevent the valgus deformity of the heel. The peroneus longus depresses the first metatarsal and the extensor hallucis longus forces the toe into cock-up position, further depressing the first metatarsal. A paradoxical situation arises; dorsiflexion of the foot causes the foot to evert through the action of the long extensors of the toes. However, on weight bearing the fixed depression of the first metatarsal head forces the foot into varus position.

Transferring the long extensor of the great

Figure 38. Prolonged equinus position of the foot either secondary to paralysis or clubfoot produces a flat tibiotalar articulation. This deformity of the bone prevents dorsiflexion.

CALCANECAVUS DEFORMITY

Figure 39 A, Paralysis of the triceps surae muscles prevents active plantar flexion. Unopposed dorsiflexor muscles pull the foot into dorsiflexion. The long and short muscles of the plantar aspect contract to compensate for the triceps surae in walking and produce cavus deformity. B, The deformity of the os calcis and midtarsal bones is corrected and the foot stabilized by triple arthrodesis. C, The tibialis posterior tendon and the peroneal tendons are transferred to the os calcis to provide limited plantar flexion and counteract the deforming pull of the plantar muscles.

toe to the neck of the first metatarsal helps to elevate the metatarsal and eliminates the dorsiflexion of the toe. Transfer of the peroneus longus tendon to the dorsum of the foot in the region of the base of the second metatarsal eliminates the depressor effect on the first metatarsal and aids in dorsiflexion.

Intrinsic Muscle Paralysis of the Foot. Cavus deformity with claw toes may be produced by intrinsic paralysis of the muscles of the foot. Loss of the lumbricales and interossei and short flexors of the toes, which normally produce extension of the interphalangeal joints, allows hyperextension of the toes at the metatarsal-phalangeal joints and the long flexors of the toes produce flexion of the interphalangeal joints. This deformity depresses the metatarsal heads and, coupled with soft tissue contracture of the plantar structures, cavus deformity results.

Before fixed bony deformity develops, transfer of the long extensor tendons to the necks of the metatarsals eliminates the dorsiflexion of the toes and aids in elevation of the metatarsal heads. Interphalangeal joint fusion of the great toe is usually necessary to prevent excessive plantar flexion at this joint. Plantar fasciotomy may be necessary to correct a mild cavus deformity. Often coupled with this defect is insufficiency of the tibialis anticus, producing an equinovarus deformity. The calf muscles or Achilles tendon

Figure 40. Weight-bearing x-ray of calcanecavus foot. The os calcis is vertical and the forefoot relatively plantar flexed. Toes are contracted.

longus is transferred to the base of the third metatarsal to produce greater dorsiflexion power.

When fixed cavus deformity has occurred, dorsal wedge section through the cuneiform-navicular joints and through the body of the cuboid is demanded. The high arch is further depressed by plantar displacement of the distal lever of the foot.

Paralysis of the Plantar Flexor Muscles. Paralysis of the triceps surae, or calf muscle group, produces one of the most serious disabilities in the growing child—the calcaneus or calcanecavus foot (Fig. 39A). In bilateral paralysis, which may occur in poliomyelitis or spina bifida with myelodysplasia, the disability may be previously

pointed out, the forward sway of the body in balancing while standing is counteracted by the strong calf muscles. When paralysis of this muscle group takes place, this effect is lost and these people cannot balance well without external support. When walking, the normal push-off is lost and the foot is forced into dorsiflexion. When the pull of the triceps surae is lost on the growing calcaneus, the unopposed intrinsic muscles of the foot along with the plantar aponeurosis and the flexors of the toes tend to approximate the heel toward the metatarsal heads (Fig. 40). The os calcis grows vertically, producing an abnormally high arch. The weight-bearing surface of the heel becomes a peg and provides less bearing surface. Valgus or varus of the heel may also be coupled with the deformity when there is weakness of the invertors or evertors.

Since the calf muscle group is more powerful than all of the other long muscles to the foot combined, it is almost impossible to reproduce normal plantar flexion power by tendon transference to the heel. However, every effort should be made early in the development of the deformity to prevent progressive changes.

Long-leg braces should be used to prevent hyperextension at the knees, and a checkrein at the ankle should be incorporated in the brace to prevent excessive dorsiflexion. Plantar fasciotomy may lessen the pull on the metatarsals and os calcis and lessen the bowstring effect. Early transfer of available active muscles to the os calcis is essential. When the peroneals and posterior tibial are normal, they may be transferred to the os calcis and the foot will remain balanced medially and laterally and the forefoot depression is lessened (Fig. 39B and C). If maximum power is required, the tibialis anticus may be transplanted posteriorly into the heel through the interosseous membrane. If the calf muscle group is completely paralyzed, the transferred muscles will not produce enough power to allow tiptoe walking; however, they tend to counteract the vertical growth of the os calcis and eliminate some of the excessive dorsiflexion power. Practically all feet affected with this deformity require some bone correction, either dorsal wedge section to correct the forefoot drop or triple arthrodesis with removal of appropriate bone wedges to correct the deformity and stabilize the foot. The bone procedures must await the time when the foot is more mature and are seldom done before the patient is ten or twelve years of age.

When the foot is completely flail, there is little tendency to progressive or fixed deformity other than flatfoot. To secure a stable base for walking or standing, it may be necessary to arthrodese the ankle joint along with the subtalar and calcaneocuboid and talonavicular joints.

Spastic Paralytic Deformities. Spastic paralysis of the lower extremity may produce changes in the foot similar to those enumerated above. However, the most frequently encountered deformity is equinus due to spasticity and contracture of the calf muscle group. Tendon transference in spastic paralysis is much less useful than in flaccid paralysis, as normal muscles are usually not available to transfer and the deformities result from overactive abnormal muscles.

Lengthening of contracted muscles and soft tissues is useful, either by stretching casts or by surgical lengthening of tendons or section of fascia and soft tissue. Occasionally a deforming muscle pull may be weakened by partial denervation of the muscle. The often encountered equinus deformity tends to be recurrent, particularly during periods of rapid growth. The use of splints worn at night is helpful in preventing the deformity. These splints hold the foot in dorsiflexion, preventing contracture of the calf muscle. Gait training is essential. The child is taught the importance of making the heel contact the ground in walking.

If the deformity progresses, wedged and stretching casts are useful. The stretching cast is applied below the flexed knee with the foot in maximum dorsiflexion. An anterior heel is incorporated in the cast. When the knee is straightened in walking, the gastrocnemius muscle originating on the femoral condyles is stretched. If the soleus muscle is not excessively contracted, this method of treatment will re-establish dorsiflexion in walking. However, the procedure must be repeated as the child grows. If excessive spasticity of the calf muscle group prevents maintenance of the corrected equinus, neurectomy of the motor nerves to the gastrocnemius muscle is done in the popliteal space. This lessens the power of the muscle group and may prevent recurrence of the equinus. When the equinus recurs after this procedure, the musculotendinous junction of the triceps surae is lengthened. This procedure consists in making chevron-like incisions on alternate medial and lateral aspects of the junction of the Achilles tendon and the muscle, thus lengthening the muscle as well as the tendon.

If the Achilles tendon alone is lengthened,

a small misshapen calf muscle results and muscle function is lessened.

Flatfeet are frequently encountered with the short, contracted calf muscle group. Orthopedic shoes with rigid extended counters tend to preserve the arch after overcoming the contractures. Rarely, triple arthrodesis may be required to correct excessively deformed flatfeet.

OSTEOCHONDRITIS

Osteochondritis of the growing foot occurs usually in three locations—the second metatarsal head, the navicular bone and the apophysis of the calcaneus. The etiology of the condition is not clear, but the progressive changes noted in x-ray examinations of the bones suggest interference with the blood supply of the bone with necrosis, followed by substitution of new bone. Local metabolic, toxic or traumatic factors may have a place in the etiology of the disturbance. The osteochondritic lesions occur during the periods of rapid growth between four and thirteen years of age in the case of the calcaneal apophysis and navicular bone, and near the age of closure of the epiphysis at

the involved bone. The onset of symptoms may be acute or gradual and the disease is self-limited but may be symptomatic for weeks to months.

X-ray findings are irregular density of bone, fragmentation and at times abnormal growth of bone.

When the condition occurs in the region of the second or third metatarsal head, it is called Freiberg's infraction. The symptoms are pain and swelling about the involved joint, particularly at the push-off phase of the step. Enlargement of the head and distal shaft of the bone, flattening and widening of the joint surface, irregularity of the epiphysal plate and increased joint space between the proximal phalanx of the toe and the metatarsal head characterize the lesion. Degenerative arthritic changes in the joint occur later and may produce symptoms in adult life.

During the acute, painful stage of the disease, weight bearing should be relieved with crutches. Hot packs to the foot may be applied several times daily. Usually the acute distress is of short duration—a week or two. Following relief of the acute pain and swelling, the foot should be fitted to a stiff-shank, low-heel shoe with a stiff leather sole to pro-

tect the metatarsal head. A felt pad is placed in the shoe just back of the metatarsal head to relieve pressure on the head and joint and a transverse metatarsal bar is placed on the sole of the shoe.

Alteration of growth of the metatarsal joint surface may lead to chronic degenerative arthritic changes in adult life which, if not relieved by pads and arch supports, may require resection of the proximal third of the phalanx of the toe to form a painless pseudarthrosis. Excess bone about the head of the metatarsal may be removed at the same time if the bone is prominent.

When the condition occurs in the navicular bone, it is termed Kohler's disease and is found between the ages of four and ten years. Pain and swelling about the navicular bone on weight bearing are the usual symptoms. Non-weight bearing during the acute phase may be necessary; however, the symptoms are usually mild and padding the shoe with felt may relieve the strain on the longitudinal arch.

X-ray studies reveal a progressive narrowing of the navicular bone between the talus and cuneiform bones. The bone increases in density and may project dorsally above the level of the adjacent bones. Substitution of bone takes place slowly, but in several years the navicular bone is usually completely restored with little, if any, residual deformity.

Calcaneal apophysitis occurs in the apophysis of the os calcis (Fig. 41). Pain is present at the prominence of the heel on weight bearing and about the attachment of the Achilles tendon. The symptoms frequently appear between the ages of seven and thirteen years. X-rays show increased density of the calcaneal apophysis with fragmentation and irregularity of the epiphysal plate. Non-weight bearing with crutches may

Figure 41. Osteochondritis of the apophysis of the calcaneus.

be necessary for several weeks, followed by limited weight bearing with a built-up heel and sponge rubber pad in the shoe to lessen the pull of the Achilles tendon and to cushion the heel. Healing takes place over several months with no residual deformity.

ARTHRITIS

Rheumatoid arthritis, gout and osteoarthritis may affect the foot in varying degrees. Rheumatoid arthritis and gout affect peripheral joints characteristically. The toes and metatarsophalangeal joints are frequently affected, however, any and all parts of the foot may be involved. Osteoarthritis may be found in the first metatarsophalangeal joint secondary to trauma or hallux valgus, but the disease frequently involves the midtarsal area and the subtalar joint. During the acute phase of rheumatoid arthritis, the inflammatory process may be confined to the interphalangeal joints or may progressively affect the metatarsophalangeal joints, the midtarsal, subtalar and ankle joints. The tissues swell and there is increased local heat. Weight bearing is often impossible. Frequently the heel pad becomes painful over the plantar aspect and about the margin of the heel. The plantar fascia may become tender, as may the Achilles tendon. Rheumatoid nodules may form over the dorsum of the foot in the bunion areas about the heel and occasionally on the plantar aspect of the foot. Bursae filled with fibrin-flecked yellow, cloudy fluid may form over the metatarsal heads. Later in the course of the disease, debris and fibrin may form cottage cheese-like deposits in these bursae. As the disease progresses the joint surfaces are destroyed by a synovial pannus and fibrous ankylosis may take place in the joints of the foot and toes. Contractures of the toes may develop early. The usual deformity is one of dorsal dislocation and hyperextension of the proximal phalanx and flexion of the interphalangeal joint. All of the toes may deviate laterally. As the subtalar joint is destroyed, lateral motion is lost and the foot becomes more rigid. Destruction of the joint capsules and loss of elastic tissue in the ligaments may lead to flatfoot deformity. When the toes contract, the metatarsal heads become prominent in the sole of the foot and the fat pad in the ball of the foot atrophies. Weight bearing then results in callous formation over these areas of pressure.

During the acute phase of the disease, the patient is placed at bed rest and no weight bearing is allowed. Since contractures de-

velop early, equinus deformity is prevented by placing a padded footboard at the bottom of the bed. The weight of the bed clothing is removed from the feet and the feet are kept in neutral position with the sole of the foot supported by the board. Often the heels are tender and pain is produced when they are resting on the mattress. A small pillow under the calf of the leg lifts the heel off the mattress and relieves the pressure. Hot, moist packs applied several times a day for one hour help relieve the pain and prepare the feet for mild active exercise. Muscles atrophy rapidly in rheumatoid arthritis and joints tend to stiffen quickly. To minimize this, the patient is instructed in active exercise of the foot without weight bearing. The toes should be flexed and extended, the foot inverted and everted and plantar flexed and dorsiflexed several times following use of the hot packs. Vigorous massage, whirlpool baths and stretching aggravate the condition and should not be employed during the acute phase of the disease. Administration of steroid and salicylate drugs and the general supportive measures for the treatment of rheumatoid arthritis should be started.

When the pain, heat and swelling subside, weight bearing may be started on a very restricted schedule, walking only a few minutes of each hour or several times a day. A low-heel, well-fitted Oxford must be used, not a soft bedroom slipper, as the weakened ligaments demand support. Usually, rigid arch supports and metatarsal bars are not tolerated. Felt pads placed in the shoe and occasionally a foam-rubber insole help to support the arches and cushion the weight-bearing surface of the foot.

Rheumatoid nodules and bursae may be excised if they persist and are subject to pressure. Injection of compound F into joints and bursae has been disappointing.

When deformities have occurred, they usually involve the forefoot. If relief of contracted toes and plantar calluses is not obtained with arch supports, operative correction becomes necessary. Since the joint surfaces are destroyed, the extensor tendons of the toes contracted and the metatarsal heads prominent, the proximal phalanx of the lateral four toes is resected. This allows the toes to fall into a more normal position and shoes can be fitted more comfortably. The Keller type resection of the proximal third of the proximal phalanx will relieve pain in the metatarsal-phalangeal joint. The prominent metatarsal heads are shaved flat, parallel to the plantar surface of the foot. This

converts the rounded marble-like head into a flat spatula. Adjacent remaining fat tends to cover the partially resected bone and a fairly effective cushion at the ball of the foot is re-established. Arthrodesis of other painful joints may be done. Following operative correction of deformities, an adequate supporting low-heel Oxford with transverse and long flexible arch supports should be used permanently.

OSTEOARTHRITIS

Osteoarthritis frequently follows trauma to the joints of the foot. The trauma may be massive, producing fractured joint surfaces, or it may be minimal and often-repeated, occurring with abnormalities of weight bearing. The degeneration of cartilage and the production of osteophytes about the margins of the joint is a slow process and symptoms may not develop in the foot until the changes are far advanced or the foot is suddenly traumatized or strained by unusual activity. Pain is often confined to one joint. The subtalar joint following fracture of the os calcis is frequently the site of painful osteoarthritis. The great toe joint degenerates in time when hallux valgus or rigidus is present. Pain usually is produced by chronic synovitis secondary to the destruction of joint surfaces. When acute synovitis is present, rest, heat and elevation of the foot are necessary and weight bearing should be eliminated. Usually the symptoms subside quickly. The foot is then fitted with a supporting Oxford with appropriate arch supports. If the foot is flat and fairly rigid because of the joint changes, radical raising of the arch should not be attempted. Fixed joints do not tolerate extensive position changes. Pads should be built

pain for varying periods. Salicylate drugs are helpful.

Occasionally, arthrodesis of the subtalar joint is necessary in the younger patient with adequate circulation. Extensive operative procedures in the elderly are not warranted. The Keller bunionectomy is useful for relief of the damaged metatarsophalangeal joint of the great toe.

GOUT

Gout is a metabolic disturbance of uric acid metabolism. Greater amounts of uric acid are formed in the body periodically. Attacks of acute arthritis develop. The metatar-

sophalangeal joint of the great toe is a characteristic area for the lesion. The sudden pain, heat, redness and swelling resemble cellulitis, and fever and leukocytosis may add to the confusion. The serum uric acid level should be determined to confirm the diagnosis. The pain is intense and weight bearing is impossible. The maximum area of tenderness is usually along the medial side of the joint. The discoloration has a cyanotic tone rather than the brighter red of infection. Symptoms subside rapidly with use of colchicine and uricosuric agents and little, if any, residual change remains. Ten per cent of patients who have gout have deposits of urates in the skin, subcutaneous tissue, tendons, ligaments, bones and joints. These tophi are destructive. Severe crippling of the foot can take place if the disease is inadequately treated. Proper therapy to prevent destruction by tophi demands the routine continued use of uricosuric agents. These drugs increase excretion of uric acid by blocking tubular resorption in the kidney. The most effective agent at present is probenecid although salicylates have long been used. Colchicine is an ancient drug, specific for relief of pain in gout; however, it has no effect on the serum uric acid level. The two drugs should be combined in the management of gout.

When tophi form in the foot, they should be removed surgically when they cause pressure, interfere with tendon movement, ulcerate or destroy bones, joints and tendons (Fig 42). Because the deposits of urate are infiltrative, special surgical techniques are required to preserve vital structures.

Figure 42. Chronic tophaceous gout. Massive deposits of uric acid cause deformity and pain from Tophaceous Gout, by W. R. Latham and J. A. J. Bone & Joint Surg Vol 40-A, pp 743-772, July, 1958)

LEDDERHOSE'S DISEASE

Dupuytren's contracture of the hand is a familiar affliction. Contracture of the palmar fascia with the formation of nodules and cords producing fixed flexion of the fingers is well known. Microscopically the fascia is more cellular than normal with increased collagenous elements. A similar affliction occurs in the plantar fascia of the foot and may be associated with the Dupuytren's disease of the hand. The condition in the foot is called Ledderhose's disease. Painful nodules develop in the plantar fascia of the foot. The nodules slowly increase in size and pain on weight bearing is complicated by burning pain at rest, particularly at night. The disease must not be confused with Volkmann's ischemic contracture of the foot or the fibrous contractures which follow cast immobilization for fractures of the lower extremities. These conditions may produce tight plantar fasciae and deformed toes, but the nodules typical of Ledderhose's disease do not develop.

The plantar fascia should be resected when the painful masses do not spontaneously regress. The fascia may be excised through a medial plantar incision, avoiding the weight-bearing areas of the sole of the foot. Weight bearing must be delayed until the wound is completely healed to avoid excessive scar formation—usually three weeks.

TUMORS OF THE FOOT

Tumors of the foot are uncommon lesions when compared to the many other lesions which affect the foot. The classification of tumors of the hand applies equally well to the foot with the exception of irradiation carcinoma. This lesion in the foot usually follows excessive radiation in the therapy of plantar warts but is of rare occurrence. Tumors of the foot usually demand attention when they occur on the weight-bearing surface of the foot and produce pain. When they occur on the dorsum of the foot or produce enlargement of the foot, shoe fitting is difficult.

The principles of treatment are similar to those in the hand. However, there are several differences. The plantar, or weight-bearing skin of the foot must be avoided in the excision of tumors of the foot, to prevent painful scars. If radical excisions are necessary which involve supporting ligaments, tendons or bone, stabilization of the foot by appropriate arthrodesis may be necessary.

Partial amputations for tumors of the foot must preserve adequate balance and painless weight bearing. If this cannot be done,

amputation at a higher level in the leg is mandatory.

INFECTIONS

Infections in the foot, fortunately, are usually superficial and may be caused by *Streptococcus*, *Staphylococcus*, fungus or other inhabitants of the skin. Deeper infections of the fascial spaces, tendon sheaths and bones and joints are uncommon. The plantar skin is thick and affords good protection for the deeper structures, except in the case of penetrating wounds or from extension of infection from the toes.

The most common source of infection is from blisters, bursae, corns or ingrowing toenails. Blisters usually occur over the heel near the insertion of the Achilles tendon or at the dorsum of the toes, from friction of shoes or tight stockings.

Bursae over the first and fifth metatarsal heads secondary to corns, may become infected through cracks in keratotic skin. Usually the infections are localized; however, infection in the toes may drain through the lymphatics of the superficial dorsal tissues of the foot, creating spreading cellulitis and lymphangitis. Infections about the heel drain through lymphatics on the posterior aspect of the leg to the popliteal lymph nodes. The cardinal signs of infection—heat, redness, swelling and pain—are present. Since the skin is loosely applied to the dorsum of the foot, any infection in the foot may produce swelling over the dorsum.

Weight bearing must be eliminated immediately. The foot should be elevated, and warm, moist, sterile packs applied. The foot should be splinted with a well-padded, molded, metal splint. Excessive heat should not be applied, particularly in the elderly when vascular impairment may be present. In a leg and foot with considerable arterial insufficiency, excessive heat may precipitate gangrene. If a wound or lesion is open, a culture should be obtained and sensitivity tests made for the various antibiotic drugs. If the infection is spreading after the culture is obtained, broad-spectrum antibiotics may be administered until the specific antibiotic is determined by the sensitivity tests. The wounds should be dressed as often as necessary to maintain cleanly care and remove toxic bacterial products.

When the infection originates in a paronychia (Fig. 43) or ingrowing toenail, adequate drainage may be instituted by incision through the eponychium and removal of the offending portion of nail.

If an abscess develops on the dorsum of

Figure 43 Paronychia of great toe.

the foot, it should be incised through a longitudinal incision and the wound packed open with moist gauze, and the warm, moist, sterile saline packs and splinting continued. When the drainage has stopped and necrotic tissue separated, the wound may be allowed to close.

Occasionally the deeper tissues may be involved. Infection introduced through puncture wounds in the sole of the foot or spreading along the tendons from the toes involves the fascial spaces of the foot. Pus may accumulate beneath the plantar aponeurosis or in the deep median, central or lateral plantar fascial spaces located between the short plantar muscle groups. Incision and drainage of this area of the foot are done either medially or laterally at the junction of plantar and dorsal skin. Incisions should never be made through the plantar skin or from the dorsum of the foot for drainage of the deep spaces. Incisions through plantar skin usually leave a painful scar in a weight-bearing area and adequate drainage cannot be secured through the dorsal approach, thus resulting in a chronic draining sinus.

Occasionally a collar button-like abscess originates in a plantar callus or wart. The infection forms a localized collection of pus beneath the adjacent metatarsal head or may burrow between the metatarsal heads to produce swelling on the dorsum. Pyogenic arthritis involving the metatarsophalangeal joint or osteomyelitis invading the metatarsal shaft and head may occur. This is a serious complication which usually demands surgical drainage and occasionally excision of the

affected joint and metatarsal head. The approach is through the web space where blunt dissection is carried out until the abscess is evacuated. In chronic draining osteomyelitis or pyogenic arthritis, the metatarsal head and joint may be excised by extending the incision onto the dorsum of the foot. The wound may be partially closed and a drain inserted in the web space for seventy-two hours. The original wart or callus is treated locally.

Osteomyelitis may be of pyogenic, fungus or tuberculous origin. Whenever possible, the organism must be identified. Pyogenic osteomyelitis is treated as elsewhere in the body. Rest and splinting of the part and massive doses of appropriate antibiotics are used. Saucerization of involved bones may be nec-

fusion takes place. Therefore it is essential to maintain the foot in weight-bearing position while treating the infection. This may be done with splints or casts.

Tuberculous arthritis and osteomyelitis involving the foot are extremely serious, as are the fungus infections. Before the advent of antibiotic therapy and chemotherapy appropriate for these infections, amputation was the usual result. The outlook is now more hopeful with the availability of these drugs. However, the old principle of immobilization in tuberculosis still applies. Cast fixation may be necessary with non-weight bearing for many months and surgical fusion of infected joints may be necessary to permanently arrest the lesion.

Superficial skin infections in the foot are commonly caused by fungus or yeast organisms. The condition is known as dermatophytosis (Fig 44). The common causative organisms are the *Epidermophyton*, *Trichophyton* or *Candida albicans*. These organisms are normal inhabitants on the skin. They require moisture, warmth and an alkaline medium for growth. In the presence of these conditions and lowered resistance of the skin, infection can take place. A frequent area of invasion is between the toes, particularly the fourth and fifth toes which fit closely together, and the plantar surface of the foot and toes. The lesions produce maceration between the toes in which cracks may occur, allowing secondary invading bacteria to cause spreading cellulitis. Lesions on the plantar aspect may resemble the lesions of ringworm or they may be vesicular, filled with clear or milky fluid. Occasionally nu-

Figure 44 Epidermophytosis of the feet, lesions about the toes and plantar aspect of the foot with deformity of the toenails

merous small lesions coalesce or large bullous lesions develop. The bullae may rupture, followed by crusting and peeling of the superficial layers of the skin. The disease tends to be chronic or recurrent.

Treatment is directed at cleanly care of the feet, reduction of moisture, conversion of the alkaline to an acid medium and the use of fungicides.

The feet should be washed daily and dried thoroughly. Application of undecylenic acid compounds night and morning changes the skin to an acid medium. Nystatin, a potent fungicide, may be applied daily in resistant infections. Allowing the shoes to dry thoroughly by changing shoes daily reduces the moisture content. Clean stockings should be used daily.

VASCULAR DISEASE OF THE FOOT

When peripheral vascular disease is known to be present, prophylaxis of complicating lesions in the foot should be the concern of the surgeon as well as the patient. Since the foot is the farthest point in the area of the peripheral circulation, manifestations of failure or impairment may occur early or be precipitated by acute failure.

The primary objective of prophylactic measures is the prevention of pressure and friction, exceeding the circulatory capacity, avoidance of excessive heat or cold. All of these factors may precipitate circulatory failure. Trauma is an important factor. Trim-

ming toenails or calluses to the point where the skin is damaged may permit bacteria to invade the tissues, increasing circulatory demands through infection and thus precipitating gangrene.

Toenails must be kept free from debris under the margins. Lubricating the skin with lanolin prevents the accumulation of keratotic skin which may crack or cause pressure on the underlying skin with necrosis. Careful removal of this material with an orangewood stick is helpful. Trimming the nails so that they do not grow in is important. Calluses and corns must be carefully trimmed. When the skin is broken by excessive or careless trimming, infection frequently supervenes in the devitalized tissues. Pumice stone or an emery board may be used carefully to reduce the thickness of calluses and corns. Salicylic acid should not be used as the devitalizing effect on already impaired tissues may allow infection to develop. The shoes and stockings should be carefully fitted to prevent friction and pressure. Excessive moisture and drying should be counteracted by appropriate measures.

PHYSICAL MEDICINE AND REHABILITATION

By LOUIS B. NEWMAN, M.D.

LOUIS BENJAMIN NEWMAN was interested in electrical currents as a high school student when he was sure he wished to be a doctor. Graduating from the Illinois Institute of Technology in Mechanical Engineering, he spent several years in research upon high frequency currents. He received his doctor of medicine degree from Rush Medical College and has devoted himself to the development of the relatively new specialty of physical medicine. He has had wide experience and has made many contributions to the development of his chosen field.

INTRODUCTION

Manpower is our greatest resource and must be well conserved. Physical medicine and rehabilitation, as part of total medical management, is dedicated toward the objective of maximum rehabilitation of all those disabled from disease or injury. All methods and means of helping man help himself must be used to bring him back to maximum usefulness whenever a disability exists. Physical medicine and rehabilitation properly integrated and coordinated with all of the available medical and other professional services can, through effective diagnostic and therapeutic procedures combined with clinical and basic research, reduce to a minimum the handicap associated with disability. All trained individuals are needed to aid in this tremendous job—a job having the many physical and mental complexities associated with illness. No final word has been or will be

written regarding either diagnosis or treatment

The scope and need for rehabilitation is broad and ever expanding because of the increase in disease and injury associated with a longer life span and through accidents related to home, industry, various means of transportation and others. There must be a clear, realistic awareness and understanding on everyone's part of the value and benefits derived from rehabilitation, including overcoming the psychologic and emotional problems always associated with disease or injury and with hospitalization. The philosophy of the specialty of physical medicine and rehabilitation of early intensive medically prescribed therapy for a sufficient time to meet the specific needs of the sick is basic.

The success of the rehabilitation program which endeavors to return the maximum number of disabled individuals to productive

living in industry, business and the home depends to a great extent on selective job placement. The patient's over-all physical and mental abilities must be carefully matched with the over-all physical and mental job requirements. In this way he returns to his community as a useful productive member with a satisfactory measure of happiness and contentment.

DEFINITION AND SCOPE

Physical medicine and rehabilitation is part of the total medical care of the sick and includes the diagnosis of, prescribing for and treatment of disease, defect or injury by the use of physical means and restoration to the fullest physical, mental, social, vocational and economic usefulness possible.

All activities are medically prescribed by the physiatrist (physician specializing in physical medicine and rehabilitation). In order to achieve maximum benefits for the patient, a program closely integrated and coordinated with all of the other medical and paramedical services is essential. Full cooperation and planning among the physiatrist, internist, neurologist, neurologic surgeon, orthopedist, urologist, plastic surgeon, psychiatrist, the various therapists, nurse, psychologist, social worker, vocational counselor, recreational technician and others are fundamental. The Physical Medicine and Rehabilitation Service, as established in the Veterans Administration, consists of the physiatrist, rehabilitation coordinator, physical therapist, corrective therapist, occupational therapist, manual arts therapist, education therapist, speech therapist, and blind rehabilitation therapist. The Armed Forces as well as some of the civilian rehabilitation institutions have somewhat similar organizations.

The general objective of all treatment of physical and mental disabilities resulting from disease or injury is restitution of maximum function and an achievement of realistic vocational goal.

Physical therapy: Medically prescribed diagnostic and therapeutic procedures utilizing heat, cold, hydrotherapy, ultraviolet and ultrasound radiation, various forms of electricity and therapeutic exercise.

Corrective therapy: The application for therapeutic purposes of medically prescribed activities of an exercise and self-care nature in all types of disabilities.

Occupational therapy: Medically prescribed kinetic, metric, tonic and psychiatric therapy utilizing primarily hand- and foot-operated tools in such activities as ceramics,

lapidary, jewelry making and leather tooling.

Manual arts therapy: Therapeutic and exploratory medically prescribed activities through the use of hand- and power-driven tools and equipment in woodworking, mechanical drawing, radio and electronics, photography, etc.

Educational therapy: Medically prescribed treatment to aid in exploring patients' interests, promote resocialization, improve the educational levels and increase work capacity by the utilization of academic commercial and technical studies.

Speech therapy: Medically prescribed therapy for disorders in language and communication, including esophageal voice training following laryngectomy, the training of aphasic patients, such as those seen after a cerebrovascular accident, for recovery of receptive and expressive language capacities and for the improvement of impairments of abstract ability, concept formation, calculation ability, reading ability and memory patterns.

Blind rehabilitation therapy: Medically prescribed treatment for the blinded to aid in reorganizing and adjusting their lives toward maximum usefulness through such activities as eating, walking, grooming, reading and writing braille, the use of office and industrial machines and many other daily living accomplishments.

The disabled person's residual potential abilities must be recognized early and through physical medicine and rehabilitation enhanced to the fullest capacity. As soon as it is medically feasible, a patient should receive physical medicine and rehabilitation judiciously prescribed to meet his specific needs which must include psychologic and social aid in adjusting to his disability and hospitalization.

Physical medicine and rehabilitation can be considered to consist of three phases or stages, not entirely distinct from each other but overlapping to a degree and having continuity. These phases are (1) preventive, (2) definitive and (3) maintenance.

1. Preventive rehabilitation. As long as there is no medical contraindication, preventive rehabilitation can be started even in an unconscious patient by instituting proper positioning in bed, the use of splints and passive movements of the extremity through full range of joint motion in order to prevent contractures and deformities and to aid circulation.

2. Definitive rehabilitation specific medi-

cally prescribed rehabilitation procedures are instituted to enhance function so the patient can perform the maximum possible number of self-care activities. It is no longer necessary to wait until the patient can be taken out of his bed. Treatment can be accomplished at the bedside and later continued in the clinic.

3 Maintenance rehabilitation. When maximum rehabilitation has been attained, certain therapeutic procedures should be continued so that the patient can at least maintain his accomplishments and not regress. For example, if the patient is able to feed himself and ambulate, then these activities should be continued. Frequently, continuation of maintenance activities by the patient is impossible in certain progressive disorders.

The various physical and other effective properties of ultraviolet and radiant energy, heat, cold, water, electricity, ultrasound radiation, massage, therapeutic exercise and mechanical devices are employed for both diagnosis and treatment. A rehabilitation objective must be established, including both hospital and posthospital planning. Post-hospital follow-up will usually enhance and prolong the beneficial effects of the physical medicine and rehabilitation program. It will serve as a preventive measure in some conditions to reduce the incidence of recurrences and hospital readmissions and also will result in important economic benefits.

Those patients who present special rehabilitation problems can be best served by the integrated action of their physician, physiatrist, rehabilitation coordinator and other physical medicine and rehabilitation personnel, social worker, vocational counselor, nurse, dietitian, psychiatrist, psychologist and other medical specialists when indicated. The patient should also participate in the planning to the extent of his abilities. The physical, social, emotional and vocational needs of the patient should be discussed and joint planning and concerted action toward achieving a definite rehabilitation goal could result.

BASIC AND GENERAL PRINCIPLES

Even though there are almost countless varieties of disabilities, both as to type and extent, there are certain general and fundamental physical medicine and rehabilitation principles that can be applied as an approach to the problem. There are usually psychologic and emotional problems, to a lesser or greater degree, whenever an individual suffers illness or injury. It is through

the combined integrated efforts and skills of the medical and paramedical specialists that the patient is motivated to participate in the prescribed activities and thereby is aided in overcoming these unhappy complications. He must be helped to accept his disability as well as the rehabilitation program.

Fundamental Objectives. The objectives for total rehabilitation are: To aid the patient in his psychologic, emotional and social adjustment to his disease and hospitalization, to relieve the boredom so frequently associated with the slow passage of time during illness and to enhance motivation. Effective use should be made of the hospitalization period. Selective activity participation helps to allay anxiety and fear.

To institute, as early as medically feasible, intensive physical medicine and rehabilitation for a sufficient period to relieve pain and secure a minimum degree of handicap.

To prevent general body deconditioning and deformities with their resulting detrimental effects, both physical and mental, in order to maintain the greatest possible degree of physical fitness and function for the performance of the maximum possible number of self-care and daily living activities, including ambulation.

To furnish, when indicated, and to thoroughly train the disabled person in the use of crutches, braces, canes, artificial extremities, wheel chairs and other types of assistive devices for maximum usefulness.

To establish a realistic vocational goal leading to selective job placement and gainful employment for those who because of their disability cannot return to their former type of work. The hospital program should include posthospital planning for full or part-time employment and for some individuals who require sheltered or home work.

The maximum number of self-care activities which the patient has the ability to perform must be the foundation for his total rehabilitation, the objectives upon which to build a life of usefulness. These activities are daily accomplishments for the normal person. The Veterans Administration "Self-Care Activities—Functional Evaluation" form lists 154 activities, which have been divided into a number of groups, such as those of eating (drink from cup or glass, eat with fork and spoon, cut with knife), communication (write, type, use telephone, open envelope, remove letter from envelope), hygiene (shave, wash hands and face, brush teeth, brush or comb hair, turn faucet on and off,

Figure 1 Measurement of range of joint motion. a, Measurement of elbow extension-flexion with goniometer (normal range 0 to 145 degrees) b, Measurement of finger motion with ruler

use toilet, get into and out of bath or shower), dressing (put on braces or prosthesis, use zippers, hooks and eyes, put on and remove clothing, necktie, hose, shoes, put in and remove objects from pocket), locomotion (get in and out of bed, use wheel chair, stand, get down and up from floor, walk up and down stairs, get into and out of and drive an automobile, get into and out of church pew or theater seat), household (open and close drawers, make bed, lock and unlock doors, open and close windows, get into and out of chair at table), and miscellaneous (wind watch, hold newspaper, turn pages, pick up objects from table and floor, open and close safety pins, turn door knobs, use pull cord). Other institutions have developed similar forms for checking patients' accomplishments. One must be realistic and practical, for with some disabilities many of these activities are beyond the realm of accomplishment.

Prior to institution of any treatment, the individual receives a complete initial medical examination and evaluation and

range of joint motion, muscle strength and coordination. Range of joint motion can be evaluated with a goniometer (protractor) and a ruler. For example, normal range of motion of the elbow would be recorded as extension-flexion, 0 to 145 degrees (Fig.

Figure 2. Measurement of muscle strength a, The strength of the flexor muscles of the right elbow being tested with the myometer. The patient is resisting the force attempting to overcome the strength of the flexor muscles. b, The strength of the abductor pollicis brevis muscle of the left hand being tested with the myometer.

1a). Measurements for impaired range for the elbow may be recorded, for example, as 20 to 110 degrees. Two readings are always taken so that not only are the actual number of degrees of movement noted, but also the relation to the normal total range. Other joints are similarly measured. In most instances, range of finger movement could be objectively evaluated with a ruler (Fig. 1b). Normal functional range would be considered when (1) the tips of the fingers can touch the palm when they are completely flexed, (2) the fingers can be completely extended and (3) the tip of the thumb can touch the tips of the four fingers of the hand. Both active and passive range of joint motion are to be measured for complete evaluation of movement.

Muscle strength can be measured with a muscle dynamometer. Figure 2a shows the method of testing the strength of the flexor muscles of the right elbow with the myometer. This small hydraulic device accurately measures the resistance offered by a muscle, the reading on the gauge being equal to the force necessary to overcome the isometric contraction of the muscle under test. With the myometer, a realistic scientific value of muscle strength in pounds or fractions thereof can be secured repeatedly. On the other hand, in manual muscle testing, many terms are used to describe muscle strength, such as moderate assistance, minimum pressure, slight resistance, great deal of resistance and full resistance, which are empiric, unscientific and inaccurate since they mean different things to various testers. The strength of the abductor pollicis brevis muscle is measured as shown in Figure 2b. The strength of the other muscles or muscle

groups, pronation and supination of the forearm and the hand grip can be similarly evaluated.

When range of joint motion and muscle strength are re-evaluated, it is important that the patient and the part being tested be placed in the same position as in all previous tests.

Coordination can be tested by the patient's ability to perform movements such as writing, handling eating utensils, shaving, brushing teeth and picking up small objects. Work capacity can be determined by totaling the amount of activity the patient has performed over a specified time.

When properly instructed and with periodic re-evaluations, many patients upon discharge from the hospital can continue certain activities such as therapeutic exercises and heat applications at home and thus shorten their hospitalization period. Frequently therapists can visit the patient at home in order to continue treatment. The home-care program must be under close direction and supervision of the physiatrist. Definite economic and social benefits will be gained, including greater independence with an earlier possibility of gainful employment.

ELECTRODIAGNOSTIC PROCEDURES

Electrodiagnostic techniques are of definite aid in evaluating the status of neuromuscular disorders, specifically those of lower motor neurons. The response of motor nerve and muscles to suitable electrical stimuli must be analyzed and properly interpreted. Formerly the response was noted when using the tetanizing (faradic) and direct current (galvanic), thereby indicating the state of innervation. In denervated muscle, there is a classical response called RD

(reaction of degeneration). Testing for this response is helpful when dealing with a degenerated nerve or a denervated muscle, but the procedure is of little value in detecting regeneration.

At present it appears that the use of (1) tetanizing current, (2) direct current, (3) electromyography and (4) electrical skin resistance measurements can contribute valuable information in diagnosing degenerating, denervated and regenerating nerve-muscle disorders. In electrodiagnosis, a small active electrode approximately $\frac{1}{2}$ to 1 inch in diameter is placed over the motor point of the muscle. The large dispersive electrode is placed on the body some distance from the active electrode.

Tetanizing Current. The tetanizing current frequently used is a type of alternating current induced in the secondary of an induction coil by the rapid interruption of the current in the primary coil, commonly called faradic current. Normally innervated muscles respond to tetanizing current. However, in from ten to fourteen days after a nerve is severely injured, the nerve and muscle do not respond to this current unless the strength is greatly increased beyond pain tolerance. This is the simplest, most accurate, and earliest electrical sign of a severe nerve injury.

Direct Current Impulse Stimuli. A direct current impulse stimulator is extremely useful in electrodiagnosis. It may be a simple battery or a more complex generator, producing square waves which can be varied in polarity, in duration from 0.1 to 1000 milliseconds, in the interval between stimuli in milliseconds and in intensity of current in milliamperes. The type of contraction of the muscle being tested is carefully observed.

Table 1. *Electrodiagnostic Data Guide*

	NORMAL	DEGENERATING	DENERVATED	REGENERATING
base	Normal	High to lower than normal	Below normal	Higher than normal
upstroke duration curve	Continuous flat slope	Discontinuous steep slope	Continuous steep slope	Discontinuous steep slope
onset (milliseconds)	Less than 1	More than 15	More than 15	
direct current tetanus ratio	3.5 to 6.0	10.0 to 1.0	1.0 to 1.5	
positive stimulation	Descending curve	Ascending curve	Ascending curve	
base ratio	1.5 to 3.0	3.0 to 1.0	1.0 or less	

Figure 3 Strength-duration curves a, Normal—continuous flat slope; b, denervated—continuous steep slope, c, regeneration—discontinuous steep slope.

Normally, a rapid twitch is obtained, while in denervation a slow contraction is seen. Usually muscles both proximal and distal to the injury are tested.

The following data, if obtained during examination, are helpful: rheobase, strength-duration curve, chronaxie, direct current tetanus and its ratio, repetitive stimulation and rheobase ratio (Table 1).

Rheobase. This is the minimum amount of direct current, lasting a minimum of 500 milliseconds, necessary to produce a minimal muscle contraction.

Strength-duration curve. This is obtained by plotting the current in milliamperes necessary to produce a minimal contraction with decreasing duration of stimulus down to 0.1 millisecond. Figure 3 shows strength-duration curves.

Chronaxie. The number of milliseconds required to produce a minimal contraction when the strength of the stimulus is twice the rheobase is the chronaxie. Normally this is less than 1 millisecond.

Direct current tetanus ratio. This is the quotient resulting from dividing the intensity of the direct current required to produce a tetanic contraction by the rheobase. When the intensity of the direct current for rheobase is increased three to five times, normal muscle remains in tetanic contraction (direct current tetanus).

Repetitive stimulation. The intensity of the direct current stimuli of 1 millisecond required, at intervals of 1, 5 and 12 milliseconds between stimuli, to produce a tetanic contraction is recorded as a strength-interval curve for repetitive stimulation. The thresh-

old normally is less for 12 than for 1 millisecond.

by dividing the anodal rheobase by the cathodal rheobase. The normal is 1.5 to 3.0.

All of the above guide data must be interpreted in relation to the time elapsed since injury or surgery, the length of the distal segment, edema of the skin at the site of the stimulating electrode, traumatic muscle damage and situations of dual or "overlap" innervation. An increase in rheobase and in direct current tetanus ratio is frequently the earliest sign of nerve regeneration. However, the appearance of discontinuities in the strength-duration curve may appear first. Chronaxie is usually last to return to normal during nerve regeneration.

Electromyography. The electromyograph is an electronic device by means of which the electrical voltages generated by muscle activity can be seen, heard, photographed and recorded (Table 2). There are several methods that can be used to "pick-up" the voltages from the muscle being studied. It can be done by means of skin surface electrodes, one surface and one monopolar intramuscular needle, by the use of two intramuscular needles or by means of a single or double coaxial (concentric) needle. Needle electrodes are the most sensitive and reliable. After being amplified these voltages are converted to visible wave forms by a cathode-ray oscilloscope and into sound by means of a loud speaker. For permanent records, the wave form on the oscilloscope is photographed and also recorded on a mag-

Table 2. Electromyographic Data Guide

	AMPLITUDE	DURATION	FREQUENCY	SOUND PRODUCED
Normal resting muscle	0	0	0	Silent
Normal motor unit	500-2000 microvolts	2-10 milliseconds	5-30 per second	"Sharp rumble"
Fibrillation potential (denervation)	5-100 microvolts	1 millisecond or less	2-30 per second, not constant	"Clicking"

netic recorder for future playback. The electromyograph is of greatest value in demonstrating lesions of lower motor neurons.

Various types of motor unit potentials are seen on electromyographic examination, the type of potential depending on the neuromuscular conditions at the time of examination (Fig. 4). There are many normal variations in the so-called characteristic potentials observed during tests. Electromyographic examination of a normal muscle at rest reveals no demonstrable electrical potential, there being an undisturbed iso-electric base line seen on the oscilloscope, and is referred to as electromyographic silence (Fig. 4A). A normal contracting muscle produces rather characteristic motor unit potentials (Fig. 4B). It will be noted that small positive phases both precede and follow the large characteristic negative phase.

Approximately two weeks after a nerve or nerve root has been severed or severely injured, spontaneous denervation fibrillation voltages (Fig. 4C) and denervation positive voltages (Fig. 4D) appear even though the muscle is at rest. The denervation fibrillation

potentials are of extremely short duration, having an initial positive phase immediately followed by an almost equal negative phase. The denervation positive potentials show an initial positive phase having a rapid rise and a long negative phase of relatively low amplitude. Denervation fibrillation potentials and denervation positive potentials are continuous as long as the muscle is not completely fibrosed or degenerated or until it becomes reinnervated. These potentials do not occur in upper motor neuron lesions.

When a nerve is degenerating or regenerating, complex or highly polyphasic motor unit potentials are frequently seen on electromyographic examinations during voluntary effort (Fig. 4E). These potentials have many positive and negative phases.

During electromyographic examination of myotonic muscles, there is a rapid discharge of very high frequency potentials immediately after insertion of the needle electrode (Fig. 4F). The sound of these potentials over the loud speaker has been compared with the sound of a diving airplane.

In spinal lesions resulting in faulty innervation, as for example in progressive muscle atrophy and chronic poliomyelitis, fasciculation potentials are frequently seen on electromyographic examination. These are spontaneous, involuntary, complex or highly polyphasic potentials.

Electromyography is an excellent aid in localizing the level of a lesion which is producing nerve root pressure, such as those that may be associated with herniated nucleus pulposus, vertebral fractures, arthritic spurs, vascular anomalies and tumors. The technique for localizing the level of the lesion consists in exploring the muscles which derive their innervation above, at and below the suspected level. The muscles innervated by the involved nerve root will show degeneration fibrillation potentials on electromyographic examination. This examination is not conclusive from the negative aspect until at least two to three weeks have elapsed since the onset of symptoms. Like many diagnostic

Figure 4. Electromyographic wave forms. A, Normal muscle at rest. B, Normal voluntary effort. C, Spontaneous denervation positive potentials from a denervated muscle (lower motor neuron disease). D, Denervation positive potentials during voluntary effort from a recently reinnervated muscle. E, Complex or highly polyphasic motor unit potentials during voluntary effort from a recently reinnervated muscle. F, High frequency potentials from a muscle of a patient having myotonia.

procedures, electromyography must be correlated with the complete clinical picture.

When a dual beam cathode-ray tube is used in the electromyograph, action potentials of reciprocal innervation of the agonist and antagonist muscles can be studied simultaneously. This can be of definite aid in the exact study of kinesiology. In difficult problems of neuromuscular re-education, the patient can understand and co-operate better when he is able to see or hear the action potentials produced while attempting to contract his muscles. The degree of muscle relaxation can also be established.

With the aid of the electromyograph, conduction velocity of a nerve can be measured, augmenting the neurophysiologic studies helpful in the diagnosis and understanding of neuromuscular disorders.

Electrical Skin Resistance Measurements. To further aid in the diagnosis of certain neurologic conditions, electrical skin resistance measurements can be of practical aid. The resistance of the body to small amounts of direct current is almost entirely by the skin. Skin resistance, which depends upon the sympathetic innervation, decreases with sweat gland activity and increases when the sweat glands are inactive, thus denervation increases skin resistance.

Normally, in areas of the body where there is an abundant supply of sweat glands, as in the oral region of the face, in the palms of the hands, soles of the feet and the axillae, the electrical resistance is low. In other areas and in scar tissue, the electrical resistance is high. In testing electrical skin resistance, the resistance of the skin to a small amount of direct current (maximum 50 microamperes) is measured. The deep tissues of the body are good conductors while the skin is a poor conductor of electricity. The surface of the skin supplied by the sympathetic fibers and the sensory fibers is almost identical.

The instrument for measuring skin resistance consists essentially of a microammeter (0 to 100 microamperes), dry cell batteries, the necessary resistances and switches and two electrodes. One electrode is attached to the lobe of the ear, while the other, which is the exploring one, is moved over the skin from high to low resistance, thereby mapping the area of sympathetic loss. There is usually a rather sharp line of demarcation between denervated and normal areas if the lesion is distal to the point where the sympathetics join the nerve. In conditions in which the nerve injury is proximal to the point where

the sympathetic fibers join the nerve, as following posterior rhizotomy, there will be no change in the electrical skin resistance even though there is loss of sensation. For example, in a herniated nucleus pulposus between L5 and S1 there may be sensory changes corresponding to the root distribution with no change in electrical skin resistance. Further, a lesion of the sciatic nerve in the thigh would result in sensory loss over the nerve distribution, together with a marked increase in electrical skin resistance over the corresponding area.

SWEATING PATTERN TESTS

The skin area with loss of sweating (anhidrosis) corresponds very closely to the area of sensory loss which accompanies peripheral nerve injuries, since the skin area supplied by the sympathetic nerve fibers corresponds in the main to the area supplied by the homologous sensory fibers. Sweating pattern tests should not be substituted for careful sensory examinations.

Sweating pattern alterations can be demonstrated by colorimetric changes using any of the following techniques.

Starch-Iodine Test. The area to be tested is first painted with aqueous iodine solution and after drying is uniformly dusted with

Figure 5 Sweating pattern after severe injury to the common peroneal nerve of the right leg.

powdered starch. Wherever sweating occurs, a blue-black color will result; the dry areas remain white.

Cobalt Chloride Test. A saturated cobalt chloride solution in 95 per cent alcohol is painted over the skin area to be studied. The area where sweating occurs will change from blue to red.

Quinizarin Dye Test. The area to be tested is uniformly covered with the powdered reddish-gray dye. Sweating will change the color to a deep purple, thereby outlining the pattern.

In all of the three tests, the patient is subjected to dry heat or placed in a warm room in order to induce sweating. The sweating pattern areas can be photographed or traced for permanent records to aid in evaluating any recovery. Figure 5 shows the sweating pattern following a severe shell fragment injury to the common peroneal nerve of the right leg.

HEAT THERAPY (THERMOTHERAPY)

The value of heat, which is frequently used with other measures in the treatment of disabilities, has been well established. When indicated and judiciously used, heat is extremely valuable for both local and systemic effects, such as improving blood and lymph circulation, in relieving pain, for its beneficial effects in inflammatory conditions and for its relaxing effect. Mild heat applied to shortened structures for approximately thirty minutes prior to and during the stretching of contractures will greatly facilitate this procedure.

Intense heat even for short periods is definitely contraindicated and dangerous. Heat in any form should be used with extreme caution, or not at all, over areas with impaired sensation or over extremities with inadequate circulation as in peripheral vascular disease. Heat is further contraindicated over malignant areas, in hemorrhagic diseases and usually in very acute traumatic lesions.

The different varieties of apparatus for heating tissues have been classified into three main types: external heat applicators, radiant heat generators and diathermy apparatus.

External Heat Applicators. With these types of applicators, heat is applied to the body by means of hot water bottles, hot water packs, electric pads, chemical pads, paraffin baths, hydrotherapeutic apparatus (warm baths, whirlpool baths, Hubbard tanks, contrast baths), cabinets and other

devices wherein heated air is used. These provide a simple but superficial type of heat.

For the paraffin bath a mixture of seven parts of paraffin and one part of paraffin oil is heated to approximately 120° F. and into this the hand or foot is immersed for thirty to forty-five minutes. When a shoulder, neck or back is to be treated the paraffin can be painted on the part with a brush. The paraffin coating can be kept in place for several hours, thereby maintaining hyperemia.

Hydrotherapy is extremely valuable for heat application and in addition, because of the buoyant effect of water, the patient can actively exercise the extremity even with minimal muscular strength, thereby enhancing function. In the presence of ulcers and wounds, a bland liquid soap or mild detergent should be slowly dripped into or added directly to the continually changing water for both cleansing and bacteriostatic effects (Fig. 6). Following hydrotherapy, the area should be carefully dried with warm air by means of the ordinary hair dryer. This is followed by local ultraviolet radiation to the ulcer or wound.

Contrast baths, whereby the extremity is alternately immersed in warm (105° F.) and cold (65° F.) water for short periods, may aid circulation and decrease pain.

With the exception of artificial fever therapy, and other situations in which the entire body is exposed to heat, treatments should

Figure 6 Method for producing soapy solution in the whirlpool tank when hydrotherapy is given in the presence of open wounds.

usually be given for prolonged periods several times each day, using very mild heat.

Radiant Heat Generators. These types of generators permit the application of dry heat without direct contact between the source of heat and the body and produce tissue heat somewhat deeper than that produced by external heat applicators. Radiant heat generators consist of electric incandescent lamps (tungsten or carbon filaments) or resistance coils, frequently mounted in a parabolic reflector for local application. When the spectral band of the radiation being generated is invisible, the device is known as an infrared generator. The heating unit can also be mounted in a frame or hood and such generators are known as light cradles or bakers.

Diathermy Apparatus. By this method, known as medical diathermy, the heating effect results from the resistance of the tissues of the body to the passage of high-frequency currents. The frequencies of the currents used are sufficiently high so that nerves and muscles are not stimulated. The intensity of current is below that which would destroy or impair tissue function. Diathermy is applied locally by two methods: short wave diathermy with an electric field using air space or insulated electrodes or cuffs or a cable or drum operating at a frequency of 27.12 megacycles (wave length of 11.6 meters), and microwaves using a reflector type of applicator, the frequency being 2400 to 2500 megacycles (wave length of approximately 12 cm.). Diathermy produces the deepest heat penetration of tissue.

COLD THERAPY AND HYPOTHERMIA

Prompt application of cold in acute strains, sprains and fractures, for perhaps the first twelve to twenty-four hours after injury, is usually indicated as it not only diminishes pain but also hemorrhage and exudation, consequently there is less swelling. The lowering of body temperatures to about 60° F. has been reported to relieve pain in generalized metastatic carcinoma. Cold has also been used locally over an extremity to relieve pain and to diminish circulation and metabolism following an embolism when the patient's condition precludes immediate surgery. It further aids in controlling toxemia and pain in extensive gangrene of an extremity while awaiting the opportune time and site for amputation.

Generalized hypothermia (lowering of body temperature) which results in a slowing of all physiologic processes is used in con-

junction with some cardiovascular surgical procedures, blood vessel grafting and neurosurgical operations.

THERAPEUTIC EXERCISE

Therapeutic exercises are an extremely important phase of physical medicine and rehabilitation and, if properly prescribed and administered, are rarely contraindicated. Exercises should be specifically prescribed and instituted only by those having a thorough knowledge of functional anatomy, the existing pathologic conditions and the physiologic effects of the exercises. Movement is a physiologic procedure, while prolonged or injudicious rest is unphysiologic and debilitating. Exercise aids in improving and maintaining proper functioning of the cardiovascular, respiratory, muscular and nervous systems. Prolonged bed rest often results in a negative nitrogen balance and other metabolic changes associated with significant loss of calcium, phosphorus and potassium. Further, muscle strength and work capacity, as well as the ability to perform speed and coordination tests, are diminished, while patient irritability is increased.

In the care of the sick, a scientific balance between activity and rest must be established. No fixed rules can be instituted, the criteria being the general over-all conditions and the specific exercise needs of the patient. Preliminary mild warming of the body, or the parts to be exercised, may enhance activity.

Exercises, especially those associated with posture training, correcting faulty body mechanics and ambulation, are best performed in front of a full-length mirror.

There are four types of exercises: active exercise, active assistive exercise, active resistive exercise and passive exercise.

Active Exercise. Active exercise is that produced by the patient's voluntary contraction of muscles without any external aid, is often referred to as "free exercise" and should be instituted whenever possible as it increases blood flow and muscle strength. All types of exercise should be performed slowly and rhythmically without any jerky movements through as full a range as possible. This is especially true when stretching contractures. Exercises should never be performed to the point of exhaustion.

In instances of marked muscular weakness, it may be necessary to position the part to be exercised so as to decrease the effect of gravity so the patient can institute his own active movement. This can also be accom-

plished by supporting the part on a powdered board or on a board which moves freely on ball-bearing casters or by means of suspension slings. The effect of gravity can also be utilized to assist movement. If active movement is still impossible to accomplish, assistance to the movement must be given, this is designated as active assistive exercise.

Isometric muscle contraction, sometimes designated as muscle setting or static exercise, is accomplished without any change in muscle length and is employed when the joint cannot be moved because of a cast, splint or brace. Vigorous isometric contractions will help to prevent or delay atrophy and maintain circulation. Movement in an involved extremity can be frequently enhanced by the simultaneous active resistive exercises of the opposite extremity.

Exercises for correcting and improving faulty posture and body mechanics, as well as for enhancing respiratory movements, are frequently indicated. Parallel bars have proved to be indispensable in training the disabled person, such as the hemiplegic, paraplegic, amputee and arthritis, to stand, balance and ambulate. In addition, they are extremely safe and effective.

Scientific relaxation exercises, both local and general, are frequently an important phase of any activity program to aid in improving both function and general well-being.

Active Assistive Exercise. Active assistive exercise is the patient's voluntary movement aided by external assistance, as from the

physician or therapist or through the use of pulleys and weights. This type of exercise is often employed when the patient's muscular strength is insufficient to satisfactorily move the part, and also to increase range of joint motion when limitation may be due to muscle shortening, contractures, adhesions and other joint change in such conditions as rheumatic disease, neurologic disorders and orthopedic conditions.

In the DeLorme technique of progressive load assistive exercises, the load assists the movement of the part of the body, with some modifications. The minimum amount of load assistance the muscles need to perform ten repetitions (ten repetitions-minimum load) is determined. With the first ten repetitions, use an assistive load equal to twice the ten repetitions-minimum, with the second ten repetitions use one and one-half times the ten repetitions-minimum load, and with the third ten repetitions use ten repetitions-minimum load. Figure 7a shows load assistive exercises to develop the elbow flexor muscles.

Active Resistive Exercise. Active resistive exercise is used to aid further in the development of muscle strength by giving resistance to the movement. To produce maximum hypertrophy and strength of the muscle, progressive resistive exercise is initiated. Muscles contracting repeatedly, with relatively few repetitions against heavy resistance, will increase in size and strength, in contrast to a muscle contracting against light resistance for numerous repetitions which will increase its endurance with very little change in strength. Usually it is desirable to first improve strength and later endurance.

DeLorme's technique of progressive load resistive exercise (the load resists the movement of the part of the body) is, in general, as follows. Determine the maximum load that can be lifted for ten repetitions (ten repetitions-maximum). Three sets of exercises, each set consisting of ten repetitions, are performed once daily four to five times each week. All resistances are based on ten repetitions-maximum load. The first ten repetitions are done with one-half of the ten repetitions-maximum load, the second ten repetitions with three-fourths of this load and the last ten with ten repetitions-maximum load. Figure 7b shows load resistive exercises to develop the elbow flexor muscles. With the "Oxford technique," the DeLorme procedure is modified so that the load is decreased with each ten repetitions-maximum

Figure 7 Elbow flexor exercises. a, Load assistive, b, Load resistive

There appears to be evidence that a lesser number of repetitions against maximum resistance is sufficient to secure maximum strength. This is certainly true after maximum strength has been reached, for in order to maintain maximum it is only necessary to secure one or two repetitions with maximum resistance three to four times each week. However, it is important that during exercise the part be moved slowly and rhythmically through the maximum possible range and that each contraction be held for five seconds before relaxing.

Active resistive exercise is often employed to stretch a shortened agonist muscle when opposed by a weakened antagonist. For example, the flexor muscles of the elbow may be shortened in the presence of weak elbow extensors. Active resistive exercises of the extensor group will not only aid in stretching the shortened flexors but will strengthen the weakened extensors.

Passive Exercise. Passive exercise, sometimes referred to as relaxed movement, is done entirely by the physician or therapist or through the application of external force. The part being exercised must be properly supported and relaxed. The main therapeutic value in passive exercise is for the maintenance of range of joint motion by preventing adhesions, contractures and joint fixation. For example, in peripheral nerve injury with paralysis, normal joint motion is maintained through passive exercise while nerve regeneration is taking place. This is of tremendous importance for, without this type of movement, fixed joints with loss of function will result even though the nerve eventually may regenerate. In contrast to active exercise, passive exercise produces little change in blood flow or muscle strength.

Portable Pulley Apparatus. To aid the patient in improving the function of the upper extremity and shoulder, a portable overhead pulley apparatus is helpful (Fig. 8). The horizontal member is notched so that pulley positions can be adjusted to secure the most favorable direction of pull. The baseboard, which has metal glides attached to the undersurface for ease in moving, is large so that it will hold a wheel chair, ordinary chair or stool, giving stability to the apparatus. This exercise arrangement permits the patient to institute all forms of exercises in functional impairment of upper extremities as seen in neurologic conditions, various types of rheumatic disease and orthopedic conditions. If the patient cannot grasp the hand grip at the end of the rope,

Figure 8 A portable overhead pulley apparatus with adjustable pulley positions being used by a patient with right hemiparesis to improve function of the right upper extremity.

he wears a glove which is then strapped to hold the fingers in position on the grip.

Neuromuscular Re-education. This is another useful technique to enhance function. The patient repeatedly attempts to contract muscles, thereby aiding in the establishment of voluntary movement patterns for purposeful movements. These are at first simple in pattern and gradually progress to more complex ones. For example, following a muscle transplant the individual through this type of training may learn to use the muscle as an extensor instead of a flexor as it was formerly used. Frequently, by producing a contraction of a muscle by electrical stimulation at the same moment that the individual attempts to contract the muscle voluntarily, neuromuscular re-education is facilitated. The use of tonic reflexes to facilitate voluntary movement of an involved extremity in an upper motor neuron lesion should be tried.

MASSAGE

Massage with its various techniques is essentially manipulation of the body tissues, usually with the hands, and at times by means of a mechanical vibrator. Even though this technique has been used since ancient times, its scientific value for increasing circulation as compared to heat, exercise, electrical stimulation and physical means

is rather limited. Its psychologic effect through the "laying on of hands" may, in some instances, have a definite therapeutic value. There is frequently a relaxing or sedative effect from mild, slow, superficial massage or mild vibration as accomplished with a mechanical vibrator.

Circulation in an extremity is enhanced to a much greater degree when active exercise of a part can be instituted than when massage is used. In patients with flaccid paralysis of the extremities, it is necessary to employ a vigorous forceful deep kneading massage in order to produce a significant increase in blood flow. This is a traumatic procedure and may result in muscle hemorrhage and eventually fibrosis. Under these circumstances, mild heat, passive exercise and electrical stimulation of the paralyzed muscles would not only enhance the circulation and retard the development of contractures, but also maintain passive joint range of motion.

Massage should not be used in skin diseases, in the presence of benign or malignant growths, in acute phlebitis or thrombosis, over inflamed joints or in any inflammatory condition of the skin or underlying structures.

There are several techniques usually employed in massage: namely, superficial and deep stroking or effleurage, kneading or compression massage also known as petrissage, friction massage and percussion or tapotement massage.

Superficial and Deep Stroking. Superficial stroking is frequently used for its sedative effect on the patient. It consists of slow, long, smooth, rhythmic movements with light pressure, usually in a centripetal manner. The area to be massaged is lubricated with talcum powder, mineral oil, cocoa butter or lanolin. Deep stroking is similar except that heavy pressure is used in the movements of the hands. Superficial or moderately deep stroking carefully applied may be indicated in patients having painful conditions such as rheumatic diseases, orthopedic conditions and certain neurologic disorders.

Kneading, or Compression, Massage. Kneading, or compression, massage is accomplished by rolling or squeezing the muscles between the hand and the underlying structures or between both hands, the movements being in a rolling or circular movement, following the pattern of the large muscle groups and primarily in a centripetal direction. Frequently, kneading and deep stroking are used simultaneously.

Friction Massage. Friction massage is

done, with or between the tips of the fingers, in a small circular or lifting movement without the use of any lubricant on the skin. Contrary to the stroking and kneading type of massage, there is no movement between the fingers and the skin when friction massage is used. The skin is caused to move over the underlying tissues, thereby aiding in loosening scars and adhesions.

Percussion Massage. Percussion massage, which is rarely used, consists of tapping, cupping, hacking or beating movements done with the fingers, palms or edges of the hands.

ASSISTIVE AND SELF-HELP DEVICES

In order for some disabled individuals to perform self-care activities, assistive and self-help devices, splints, braces and crutches are needed. There are numerous excellent devices that serve many useful purposes. These help in protecting weakened muscles, in preventing and correcting contractures and deformities, in holding the part of the body in a better functioning position and permitting voluntary movement of the nonparalyzed muscles while aiding in the movement of the paralyzed muscles. For example, in a radial nerve injury the assistive dynamic splint (Fig 9) holds the wrist and the metacarpophalangeal joints in a functional position by means of elastic or springs and yet permits the patient to flex the fingers and wrist voluntarily in order to grasp. Upon relaxation of the flexor muscles, the device will bring the fingers and wrist back to the neutral or extended position ready for the next grasping movement.

In conditions in which for all practical purposes there are no voluntary movements in the hands, following a cervical cord or brain lesion or in the chronic ankylosing type of arthritis, a simple assistive splint can be easily fabricated of plastic or metal that is placed over the palm of the hand and held

Figure 9 Dynamic splint for radial nerve paralysis. The spring wire holds the wrist and metacarpophalangeal joints in extension while the elastic band maintains the thumb in extension and abduction. This type of splint permits the patient to perform numerous hand activities.

Figure 10 Assistive device for functionless hand. A plastic plate is held in the palm by an elastic strap. Numerous detachable and interchangeable utensils can be inserted into the hollow barrel enabling the patient to perform many self-care activities.

in place with an elastic or leather strap (Fig. 10). This basic device can be fitted with a detachable fork, spoon, pencil, brush, safety or electric razor and numerous other daily used items. If the individual cannot grasp completely in order to hold objects, then a simple assistive hand device can be fabricated, consisting of a large hollow plastic handle with detachable interchangeable utensils, such as a comb, brush, fork, spoon, toothbrush, razor and small tools. The size of the handle will be governed by the patient's function and can be decreased as the patient's grasp improves. A combination knife-fork eating utensil is available for those who must eat with one hand, such as hemiplegics, certain amputees and others. This device permits the person to cut and then bring the food to his mouth using only one hand.

Recently, hand-moving devices have been developed which are operated by wrist motion, shoulder-controlled cables or motors. Simple assistive devices are easily designed to enable the seriously disabled person to type, use a telephone, walk and perform many coordinated activities, without which he would be quite helpless and dependent upon others for assistance.

Training in the correct use of properly fitting crutches (full-length and forearm type), canes, braces and wheel chairs further aids in the performance of many self-care and daily living activities. Braces help in supporting body weight, in the prevention and correction of contractures and deformi-

ties and in controlling abnormal movements. Since the majority of persons who wear braces also require crutches in order to ambulate, it is extremely necessary that proper gait training be instituted.

Gait training, either within or outside the parallel bars, is best accomplished in front of a full-length mirror. In this way the patient can observe his locomotion and posture and thereby attempt to correct any faulty body mechanics.

Crutch Ambulation. For successful crutch ambulation the following factors must be carefully considered:

- 1 The development of function of the muscles necessary for ambulating with crutches.
- 2 Selection of the proper type and measurements of the crutches, such as the wooden full-length crutches (Figure 11a) or the metal forearm (Canadian) crutches (Figure 11b).
- 3 The selection and training in the best suited crutch gaits. Much depends on the disability and the general over-all medical condition of the patient and one must be realistic in selecting those who should be taught crutch ambulation. The energy expenditure may be beyond the patient's physical and mental abilities and reserves, for with some patients the weight of the body must be supported by the shoulder girdle and upper extremities. The flexors of the shoulders move the crutches forward, the extensors of the elbows and wrists permit

raising of the body from the floor, the shoulder girdle depressors and downward rotators support the body when it is raised from the floor and the flexors of the fingers grasp the hand grip on the crutch.

The shoulder portion of the crutch should be covered with a resilient axilla pad, while the end has a large $1\frac{1}{2}$ inch diameter suction tip to prevent slipping.

A simple method for measuring for long crutches is to have the patient supine and secure the length from the anterior fold of the axilla to the foot and add 2 inches. The hand grip is so placed that the elbows are flexed at 30 degrees.

Prior to the use of crutches, the patient should master the indicated gait in parallel bars. As part of crutch ambulation training, the patient must first be taught to balance and shift his weight, preferably while standing against a wall. The body weight is taken mainly on the hands, the elbows being slightly flexed and the shoulders down. The crutches must clear the axillae. Ambulation should be taught on level ground, inclines, curbs and stairs when feasible. In those patients in whom non-weight bearing of one extremity is indicated, the shoe on the opposite extremity should be built-up approximately 1 to $1\frac{1}{2}$ inches.

Types of crutch gaits and their sequences

- 1 Four-Point Alternate Crutch Gait. right crutch, left foot, left crutch and right foot
- 2 Two-Point Alternate Crutch Gait. right

crutch and left foot simultaneously, then left crutch and right foot simultaneously. The gait is just a speeding up of the four-point alternate gait.

3 Three-Point Crutch Gait: both crutches and the weaker lower extremity simultaneously, then the stronger or normal lower extremity. This gait is for those having one lower extremity that cannot take full weight bearing while the other lower extremity can support full body weight.

4 Tripod Crutch Gaits

a Tripod Alternate Gait: right crutch, left crutch, then drag body forward.

b Tripod Simultaneous Gait: both crutches simultaneously, then drag body forward

5 Swinging Crutch Gaits

a Swing-to Gait: both crutches simultaneously, then left and swing body to crutches.

b Swing-Through Gait: both crutches simultaneously, then lift and swing the body beyond the crutches

The metal forearm crutches are for those patients who have developed sufficient strength, balance and coordination for safe ambulation. However, it is well even for these individuals to first master ambulation with full-length crutches.

It should be stressed that a very careful evaluation must be made of the patient's total disability and his general medical condition in order to (1) decide whether the patient should be taught crutch ambulation, (2) select the proper type of crutches and fit them properly, and (3) provide sufficient training in the properly selected gait to meet the specific needs of the patient. There will be certain disabled patients for whom crutch ambulation would be unrealistic and contraindicated.

Wheel Chairs. For patients with severe disabilities, wheel chairs can be secured with special features which will enable the individual to perform many additional self-care activities. In general, wheel chairs should be of the folding type with the large driving wheels placed posteriorly and with arm and adjustable footrests and a thick foam rubber cushion seat. Hand brakes are essential for stability, especially for getting in and out of the chair. When indicated, a zipper-back is indispensable for entering and leaving the wheel chair from the rear, as in getting in and out of bed and on and off the toilet. For those wheel chair patients who have the use of only one arm, a special "one-arm" drive is available. There are other additional special

Figure 11. Crutch ambulation a, Full-length wooden adjustable crutches having resilient axilla pads, suction tips and adjustable position for hand grip. b, Metal forearm (Canadian) crutch

devices and attachments such as a semireclining back, commode seat, detachable arms and adjustable leg rests, which should be considered to fill the specific needs of the wheel chair patient. A battery-operated electric wheel chair is available for those severely disabled persons who are unable to use the hand-powered chair

All disabled persons should be carefully and selectively fitted with assistive devices for specific needs so they can perform activities essential for maximum rehabilitation.

It is imperative that neuromuscular re-education and therapeutic exercises be continued while the patient uses an assistive device. If voluntary function is eventually accomplished, these various devices can be modified or entirely eliminated.

ELECTRICAL STIMULATION

Electrical stimulation to produce contraction of a denervated muscle has therapeutic value. A frequent and difficult problem encountered in denervated muscle is that of atrophy and fibrosis. Electrical stimulation of the denervated muscle is used to help retard atrophy so that, in the event reinnervation occurs, there will be better functional recovery. Although this subject is still controversial, most of the recent evidence indicates that atrophy and loss of muscle weight can be retarded by properly instituted electrical stimulation. This form of therapy must be started as soon after denervation as possible. The stimulation should be capable of producing vigorous muscular contractions starting with the muscle in a stretched position. During the movement of the part, resistance is applied by the operator's hand or by means of elastic, springs or weights. Stimulation may be given for a period of fifteen minutes twice each day. However, it appears that best results are obtained by shorter periods given three to four times each day. Vigorous contraction also has a favorable influence upon the nutrition of the muscle by increasing circulation.

Interrupted direct current or an alternating current of proper intensity, with a carrier frequency of 10 to 25 cycles per second, amplitude modulated so that the muscle contracts approximately fifteen to twenty times per minute, can be used. The ideal type of stimulating current for any given situation is not thoroughly understood. Since the threshold of reaction of the muscle varies with the type of current used for stimulation, it is well to select the current frequency and

wave form that produce the most satisfactory contraction. Electrical stimulation of denervated muscles is at best a poor substitute for the physiologic nerve impulses in a normally innervated muscle. Electrical stimulation is sometimes used in the flaccid stage of hemiplegia to aid in preventing and correcting contractures. In upper motor neuron lesions, using the electrical current to maintain the spastic muscle in a firm tetanic contraction for twenty to thirty minutes twice each day may be of help in decreasing the muscle spasticity and the frequency and intensity of the spasms. This no doubt produces fatigue of the muscle which is a factor in decreasing the spasticity. It has also been recommended as an aid in preventing and "freeing" adhesions and in removing traumatic exudates following sprains and contusions. Electrical stimulation is helpful as an aid in teaching the patient neuromuscular re-education.

There are two principal methods of electrode application that can be used for electrically stimulating muscles to produce contraction. The first method is to use an active and a dispersive electrode. The active electrode is relatively small, being approximately 1 to 4 square inches in area, and is placed over the point of maximum electrical sensitivity of the muscle to be stimulated. This point is designated as the motor point. The dispersive electrode is large, being many times the size of the active electrode, and is placed on the body at a distance from the muscle being stimulated.

The second method utilizes two small electrodes of equal size, which are placed over the ends of the belly of the muscle to be stimulated. With this technique, there is less spread of the electrical field to the adjacent muscles and, at times, it may be more satisfactory for stimulating smaller muscles.

ULTRAVIOLET RADIATION

The various sources of ultraviolet energy are the sun, which is a natural source, and artificial sources which are the carbon arc lamp, the low-voltage (hot) mercury vapor quartz lamp, including the Kromayer lamp, the high-voltage (cold) mercury vapor quartz lamp and the sunlamp.

Ultraviolet is a form of invisible radiant energy having a wavelength of 10 to 3900 A.U. (Angstrom units). The therapeutic dosage of ultraviolet radiation is based on the reaction of the individual to the radiation from a specific lamp and is determined by having small areas of ¹ s unit

skin, usually over the forearm or back, exposed for varying times with the ultraviolet lamp placed at a fixed distance, usually 30 inches from the skin surface. The time of exposure producing the slightest erythema which becomes visible in from four to twelve hours is called the M.E.D. (minimal erythema dose). This M.E.D. for a specific distance is used as a guide in prescribing ultraviolet radiation. This test, however, should be repeated every few months as the output of ultraviolet generators decreases with use.

Local and general ultraviolet radiation has been used in the treatment of many conditions. However, its greatest value appears to be in certain skin disorders. Because of its mild bactericidal effect and beneficial stimulation of granulation tissue, ultraviolet is also of value in the healing of decubitus and indolent ulcers and wounds.

If hydrotherapy is used in the treatment of this type of lesion, the area, after hydrotherapy, should be gently dried by using an electric hair dryer in order to counteract the macerating effect of the warm water, and is then exposed to local ultraviolet radiation. In order to secure and record the exact size and shape of these lesions, a simple plastic tracing device is used.

There is usually a so-called general tonic effect from extremely mild full-body exposures. Caution should always be observed to avoid excessive sunburn, the possibility of flare-up of certain skin diseases and various untoward reactions in light-sensitive or caustic individuals and in those who are using drugs or having ointments applied to the skin that is being exposed to the radiation. Ultraviolet radiation of blood, known as the Knott technique, has been used for many years in numerous conditions including bac-

teremia, wound infections and bronchial asthma, without as yet acceptable scientific clinical proof of its worth.

Ultraviolet lamps can be used as diagnostic aids. Many organic substances, including certain pathogenic fungi, fluoresce under ultraviolet radiation. Ringworm infections of the skin can be detected by the fluorescence seen when a Wood's filter or its equivalent is used to screen out most of the visible radiation.

ULTRASOUND THERAPY

Ultrasound therapy in recent years has been used in the treatment of many disorders and consists of vibrations, usually at a frequency of 1,000,000 cycles per second. These waves are produced by a quartz plate which is caused to vibrate synchronously with a high frequency electric field of 1,000,000 cycles per second. These ultrasound vibrations are emitted only from the face of the treatment head which contains a quartz plate. The energy density at the head can be controlled up to approximately 4 watts per sq. cm. in some machines. The face of the treatment head averages approximately 5 sq. cm.

Ultrasound energy transmission from the treatment head into the body tissues can be accomplished by three kinds of coupling, namely, direct contact, underwater contact and with water cushions. Treatment by means of direct contact of the head to the skin is the simplest (Fig. 12a). Inasmuch as air forms an almost impenetrable obstruction to the passage of ultrasound radiation, mineral oil spread over the skin is used as the coupling medium between the treatment head and the skin. During treatment, which may be given for five to eight minutes, depending on the condition being treated and the wattage used, the treatment head is con-

Figure 12. Ultrasound therapy. a, Ultrasound therapy being given to the shoulder by the direct contact method. Mineral oil is used as the coupling medium. b, Ultrasound therapy being given to the hand by the underwater contact method. The ultrasound head is kept at a short distance from the hand.

tinually and slowly moved over the involved area.

When, for example, small areas or joints in the hands and feet are to be treated, the underwater method is preferred (Fig 12b). With this technique the part of the body, such as a hand, is immersed in a vessel filled with degassed water and the ultrasound treatment head is placed at a distance of 1 to 2 inches from the body surface.

In conditions in which it is difficult or impractical to use the direct contact or underwater technique, such as in the region of the head, axilla or perineum, the water cushion method is used. This cushion consists of a thin rubber bag completely filled with degassed water, which is placed between the treatment head and the skin surface.

Ultrasound therapy is also given over both the local area of involvement and the spinal nerve roots which supply the involved area. For example, in treatment of rheumatoid arthritis of the hand, ultrasound therapy by the underwater contact method may be given for approximately five minutes at $\frac{1}{2}$ to 1 watt per sq. cm. and approximately the same dosage may be given over the seventh and eighth cervical and first thoracic spinal nerve roots just lateral to the vertebral spinous processes. The total dosage in any condition is varied according to the specific disorder being treated.

When ultrasound energy is directed into the tissues, there are in all probability a number of physiologic, physical and biologic changes that occur. Many workers have reported beneficial results from the use of ultrasound therapy in various types of rheumatic diseases (rheumatoid arthritis, degenerative joint disease, bursitis, fibrositis), inflammatory processes (lymphangitis, carbuncles); relief of pain in neuromas and scars; and numerous other conditions. Further research, both basic and clinical, is still in progress in order to evaluate the indications, results and contraindications to ultrasound therapy.

TRACTION

Cervical Traction. Patients with cervical lesions, such as fractures, fracture-dislocations, herniated nucleus pulposus and cervical arthritis, who have pain in the neck region, with or without radicular radiation of pain to the shoulders and arms, are frequently benefited by properly instituted cervical traction.

Traction is secured by using a head halter, while heat is applied to the neck and poste-

Figure 13 Cervical traction. The patient's head is supported on a padded roller board. The height of the pulley is adjusted for the proper angle of traction. Heat is applied to the neck and shoulders during traction.

rior shoulder muscles by means of an electric pad or warm compresses. The head is supported on a well-padded board having four ball-roller casters attached to the under-surface (Fig 13). This board, when placed on a hard surface, gives almost frictionless movement, so that the force of traction on the neck is practically equal to the weight applied. The best results are usually obtained by gradually increasing the weights until a maximum is reached that can be comfortably tolerated by the patient while in a lying position. This amount of pull is maintained for long periods during which the patient, at periodic intervals, slowly rotates his head as far as possible to the right and then to the left. This procedure tends to increase the range of rotation of the head, which is frequently limited. At the end of this period, the weights are gradually decreased and traction terminated. It is important to adjust the height of the pulley in order to secure the proper angle of pull.

In those patients in whom true radiculitis is present due to narrowing of the vertebral foramen, the best results from cervical traction occur when the neck is in partial flexion. In this position there is greater widening of the foramen than when the head is in a straight line with the long axis of the body or when it is extended. The head end of the table is elevated approximately 7 inches to prevent the patient from slipping in the direc-

tion of the traction. Prolonged traction with a moderate force while the patient is in a horizontal position is preferred to a strong pull for a relatively few minutes. The exact direction of traction and the amount of force applied should be individualized for the specific conditions under consideration.

Lumbar-Pelvic Traction. In the conservative management of low-back pain, with or without evidence of herniated nucleus pulposus or sciatic pain, lumbar-pelvic traction may be used. It is important, however, to use proper apparatus and technique in order to achieve best results.

A simple but effective arrangement for lumbar-pelvic traction is shown in Figure 14. Traction is applied to the lumbar spine and muscles by means of a properly fitted pelvic corset or belt, to which is attached the necessary straps and spreader bar and from which an adjustable weight is suspended over a pulley. In order to actually secure a known effective amount of pull on the lumbar region when a certain weight is suspended on the cable passing over the pulley, it is important to reduce to a minimum the resistance of the patient's hips and lower extremities to this pull. This is accomplished by having only the hips and lower extremities resting on a well-padded roller board having six ball-roller casters fastened to the underside, this rolls almost without friction on a hard surface, such as metal, formica or similar ma-

terial. The upper portion of the body above the lumbar area rests on a padded surface which is held on the table by a strap. A mattress split completely across can be used under the patient, one section being placed over the roller board to support the hips and both lower extremities while the other section is placed under the upper half of the body. With this method, the force of traction on the lumbar area is practically equal to the weight suspended over the pulley. The roller board is self-aligning during traction.

It must be remembered that if treatment is applied with the patient lying on a bed or treatment table without the use of a roller board under the hips and lower extremities, a tremendous force is necessary, depending on the size of the individual, to overcome the weight of the hips and lower extremities (approximately one-half of the total body weight) before any pull is actually exerted on the lumbar spine and muscles. Even then the exact amount of pull on these structures is not readily known.

In order to keep the patient's body from sliding in the direction of the traction, the foot end of the table is elevated approximately 7 inches. The height of the pulley should be adjusted so that the direction of the traction is at the proper angle, usually with the patient's pelvis somewhat flexed. As a rule, the best results are obtained by gradually increasing the weights during the first

Figure 14 Lumbar-pelvic traction. The patient's hips and lower extremities are supported on a padded roller board while the upper portion of the body rests on the upper section of a split mattress or pad. The pulley height is adjusted for proper angle of traction.

Figure 15 Tracing device for evaluating surface lesions A, Device is shown in position for tracing a decubitus ulcer. B, Periodic tracings show changes in contour of the lesion

thirty minutes until a maximum pull is reached that is comfortable to the patient. This amount of pull is maintained for one hour or longer and then gradually decreased for the final fifteen minutes when the traction is terminated

During the entire period of traction, in order to secure added comfort and additional therapeutic effects, heat is applied to the lumbar area by means of an electric pad or warm compresses. A pillow under the head, and others properly placed to hold the knees and hips partially flexed, results in a more restful position during traction. During the traction treatment, the patient can move his upper and lower extremities and even roll somewhat to the right and to the left in order to avoid the discomfort of lying in a fixed motionless position

In addition to traction as part of conservative treatment, proper therapeutic exercises should be gradually instituted to correct faulty posture and abnormal body mechanics and to improve muscle tone and strength as well as mobility of the neck and back.

EVALUATION OF SURFACE LESIONS

In order to check the progress of any surface lesion, such as decubitus ulcers, varicose ulcers, wounds of all types and other skin lesions, a simple tracing device can be

used to secure and record the exact size and shape of the lesion. Tracings of the lesion can be made periodically and checked with the previous tracing to note any change in size or contour.

The tracing device consists of a transparent rectangular plastic plate having three adjustable legs (Fig. 15). This device is placed over the surface lesion, but direct contact should be avoided. By looking through the plastic plate onto the lesion, and with a skin marking pencil, the operator draws the outline of the lesion (Fig. 15A). When the tracing is completed the device is removed from the patient. A standard size sheet of transparent paper is placed over the tracing device and the outline then traced on this paper with pen or pencil. This sheet, together with the patient's name, diagnosis, dates of tracings and other information becomes a permanent part of the patient's record. Periodic tracings of the same lesions are made on the original sheet in different colors for comparison (Fig. 15B).

FRACTURES, DISLOCATIONS, SPRAINS AND STRAINS

Objectives. In conjunction with the indicated medical regimen, the objectives of physical medicine and rehabilitation are to alleviate pain, enhance the healing process,

prevent or correct deformities, secure maximum function possible of the involved portion of the body and maintain the greatest degree of physical fitness, all of which lead to the return of the disabled person to maximum usefulness.

Physical Medicine and Rehabilitation Procedures. *Cold.* During the first twelve to twenty-four hours after injury, the application of cold is indicated to diminish pain and swelling.

Massage. If the injured part is accessible, superficial stroking, progressing to deeper stroking as healing progresses, may be of benefit.

Heat. After the first twenty-four to forty-eight hours, mild heat will frequently relieve pain and aid in the absorption of exudates. Heat should not be applied through a cast, as it is impossible to judge the amount of heat being absorbed by the tissues and the procedure may predispose to burns. Further, any sweating under a cast would tend to macerate the skin.

Ion transfer. Ion transfer, by direct current of a 1 per cent procaine hydrochloride solution into painful tissues, is in some instances helpful for relieving pain associated with sprains and strains thereby permitting active exercise of the involved part. The active electrode is saturated with the procaine solution and is connected to the positive terminal of the battery or direct current generator. The dispersive electrode is placed on the body at a distance from the active electrode and is connected to the negative terminal.

Therapeutic exercise. When the injured part is immobilized, isometric muscle contractions should be started. As soon as motion is indicated, gentle active and active assistive exercise should be instituted with gradual transition to progressive resistive exercise to secure maximum range and strength of movement. Active exercise of one extremity will improve circulation and delay atrophy in the contralateral extremity, even though the latter may be immobilized in a cast or splint. In hip arthroplasty, special therapeutic exercises are extremely helpful in restoring function. Conditioning exercises to all of the body should be started early to avoid the ill effects of inactivity and deconditioning.

Occupational therapy, manual arts therapy and educational therapy. These activities help to further improve function, assist the patient to perform self-care activities, and the patient psychologically in his hospitaliza-

tion and serve as an exploratory activity to determine the future type of employability.

NEUROLOGIC DISORDERS

Physical medicine and rehabilitation is indicated and of benefit in most neurologic disorders as an aid in diagnosis, prognosis and treatment. Diagnostic procedures include:

Measurement of range of joint motion and muscle strength

Sensory and reflex tests.

Electrodiagnostic tests including the use of direct and alternating currents, electrical skin resistance measurements and electromyography, including nerve conduction tests.

Sweating pattern tests.

Performance of self-care and daily living activities.

UPPER MOTOR NEURON DISORDERS

Upper motor neuron lesions may result in a variety of disabilities such as partial or complete hemiplegia, paraplegia and quadriplegia—with or without speech disorders such as aphasia. In many instances motor and sensory disturbances are combined and present a most difficult medical situation, taxing the ingenuity of all concerned.

Objectives. The objectives of treatment are to prevent and treat any deformity promptly; to aid circulation, to develop as much function in the involved extremities as possible; to use any possible assistive devices—including braces, crutches, canes, wheel chairs—leading toward the performance of self-care activities and ambulation. Speech therapy should be judiciously instituted for those with aphasia. The patient should be motivated toward the acceptance of his disability and the treatment program, with gainful employment as the goal, if feasible. Many neurologic patients, such as those with paraplegia, can be taught to drive safely an automobile equipped with proper operating hand controls.

Physical Medicine and Rehabilitation Procedures. *Proper positioning.* The patient is properly positioned in bed to aid in preventing contractures. The use of pillows, sandbags and simple splints is an extremely important preventive measure. For example, in a patient with hemiplegia, the extremities must be placed in proper position and alignment so as to prevent contractures in the upper extremity resulting in deformities of flexion and adduction of the shoulder, and flexion of the elbow, wrist and fingers. In the lower extremity, contractures usually result in deformities of flexion and external rota-

tion of the hip, flexion of the knee and plantar flexion and inversion of the foot.

Therapeutic exercises. Passive exercises and, in those patients having some voluntary movement, active assistive and active exercise should be instituted to prevent or correct contractures and to secure the maximum possible degree of function in the involved as well as the uninvolved extremities.

Spasticity and spasms are a frequent and difficult problem and, therefore, all exercises, and especially those for stretching, must be done extremely slowly so as to avoid stretch reflexes as much as possible. Pulleys and sling suspension exercises are of benefit. Relaxation procedures, especially for muscles with spasticity, should be started early. General conditioning exercises are also included. Fatigue should be avoided.

Neuromuscular re-education and relaxation. In order to secure maximum results these procedures must be taught to the patient and continued by him long after he is discharged from the hospital.

Heat. Mild heat, including hydrotherapy, is indicated to relieve pain and facilitate stretching of shortened structures. This may also be helpful in some patients to diminish spasticity and spasms. Massage may be of additional value if done slowly and superficially and if it does not elicit spasms.

Self-Care Activities. The performance of these activities with the further aid of occupational therapy, manual arts therapy and educational therapy is a vital part of the total program. A portable double-bilateral assistive sling device (Fig 16) is extremely valuable when the patient does not have sufficient strength in the upper extremities to bring the hands toward the head in order to eat, shave and brush the teeth, even though the utensils employed may be held in the hands. The adjustable slings are counterbalanced by sufficient weights to assist in moving the extremities. The elbow rests in the posterior sling, which assists shoulder movements, the wrist and forearm rest in the anterior sling, which assists elbow flexion. The device can be constructed with coiled springs instead of cables and counterweights and also be made to be fastened to a chair, wheel chair or to the head of the bed. Ambulation should be started whenever realistic, even though for short distances, with or without the aid of braces, crutches or canes. The paraplegic patient may need bilateral long leg braces and crutches, while the hemiplegic patient usually requires a short leg brace to prevent foot-drop and a cane in order to at-

Figure 16 Portable double-bilateral assistive slings. A partial quadriplegic patient feeding himself with the aid of the assistive slings. Similar devices can be attached to the wheel chair or bed and also made with suspension coiled springs instead of the cables and counterweights.

tempt ambulation after sufficient training in the parallel bars. If ambulation is beyond the realm of possibility, then the patient should at least be placed in an upright weight-bearing position for short periods once or twice each day. This can be accomplished by means of bilateral long leg braces or on a tilt-board or table. Patients who are unable to stand because of paralysis can be placed in the parallel bars and held securely in a vertical position by means of well-padded straps. One strap is placed behind the feet, one in front of the knees and the other across the buttocks (Fig 17). If needed, for example, with a quadriplegic patient, an additional strap can be placed in front of the chest for further stability during standing. These techniques are of definite help in preventing decubitus ulcers, genitourinary complications and nutritional deficiencies and for their favorable influence in diminishing the frequency and severity of spasms. It is ex-

remely important, in treating the difficult problems associated with upper motor neuron lesions, that both preventive and definitive physical medicine and rehabilitation procedures be instituted early, intensively and for a sufficient time.

Many patients with severe disabilities may require the use of a wheel chair for varying periods during and after their rehabilitation. Other patients will be unable to ambulate and will have to lead a so-called wheel chair life. A great deal of consideration should be given to the exact type of wheel chair a patient is to use for many variations and attachments are available. A complete evaluation should be made of the patient's abilities and a wheel chair secured to meet his needs.

Postural hypotension may be associated with a variant of neurologic lesions and presents a definite problem in rehabilitation. When the patient is placed in a sitting or standing position, the blood pressure drops, the pulse becomes weak and very rapid and the individual becomes pale and may even lose consciousness. A tilt-table that can be gradually elevated from a horizontal to a vertical position is useful in the management of this condition (Fig. 18). The patient is placed on the table in a horizontal position and held securely by several well-padded straps. The table is then elevated approximately 5 or 10 degrees. The blood pressure, pulse and general condition are observed at frequent intervals. The degree of elevation and the time in this position are gradually

Figure 17 A paraplegic patient standing in the parallel bars prior to the use of long leg braces. Note the three well-padded straps for stabilization. When necessary, an additional padded strap can be placed across the front of the chest.

increased until the patient can remain in a vertical position without the development of these untoward effects

LOWER MOTOR NEURON DISORDERS

Objectives. The aims of treatment are to prevent or correct promptly any deformities; to stimulate circulation of the involved part, to institute any indicated dynamic splinting so that if reinnervation takes place the extremity will be able to function in response to voluntary nerve stimuli, to improve and maintain the general physical condition, and to aid in the psychologic adjustment of the patient. In those individuals having poliomyelitis with respiratory involvement requiring the use of a mechanical respirator, the physical medicine procedures must be accomplished during the period the respirator is in use as well as after its employment has been discontinued.

Physical Medicine and Rehabilitation Procedures. *Heat.* To stimulate and maintain circulation of the involved parts, mild heat should be given

Therapeutic exercise. Until active motion is possible, passive exercises to prevent contractures and preserve function of the joints are promptly instituted. Exercise to prevent general deconditioning is imperative

Electrical stimulation. To delay atrophy and aid circulation, electrical stimulation of the paralyzed muscles is indicated. The value of electrical stimulation in poliomyelitis is questionable, for during the process of stimulating the paralyzed muscles the current may spread and produce contraction of the unparalyzed antagonist muscles, resulting in a greater degree of the already existing muscular imbalance

Dynamic splints. When indicated, appropriate splints should be worn by the patient to prevent overstretching of the involved muscles. The springs or elastic on the splint will compensate for the lost motion, while the patient voluntarily contracts the uninvolved muscles. This procedure frequently permits functional activity on the part of the patient.

Massage. Massage must be cautiously applied so as not to traumatize flaccid muscles. Heat, passive exercise and electrical stimulation are more effective in these conditions.

Neuromuscular re-education. This procedure should be started as soon as there is evidence of muscle reinnervation

Traction. Nerve root lesions in the cervical and lumbar regions due to herniated nucleus pulposus and arthritic changes frequently

produce local as well as radicular pain and limitation in motion of the spine and corresponding extremities. Rest, heat and properly instituted traction are indicated as conservative measures

In cervical lesions, traction can be secured by means of a head halter, while heat is applied to the neck and posterior shoulder muscles. The head is supported on a well-padded board having four ball-bearing casters attached to the undersurface.

In lumbar lesions, traction can be applied by means of a pelvic corset or belt while heat is given to the back muscles. The pulley and weights are attached to the foot end of the table which is slightly elevated to prevent the patient from sliding in the direction of the pull

Therapeutic exercises to correct faulty posture and abnormal body mechanics, to increase muscle tone, and to restore mobility of the spine should be gradually started as soon as the acute pain subsides. Proper bed positioning—back- or side-lying with the hips and knees flexed—is indicated. Generally, flexion movements of the spine should be limited. The patient should be taught the proper way to lift objects, to get into and out of his automobile and into and out of a bath tub, and other activities, with a minimum of back flexion. In those patients requiring laminectomy, the therapeutic exercises should be continued postoperatively

AMPUTATIONS

Objectives. In addition to the program being planned to return the amputee to a useful occupation, it is necessary to include the other important objectives, such as the psychologic and social adjustment to the loss of one or more extremities, the securing of a stump having maximum function insofar as range of motion, muscle strength and endurance is concerned, the securing and proper fitting of a suitable artificial extremity to meet the specific needs of the amputee, and sufficient training in the use of the artificial extremity to enable the individual to perform a sufficient number and type of activities that would justify its use. The value of the finest-fitting artificial extremity is markedly decreased in direct ratio to the lack of function of the stump and the motivation of the amputee.

Physical Medicine and Rehabilitation Procedures. *Proper positioning.* The patient and the stump must be properly positioned to prevent contractures of the stump activating and stabilizing muscles

Bandaging of the stump. To aid in shrinking and shaping the stump, proper bandaging should be started at least as soon as the wound has healed.

Therapeutic exercise. Probably the most valuable form of therapy for the stump is therapeutic exercise, which should be started early, in the form of gradual active and active assistive exercise, and then proceed on to progressive resistive exercise to secure a stump having maximum function. In elective amputations, therapeutic exercises should be started prior to amputation and promptly resumed postoperatively. Figure 19 shows some of the exercises used to develop function of an above-elbow stump. These exercises are performed bilaterally and, as soon as indicated, they should be done with progressive resistance.

Artificial extremities. Many types and sizes of both voluntary opening and voluntary closing terminal devices (hands and hooks), each having relative merits depending on the type of work to be accomplished, are available for the upper extremity amputee. The hooks are functionally better than the hands which are cosmetically superior. In the voluntary opening type, the pull of the control cable opens the terminal device, while with the voluntary closing type the pull closes it. An extremely practical voluntary closing hand and interchangeable hook, suitable for many amputees, is the APRIL (Army Prosthetic Research Laboratory) type, which may have the standard above-elbow harness or one of other variety. Most above-elbow amputees desire the dual control harness. The cable, when pulled, serves to flex the elbow to the desired position. The

elbow is locked, then, when the cable is pulled again, it activates the hook or hand. When the pull on the cable is completed, the terminal device automatically locks and maintains the grasp force on the object. When the grasp is to be released, the next pull of the control cable unlocks the device which then automatically returns to the fully opened position. In below-elbow amputations, a biceps cineplasty to operate the terminal device should be considered in the light of the amputee's occupation and his cosmetic requirements. It is important that the biceps muscle be well developed by resistive exercises started preoperatively and resumed postoperatively. The amputee should then be taught to disassociate elbow flexion from biceps contraction, which now will be used only for operating the terminal device.

For selected individuals with above-knee amputations, the suction-socket type of artificial leg, which eliminates the pelvic belts and shoulder harness used with the conventional type, is frequently the most suitable. In putting on the suction-socket leg, a thin piece of stockinet is placed over the stump, the stump is inserted into the socket and then the stockinet is pulled off and out through the opening in the socket for the air valve. After the stump is comfortable, the weight is put on the leg and the valve is inserted to seal the socket. The leg is held on the stump by a slight negative pressure, or "suction," created in the closed socket by the weight of the leg as it is lifted from the ground, assisted by the adherence of the stump to the walls of the socket. The muscles of the stump control all movements of the artificial leg.

Training in use of artificial extremities.

Adequate training is indispensable if the amputee is to achieve a measure of success with his new limbs.

In lower extremity amputations, a pylon (Fig. 20) is usually indicated for training as soon as the wound has healed and further aids in the shaping and shrinking of the stump. The pylon is easily, quickly and inexpensively fabricated and aids the amputee in developing a proper gait, in addition to improving the stump function. This also serves as a therapeutic test in older individuals as to their future ability to use an artificial extremity. The use of parallel bars (Fig. 20) greatly facilitates training in balance, ambulation and proper posture. The parallel bars have adjustable guide rails which aid in developing the proper gait by helping to correct common faults, such as circumduction

Figure 19. Exercises for above-elbow stump. a, Abduction; b, Adduction; c, Flexion; d, Extension; e, Rotation. These exercises are done bilaterally and with progressive resistance as soon as indicated.

increased until the patient can remain in a vertical position without the development of these untoward effects

LOWER MOTOR NEURON DISORDERS

Objectives. The aims of treatment are to prevent or correct promptly any deformities; to stimulate circulation of the involved part; to institute any indicated dynamic splinting so that if reinnervation takes place the extremity will be able to function in response to voluntary nerve stimuli, to improve and maintain the general physical condition, and to aid in the psychologic adjustment of the patient. In those individuals having poliomyelitis with respiratory involvement requiring the use of a mechanical respirator, the physical medicine procedures must be accomplished during the period the respirator is in use as well as after its employment has been discontinued.

Physical Medicine and Rehabilitation Procedures. *Heat.* To stimulate and maintain circulation of the involved parts, mild heat should be given.

Therapeutic exercise. Until active motion is possible, passive exercises to prevent contractures and preserve function of the joints are promptly instituted. Exercise to prevent general deconditioning is imperative.

Electrical stimulation. To delay atrophy and aid circulation, electrical stimulation of the paralyzed muscles is indicated. The value of electrical stimulation in poliomyelitis is questionable, for during the process of stimulating the paralyzed muscles the current may spread and produce contraction of the unparalyzed antagonist muscles, resulting in a greater degree of the already existing muscular imbalance.

Dynamic splints. When indicated, appropriate splints should be worn by the patient to prevent overstretching of the involved muscles. The springs or elastic on the splint will compensate for the lost motion, while the patient voluntarily contracts the uninvolved muscles. This procedure frequently permits functional activity on the part of the patient.

Massage. Massage must be cautiously applied so as not to traumatize flaccid muscles. Heat, passive exercise and electrical stimulation are more effective in these conditions.

Neuromuscular re-education. This procedure should be started as soon as there is evidence of muscle reinnervation.

Traction. Nerve root lesions in the cervical and lumbar regions due to herniated nucleus pulposus and arthritic changes frequently

produce local as well as radicular pain and limitation in motion of the spine and corresponding extremities. Rest, heat and properly instituted traction are indicated as conservative measures.

In cervical lesions, traction can be secured by means of a head halter, while heat is applied to the neck and posterior shoulder muscles. The head is supported on a well-padded board having four ball-bearing casters attached to the undersurface.

In lumbar lesions, traction can be applied by means of a pelvic corset or belt while heat is given to the back muscles. The pulley and weights are attached to the foot end of the table which is slightly elevated to prevent the patient from sliding in the direction of the pull.

Therapeutic exercises to correct faulty posture and abnormal body mechanics, to in-

tioning—back- or side-lying with the hips and knees flexed—is indicated. Generally, flexion movements of the spine should be limited. The patient should be taught the proper way to lift objects, to get into and out of his automobile and into and out of a bath tub, and other activities, with a minimum of back flexion. In those patients requiring laminectomy, the therapeutic exercises should be continued postoperatively.

AMPUTATIONS

Objectives. In addition to the program being planned to return the amputee to a useful occupation, it is necessary to include the other important objectives, such as the psychologic and social adjustment to the loss of one or more extremities, the securing of a stump having maximum function insofar as range of motion, muscle strength and endurance is concerned; the securing and proper fitting of a suitable artificial extremity to meet the specific needs of the amputee, and sufficient training in the use of the artificial extremity to enable the individual to perform a sufficient number and type of activities that would justify its use. The value of the finest-fitting artificial extremity is markedly decreased in direct ratio to the lack of function of the stump and the motivation of the amputee.

Physical Medicine and Rehabilitation Procedures. *Proper positioning.* The patient and the stump must be properly positioned to prevent contractures of the stump activating and stabilizing muscles.

Valuable data can be secured by skin surface temperature tests performed at controlled environmental temperature and humidity and under basal metabolic conditions.

Following application of heat to the upper extremity, the Landis-Gibbon test records the change in skin surface temperature of the lower extremities through the reflex vasodilatation mechanism.

Plethysmography involves the measurement of volume changes in a given body segment.

Alterations in skin surface temperature and sweating patterns are noted following sympathetic nerve blocks.

The step cadence is timed with a metronome in order to have a controlled rate for measured distances to aid in evaluating the circulatory requirements of the lower extremities.

Therapeutic techniques. Proper skin care and the avoidance of trauma and exposure to extremes in temperature are of vital importance.

In patients with impaired venous circulation, hydrotherapy or direct mild radiant heat of low intensity to the extremities can be used, depending upon the severity of involvement. In arterial insufficiency this procedure is dangerous and it is safer to apply heat to the abdomen, chest or back in an attempt to improve the peripheral circulation through reflex mechanisms.

By means of direct current, ion transfer of vasodilating drugs, such as histamine or Mecholyl, into the tissues can be of value in improving circulation and healing ulcers in selected patients. When histamine or Mecholyl is used, the drug is placed on the tissues under the active electrode which is connected to the positive terminal of the battery or direct current generator, while the dispersive electrode, which is placed on the body at a distance from the active electrode, is connected to the negative terminal.

The following mechanical procedures can be tried, if no contraindication exists. The results obtained must be carefully evaluated under controlled conditions.

Massage may be helpful in reducing edema. It is definitely contraindicated in the presence of any infection.

The Buerger-Allen exercises consist of a series of changes in the position of the patient and the extremities, which alters the hydrostatic pressure in the blood vessels of the extremities and may enhance circulation.

The rocking type of bed rhythmically oscillates through a variable arc of approxi-

mately 20 degrees head-down and 30 degrees feet-down, thereby slowly producing elevation and lowering of the entire body with associated changes in the arterial and venous pressures in the lower extremities.

The environmental pressure surrounding the extremity is increased and decreased rhythmically in relation to atmospheric pressure while the part is in a pavex (passive vascular exercises) boot.

By means of a rhythmic inflation and deflation of a cuff around the upper thigh, the venous circulation is occluded for approximately one to three minutes during each cycle and released for similar periods, depending upon the circulation, to produce intermittent venous compression.

The vasopneumatic machine consists of a number of narrow inflatable cuffs, applied to the entire extremity, whereby a peristaltic pressure wave of controlled constriction can be produced both in a centrifugal and centripetal direction, depending upon the circulatory condition being treated.

In those patients with intermittent claudication, a lift under the heel is frequently helpful in increasing the walking distance before the development of leg pain. With this procedure, the calf muscles during the walking process contract minimally and therefore require less blood.

The application of cold is beneficial in preventing or diminishing pain and inflammation and in lessening the absorption of toxins in a severely infected or gangrenous extremity.

THORACIC SURGICAL CONDITIONS

There are specific indications for physical medicine and rehabilitation in thoracic surgical conditions, both tuberculous and non-tuberculous, to further aid in the more rapid return of the individual to his community.

Objectives. The aims are the institution of measures that will aid in returning the patient to useful endeavors and prevent a "chest or respiratory cripple," relief of pain, prevention and correction of deformities of the trunk and restriction of motion and function of the upper extremity. Mobilization of the thorax and re-expansion of a lung, when indicated and compatible with the medical condition and the surgery performed, should be accomplished in order to secure maximum respiratory function. Maintenance of good posture and general physical condition is essential.

Physical Medicine and Rehabilitation Procedures. Orientation. The patient should be

Figure 20 Above-knee amputee learning to am-

and extreme abduction of the legs. The guide rails are adjustable in both horizontal and vertical positions. All gait training, either within or outside of the parallel bars, should be done in front of a full-length mirror.

In bilateral above-knee amputations, the pylons should be constructed about 6 inches shorter than the original length of the legs, when the patient is first learning ambulation because it lends to greater balance, stability and ease in gait training. These are called "stubbies." Later, the pylons can be lengthened to give full height to the amputee.

With the additional program of occupational therapy and manual arts therapy, the arm amputee is taught to perform the maximum number of self-care activities and increase his work capacity. Training should al-

ways start with the hook and later with the hand. Selected amputees can be taught to drive safely an automobile having the proper operating controls. The amputee is further taught the proper care of the stump and the artificial extremity.

General conditioning exercise. The early institution of graduated general exercises to the entire body is essential and an important part of the total program. Proper performance with an artificial extremity is extremely difficult with a weakened body.

Heat. To aid in relieving pain and correcting contractures, mild heat is indicated. In the presence of ulcers and wounds, hydrotherapy is beneficial for cleansing and healing.

Ultrasound therapy. As an aid in relieving pain associated with neuromas and scars, ultrasound therapy has been utilized.

Research. Intensive coordinated research has been in progress by the Veterans Administration, the Armed Forces, various engineering institutions, artificial limb manufacturers, and others to develop improved artificial extremities, utilizing plastics, metals, electronic devices and other materials and appliances. This research also incorporates the study of body mechanics and the fitting and alignment of the prosthesis.

PERIPHERAL VASCULAR DISORDERS

Physical medicine and rehabilitation is indicated as an aid in diagnosis, prognosis and treatment in selected patients having peripheral vascular disorders.

Objectives. The aims are to improve circulation in the extremities by decreasing arterial tone and spasm, to establish collateral circulation, to prevent trauma and infection and to aid the individual to perform the maximum number of self-care activities including ambulation.

Physical Medicine and Rehabilitation Procedures. The instituted program will depend greatly upon the type and extent of the pathologic processes. In many patients, the earlier that conservative treatment is utilized, the greater the possibility of benefit, even perhaps to the saving of an extremity.

Diagnostic techniques. Procedures for evaluating peripheral circulation include:

Palpation of peripheral arterial pulsation of all extremities should be performed

Oscillometric tests are used to measure the pulsatile increase of the volume of an extremity with each cardiac systole which is a reflection of the amount of blood flowing through the main arteries.

tion in ambulatory patients than in those who are confined to bed.

Occupational therapy, manual arts therapy, educational therapy and speech therapy. These additional physical medicine and rehabilitation activities, properly prescribed, can be of tremendous benefit to the patient, not only as an aid in increasing work capacity, but also in preventing or overcoming the many psychologic and emotional problems that exist in the minds of many of the sick, thereby making for better hospital adjustment.

This type of activity participation can also be of an advisory or exploratory nature toward future employment. These far-reaching beneficial effects, especially for one who cannot return to his former type of occupation because of his disability, definitely aid in the getting-well process.

SUMMARY

It is extremely significant that there be an awareness and understanding, on the part of all concerned with the care of the sick, of the importance of physical medicine and rehabilitation in the total rehabilitation of the disabled. It is not offered to supersede or supplant the best medical and surgical procedures, for its greatest benefits are derived when it is completely integrated and coordinated with all of the other professional contributions. The procedures indicated for the various conditions are to be used only as guides and suggestions. There are no routine measures, for with some patients certain techniques may be definitely contraindicated. Coexisting medical conditions may frequently alter the physical medicine and rehabilitation procedures under consideration. The patient's condition governs the type and amount of rehabilitation. It is imperative that intensive research be continued for additional and improved techniques for both diagnosis and treatment.

The role of physical medicine and rehabilitation in geriatric medicine is of extreme importance. The care of the aging and aged has added significance since aging is part of living and the older age group is increasing with time and the advances in medicine. The physiologic changes that are produced during normal aging are further complicated by the effects of disease and injury. Geriatric medicine is a challenging field in which physical medicine and rehabilitation contributes toward the usefulness of elderly individuals.

Physical medicine and rehabilitation is always medically prescribed with precise objectives toward a definite realistic goal to meet the self-care and daily living requirements of the individual person, so that he may obtain the maximum possible benefit toward his physical, mental, social and economic usefulness. Frequently, after discharge from the hospital, the person may benefit by temporary employment in a sheltered workshop before attempting full employment in a competitive environment. By minimizing the degree of handicap, total rehabilitation can bring to the disabled a satisfactory measure of happiness and contentment leading toward a fuller life.

oriented preoperatively as to the planned program. This will also include preoperative preventive treatment. Postoperatively, the treatment procedures should be gradually reinstituted as soon as medically feasible, which is usually on the first postoperative day.

Correct bed posture. Proper pillow arrangement and positioning of the patient in bed are important in helping to prevent postural deformities.

Therapeutic exercise. General body relaxation exercises are indicated and should be initiated early, particularly during the bed rest period. Active and active assistive exercises of the upper extremity and shoulder to prevent restriction of movement, especially in abduction and external rotation of the shoulder, should be promptly started. As soon as indicated, graduated resistive exercises should be instituted. General conditioning exercises should also be instituted early. Wands, pulleys and weights are helpful aids, especially for symmetrical exercises which, whenever possible, should be performed before a mirror.

Breathing exercises. Hemithorax measurements of the respiratory movements of both halves of the thorax, taken simultaneously, and spirometric readings should be secured periodically to evaluate progress.

When lung expansion is desired, diaphragmatic (abdominal) breathing, as well as segmental chest movements, is started. When not contraindicated, the use of "blow-bottles" is helpful to attempt to re-expand a collapsed lung. In pulmonary tuberculosis and following collapse therapy, such as in thoracoplasty, breathing exercises of the abdominal type only are advisable.

Heat. To aid in the relief of pain and as an adjunct in the stretching of contractures, mild heat is beneficial.

Work capacity. A selected, graded and controlled program of activity including occupational therapy, manual arts therapy and educational therapy will aid in motivating the patient in overcoming his psychologic and emotional problems and in increasing his work capacity and also will serve as an excellent vocational exploratory technique.

OTHER SURGICAL CONDITIONS

There are numerous other surgical conditions, such as abdominal operations, which can be benefited by both preoperative and postoperative properly prescribed physical medicine and rehabilitation measures.

Objectives. Through a therapeutic exercise

program including early ambulation, the individual develops a sense of well-being and is greatly aided toward a more rapid return to normal activity and economic usefulness. Many complications are prevented or minimized and the patient's hospitalization period is reduced.

Physical Medicine and Rehabilitation Procedures. The type and extent of the conditioning and early ambulation program must be guided by the type and extent of the surgical procedures and the general condition of the patient. The closest coordination between the surgeon and the physiatrist is imperative. The patient must be oriented to the necessity and benefits of the activities, for this will help to allay anxiety, apprehension and any fears, thereby obtaining his maximum cooperation toward the total rehabilitation regimen.

Therapeutic exercise. Graduated general body conditioning exercises, under close supervision, should be instituted preoperatively if possible, and promptly resumed postoperatively, to avoid the debilitating effects of bed rest. Activity frequently aids in controlling the ill effects that are temporarily produced by the procedures associated with the actual surgical intervention.

Ambulation. Shortly after surgery, ambulation is desirable and necessary. The patient should be taught the proper method of getting into and out of bed and walking with the least effort. This is easier to accomplish shortly after surgery than after the patient has been confined to bed for a number of days without activity. Walking distances should be gradually increased and attention given to correct posture. Proper breathing exercises are also included.

Prolonged immobilization in bed interferes with the normal physiologic processes of the body in the normal individual, but more so during illness, and also predisposes to psychologic and emotional problems. The latter may be a contributory factor to "hospitalitis."

Contraindications to a judiciously prescribed and individualized exercise and early ambulation program are perhaps relatively few. At certain times, however, they may not be advisable, i.e.

therapeutic Shock, internal hemorrhage and severe systemic infections are usually contraindications to early ambulation. It has been observed over many years that postoperative fever is frequently lower and of lesser dura-

THE VASCULAR SYSTEM

The Veins

By HAROLD LAUFMAN, M.D.

HAROLD LAUFMAN was born in Wisconsin and educated at the University of Chicago and Rush Medical College. His graduate education in surgery was pursued further at Northwestern University. There he has continued to make important research contributions to surgery. His talents as an artist have won recognition among that group of surgeons who have an unusual creative artistic gift along with their surgical abilities.

When man assumed an upright posture his venous system—at best a relatively inefficient conduit system—became subject to added burdens. The veins serve as little more than channels to return blood to the heart. Propulsion of blood through veins is primarily dependent upon what force remains after arterial blood has passed through the capillary bed. Venous flow is assisted by such auxiliary measures as the sucking action of respiration, skeletal muscle contraction, the valves, and gravity, except in the lower portion of the body where gravity hinders venous flow. These aids to venous circulation have not prevented the venous system of man from falling heir to the consequences of stagnant flow. When extraneous influences such as injury, infection and obstruction to flow become superimposed, the veins and the spent,

poorly oxygenated blood they carry become ready ground for pathologic alteration.

ANATOMY AND PHYSIOLOGY

In the extremities and mesentery, the veins are more or less paired with the arteries. This relationship, however, is not constant throughout the body, for in some areas, such as the liver, cranium and chest, the veins and arteries run independent courses. The muscular coat of veins is considerably thinner than that of arteries, and possesses neither the contractile power nor strength of artery muscle. Consequently, spasm in veins, though it does occur, is not extreme and distention may become marked with moderate increases in venous pressure. Persistently elevated venous pressure can overstretch and attenuate the muscular coat of vein walls to such an

are higher than normal and walking causes no drop or only a moderate drop. Actual reversal of flow has been demonstrated in some individuals with varicose veins.

The two main diseases of veins are varicosities and thrombophlebitis. It is of more than passing interest that these diseases often occur together as interdependent cause-and-effect entities, although they may appear independently.

VARICOSE VEINS

Varicose veins appear as tortuous dilated distortions of otherwise relatively straight veins. Varices may appear in several areas of the body. The commonest types aside from those of the lower extremities are esophageal varices, usually resulting from portal hypertension, varices of the spermatic veins, dilatation of the inferior hemorrhoidal veins,

varices of the broad ligament, urinary bladder and prostatic venous plexus, and varices of the central nervous system.

Incidence. Various estimates of the incidence of varicose veins have been made, but in general it probably can be said that about 10 per cent of all adults over thirty-five years of age have some degree of varicose change in their saphenous venous system.

Etiology. The fundamental defect responsible for varicosities in the legs is probably incompetence of the valves in the connecting veins between the superficial and deep venous systems (Fig. 1). When incompetent, the valves no longer prevent backflow and thus allow blood with a greater than normal pressure-head to fill the superficial system. Important factors in the etiology of varicose veins are heredity, increased postural strain, trauma, compression or constriction of veins and phlebitis of the deep venous system.

Congenital weakness of veins appears to be a familial tendency. One can often find the same defect in one or both parents. The offspring of parents with varicosities tend to develop varicosities at a young age. In addition to familial, or perhaps congenital, weakness of vein walls, other etiologic factors may be endocrine, or even chemical, changes.

Prolonged standing is said to produce enough undue strain to cause varicosities. However, examination of people who might be predisposed by their occupations (e.g., floor walkers and policemen) does not show a higher incidence of varicose veins in this group than in any other segment of the population. On the other hand, it is possible that such occupations may aggravate previously existing tendencies to varicose vein formation.

Other factors tending to increase venous pressure in the legs include constricting garters, enlarged lymph nodes, pelvic tumors and similar agents. The relatively high incidence of symptomatic varicose veins during pregnancy has aroused curiosity regarding a possible relationship. Occasionally the most severe symptoms occur in the early stages of pregnancy, long before the growing uterus reaches its greatest size. This observation has led to the speculation that an endocrine factor may produce weakness of the vein walls. However, the congestion within the pelvis during the early stages of pregnancy may more than offset the relatively small size of the uterus as a pressure phenomenon.

The superficial venous system of the leg is less able to cope with the stress of increased

Figure 1 Schematic representation of venous blood flow in superficial and deep veins of the legs. A, Normal relationship. Competent valves permit blood to flow only proximally and only from superficial to deep veins. B, Incompetent valves allow reversal of flow, from deep to superficial veins, causing the latter to dilate and become tortuous. Valves in deep vein may remain competent.

extent that the muscle loses its homeostatic ability to resume normal tonus. The result may be irreversible ballooning and tortuosity. Alterations in the vein wall itself may weaken its structure.

The veins of the extremities contain valves, whereas those of the abdomen, thorax and cranium do not. Venous valves are arranged in such a way that blood flows past them toward the heart. They are cup shaped, with their concave face pointing proximally. Their function apparently is to prevent backflow under sudden increases in venous hydrostatic pressure and to aid in the directional flow of blood when venous pressure falls to low levels. Valves are located rather irregularly along the main stem veins but invariably occur at the branching sites between deep and superficial vein systems in the extremities.

The deep and superficial sets of veins in the leg bear special consideration, since their differences and their relationship with each other may be the background for disabling disease. The superficial set of veins—the saphenous system—lies between the deep fascia and skin, surrounded only by weak superficial fascia and a variable amount of subcutaneous fat. The deep set—the femoral vein system—is housed in muscular compartments, or fascial spaces. The two systems connect at two main points, in the groin (saphenofemoral junction) and in the popliteal space (lesser saphenopopliteal junction). Valves exist at these junctions. The two systems are also connected by a number of connecting (so-called perforating or communicating) veins, each containing valves, as well as by many smaller anastomotic veins. Thus, blood flowing from the toes to the heart has many alternate routes of flow. Communications between the deep and superficial venous systems of the leg are most numerous in the foot, less in the calf and least in the thigh.

The great saphenous vein runs the entire length of the leg from foot to groin. Its course is along the medial aspect of the leg, at the ankle it is anterior to the medial malleolus, it ascends posteromedially behind the medial condyle of the femur, then directly to the fossa ovalis of the superficial fascia inferior to the inguinal ligament. It dips medially and deep to join the femoral vein. Branches at or near the saphenofemoral junction are of surgical importance, since all must be recognized and divided in order that excision of the great saphenous vein for varicocities will not be followed by recurrence of the condition. As a rule, five branches with

or without variations are seen. These are: the superficial inferior epigastric vein, which ascends from the junction to run in a cephalad direction, the superficial circumflex iliac vein, which takes an obliquely lateral course, the superficial external pudendal vein, which runs medially; the medial and lateral femoral cutaneous veins, which take an obliquely downward course. Variations on this basic anatomic pattern may be extreme, and as many as twelve or more branches may be found.

The lesser saphenous vein collects superficial venous drainage from the lateral malleolar area and posterolateral region of the calf and ascends to the popliteal space, where it dips below a strong layer of the superficial fascia to join the popliteal vein.

Neither the great nor the lesser saphenous vein is accompanied by arteries.

The deep veins of the leg, on the other hand, are paired with arteries. The anterior and posterior tibial veins approach the midline as they ascend in the leg and join approximately in the posterior midline to form the popliteal vein behind the knee. The popliteal vein perforates the adductor magnus muscle to reach the adductor canal, at which point it is known as the femoral vein or superficial femoral vein. The femoral vein and artery are closely associated in the remainder of their cephalad course, the vein lying lateral and posterior to the artery in the lower thigh, and medial to it at the inguinal area.

The profunda femoris, or deep femoral vein, collects blood from the deep thigh muscles and emerges to join the superficial femoral vein about an inch and a half below the inguinal ligament. The profunda femoris vein has generous anastomotic connections with the branches of the inferior gluteal vein above and popliteal vein below.

Above the juncture of the deep and superficial femoral veins, the common stem is known as the common femoral vein. As it dips behind the inguinal ligament it becomes the external iliac vein. In the pelvis it is joined by the internal iliac (hypogastric) vein to form the common iliac vein. The latter joins its opposite fellow to form the inferior vena cava.

Normally, venous pressure in the lower extremity is highest upon standing and lowest when the legs are elevated. Under normal circumstances, after an initial slight rise, it drops precipitously during walking. The motion undoubtedly has a milking effect which aids in emptying the veins. In the presence of i

the saphenous and communicating veins (Fig 2). With the patient sitting or lying, the leg is elevated above the level of the pelvis so that the superficial veins empty by gravity, assisted by upward massage by the examiner's hand. Compression is then made over the fossa ovalis in the groin, either by the examiner's fingers or by a tourniquet, in order to compress the saphenofemoral junction. The patient is then asked to stand. If the saphenofemoral valve is the sole source of the incompetency, the veins will remain empty for a minute or two before filling slowly from below. Removal of the compressing fingers or tourniquet before complete filling permits rapid filling from above. Rapid filling from below in the presence of the pressure indicates incompetence of one or more perforating veins below the level of the constriction. The site of the incompetency can be found by repeating the maneuver with the tourniquet placed at various lower levels. The short saphenous vein may be a contributing or the sole source of the varicosities. Incompetency of the valve at the junction of the short saphenous and popliteal veins can be tested by a similar method at that level.

Perthes' test is performed in order to test the patency of the deep venous system. The test is carried out by constricting the saphenous trunk in the thigh by use of a tourniquet. The patient is asked to exercise his leg by some such maneuver as kicking it vigorously back and forth or by walking about the room. With exercise, blood normally is routed into the deep veins, causing the varicosities to empty. If the deep veins are not patent or if there is increased hydrostatic pressure in the deep veins, the varicosities will not diminish in size. *Perthes' test* is not of much practical value in most instances because the deep veins are almost never blocked so completely that some channel will not be available for the flow of venous blood.

Several other tests have been devised to locate the position of incompetent perforating veins. However, most of these tests are of little more than academic interest to the surgeon. In the present-day surgical approach to the problem, the entire main stem is usually eradicated by stripping. Thus, all perforating branches are interrupted where they join the great saphenous vein and their exact location is not crucial.

Complications. So-called *varicose ulcer* occurs characteristically in the lower third of the leg or in the area of the malleoli. Almost

without exception, a varicose ulcer appears directly over a vein. For this reason its pathogenesis has been ascribed to periphlebitis which occurs as a sequela to localized phlebitis. The inflammatory reaction about the vein is said to choke off the nutrient blood supply to that portion of the skin. When such an area of skin is irritated by trauma, it does not heal normally. Instead, the tissue may break down and ulcer formation results. Therefore, varicose ulcer is not due to varicose veins alone, for, if it were, ulcers would occur in other areas of the legs where varicosities may be more extensive. Nor is stasis alone responsible, since ulcers rarely occur on the foot. The relatively poor blood supply to the skin in the area above the malleoli and the characteristic location of an ulcer directly over veins in this area are factors responsible for the phlebitis concept. As a rule, varicose ulcers occur more readily in limbs which have been previously afflicted with deep vein thrombophlebitis, complicated by chronic circulatory changes in the skin.

Although *edema* is not always a characteristic sequela to otherwise uncomplicated varicose veins, it occurs in a large number of the patients. The examiner must be careful to exclude the possibility of systemic causes of ankle edema if the condition is bilateral. Edema which occurs with otherwise uncomplicated varicose veins tends to be accentuated toward the end of the day and to subside with elevation of the limb. If the edema is associated with pain and with shiny skin and tenderness of tissue, one should suspect deep vein occlusion or thrombophlebitis.

Rupture of varicosities may take place with loss of considerable blood. This may occur without warning, particularly in patients who have superficially placed varicosities. In such individuals the veins have a deep blue color and are covered only by a thinned layer of dermis. Such simple activities as crossing the legs may result in bleeding, first noticed by a surprisingly large flow of blood down the leg, without pain. Such bleeding is usually easily controlled by elevation of the limb and the application of a pressure bandage.

Thrombophlebitis is a relatively frequent complication of varicose veins. Local areas of thrombophlebitis of the superficial veins are probably more the result of stasis and trauma than of bacterial invasion. The usual clinical picture is that of a painful, red, tender area of the skin overlying a firm segment of vein. Such involvement may vary from a low-grade

hydrostatic pressure than is the deep system, since it lies relatively unsupported in the subcutaneous tissue. Venous flow through the deep system is aided by the support of relatively strong tissues, such as muscle and fascia, and by the contractions of the muscles. Undue increases in hydrostatic pressure tend to follow paths of least resistance. Increased femoral vein pressure is thus transmitted through communications to the superficial veins of the leg. The valves at these junctions give way and become incompetent and the disproportionately high pressures in the poorly supported saphenous system may lead to tortuosity.

So-called secondary varicosities may follow by months or years the development of deep vein thrombophlebitis. A greater load of venous blood than is normal is shunted into the superficial venous system following blockage of the deeper veins and the ensuing incompetence of their valves after recanalization.

Pathology. Microscopic examination of the dilated, tortuous, thinned-out veins reveals areas of musculature hypertrophy interspersed with areas of remarkable thinning of the vein wall. Fibrosis is widespread. Low-grade inflammatory changes are frequent. Phlebosclerosis, with actual calcium deposition as a sequela to fibrosis, is a rather common finding, even in the relatively young patient.

Occasionally the venous stasis is carried into the tiny intradermal radicals. When this occurs, so-called spider burst or spider web varicosities are seen in the skin. Microscopic examination reveals these areas to be tortuous enlargements of the subpapillary plexus of intradermal veins.

Arteriovenous fistulae, particularly of the minute multiple type, are often associated with varicosities and have been ascribed an etiologic role in certain cases.

Symptoms. Great disparity often exists between the clinical appearance of varicose veins and the symptoms they produce. Thus, patients with minimal varicosities might have severe symptoms, while some with markedly tortuous veins have minimal or no symptoms. As a rule, the early symptoms are heaviness, drawing sensations and cramping, particularly in the region of veins, and especially while standing. Pain is a variable symptom and most often occurs in conjunction with localized areas of thrombosis. However, it may occur in the absence of thrombosis and may be accentuated by pressure or by the presence of a cluster of varices. The most severe symptoms are due to the complica-

Figure 2 Trendelenburg test. A, Incompetent great saphenous vein with marked varicosities. B, Leg elevated above level of pelvis to empty veins. Emptying aided by gentle upward massage. C, Occlusion of saphenofemoral junction by examiner's fingers, veins remain relatively empty when patient stands, refill rapidly from above when hand is removed.

tions of varicose veins such as dermatitis, ulceration and superficial thrombophlebitis. Curiously, symptoms may be more severe in the earlier, developmental stages of varicose veins than later.

Diagnosis. Because patients with varicose veins often have other infirmities of middle age, symptoms are often erroneously ascribed to the veins. On examination, static deformities, arthritis, sciatic neuritis, myositis and arterial system symptoms may be the actual cause of the symptoms present in a patient who has varicose veins. Patients often express great disappointment when symptoms do not disappear upon removal of the varicose veins. Thus, careful history taking and physical examination are important. A complete physical examination should accompany every local examination for varicose veins to search for constitutional diseases, infectious diseases, peripheral arterial disease and abdominal tumors.

Observation of the legs should begin with the patient standing. Once the extent and location of the varicose veins have been determined, it is traditional to perform the Trendelenburg test and Perthes test.

The Trendelenburg test is made to determine the location of the valves in

infarction or death from pulmonary embolism. This phenomenon, known as thromboembolism, unfortunately is still as prominent a cause of death today as it was before the advent of modern advances in treatment and prevention. Our inability to recognize the existence of bland thrombosis in the lower limbs early enough and our ever-increasing success in surgery upon poor-risk patients probably keep the incidence high. Bland thrombosis, or "silent" thrombosis, originally described by Homans in 1931, more recently has been termed phlebothrombosis by Ochsmier and DeBakey. The most usual site for this type of thrombosis is the deep veins of the legs.

Etiology and Pathogenesis. In the earliest stages of bland thrombosis, a fresh clot appears in a vein which otherwise may exhibit no obvious changes. Many theories have been devised to explain this occurrence, some based upon sound experimental or clinical

evidence, others deduced from known applicable facts.

Most instances of venous thrombosis in the lower extremities occur without a demonstrable precipitating factor. Possible causative factors may be divided into three main groups: local vessel changes, such as intimal damage; venous stasis; and changes in the coagulating properties of the blood.

It is plausible to suspect that intimal damage due to local injury or disease in the vein wall is a likely cause of bland thrombosis (Fig. 3). While extensive studies of the veins of patients dying of thromboembolism do not appear to bear out this concept, experimental thromboses can be produced by deliberate intimal damage.

Venous stasis has long been suspected as an etiologic influence in phlebothrombosis. Supportive evidence for this relationship has been provided by close examination of fresh, small thrombi seen to originate in areas

Figure 3. Natural history of venous thrombosis in lower extremity. A, Fresh clot forming on proximal surface of valves. B, Retraction of clot (more pronounced in anemia) and attachment to vein wall, beginning involvement of vein wall in reactive process. C, Further organization of clot and involvement of vein wall (note valve structure not easily discernible from organized clot, on section), propagation of fresh "tail" clot on thrombus (this portion may be swept away as an embolus). Note in sketches D and E that vein wall and organized thrombus appear almost indistinguishable from each other (adopted from Hussey).

inflammatory reaction to a severe suppurative type of lesion with systemic septic phenomena. As a rule, inflammatory types of thrombophlebitis in superficial veins do not produce embolism.

Varicose dermatitis varies from the leathery, scaly discoloration so often seen in patients with long-standing varicose veins to an acutely inflammatory, red, itching, burning type of lesion. The dermatitis is usually located over the lower third of the limb. The lesion has been termed varicose eczema and may be due in some cases to allergic phenomena. Secondary pyogenic or fungal invasion is not uncommon.

Treatment. The treatment of varicose veins can be divided into conservative and operative measures. The conservative treatment is reserved for patients who for some reason cannot withstand surgery and for those whose involvement is minimal. As a temporary palliative measure, when surgery cannot be undertaken, wearing elastic stockings from toes to groin offers symptomatic palliation. They compress the superficial veins and shunt venous flow through the deep veins. When the veins are minimal and consist only of an occasional small, tortuous twig in the absence of a positive reaction to the Trendelenburg test, such a small segment can usually be obliterated by the injection treatment.

Injection treatment consists of the injection of a sclerosing solution directly into the vein. This mode of treatment is usually temporary. There are some definite contraindications to injection treatment. It should not be carried out in the presence of an acute upper respiratory infection, uncontrolled diabetes, local ulcers or inflammation or advanced arterial disease of the legs and it should be avoided if the patient has a history of cardiovascular accident. A few deaths from embolism following the injection treatment of varicose veins have been reported. An obvious criticism of this form of treatment is that it only obliterates the immediately visible segment and there is no assurance that the obliterated vein will not become recanalized. Hence, in the presence of a positive reaction to the Trendelenburg test, the sclerosing treatment of veins is of no value, since the main stem is incompetent. Also, when the varicosities are secondary to deep vein disease, this type of treatment is worthless.

Today the greatest usefulness of the injection treatment lies in the postsurgical period, at which time small remaining vari-

ces may be obliterated if they persist after main-stem stripping.

A wide variety of solutions have been used, including hypertonic glucose solutions and alkaline soap solutions, such as sodium morrhuate, sodium ricinoleate and sodium lauroleate. They act by producing a local thrombus.

Injectations are made with the patient standing and with no tourniquet on the leg. Care must be exercised not to allow any of the irritating solution to reach the perivenous tissues. If this occurs, a painful irritation may be set up, which may lead to sloughing of the skin. Injectations are usually made no more often than a week apart.

Surgical treatment for varicose veins consists in the ligation and separation of the great saphenous vein at the saphenofemoral junction, ligation and severance of all the branches arising from this area of the saphenous vein, and removal of the entire length of the great saphenous vein from the groin to the ankle. If indicated, the lesser saphenous vein at its juncture with the popliteal vein behind the knee is similarly ligated and stripped. Separate incisions may have to be made to remove clusters of veins which are only indirectly connected with the main stream. Only by such a complete maneuver can one expect to remove most of the involved veins as well as the main, incompetent channels. If new, small varicosities should appear in the months following surgery, these may be injected or excised. Despite this radical type of treatment, a few patients, particularly those with secondary varicosities pursuant to deep vein thrombophlebitis, will have recurrences.

A most important feature of surgical treatment is patient, long-term follow-up, so that new varicosities may be handled appropriately.

PHLEBOTHROMBOSIS AND THROMBOPHLEBITIS

As the name implies, thrombophlebitis is a composite disease consisting of thrombosis of blood within a vein and inflammatory involvement of the vein wall. A wide variety of types exists, depending upon degree of severity, extent of involvement, anatomic location and amount of inflammatory reaction.

The problem of thrombophlebitis is an important one, not only because of its local effects, but because of the propensity for portions of the venous clot to break off and travel back to the heart and into the pulmonary artery. The result may be pulmonary

usually does not give rise to emboli. Thrombophlebitis occurring in an uninjured limb of an otherwise healthy person may be the first clinical indication of thromboangiitis obliterans—this happens in some 10 per cent of patients with thromboangiitis obliterans—and as an occasional first sign of carcinoma of the pancreas or lung or of certain blood dyscrasias. Hence, the occurrence of otherwise unexplained thrombophlebitis is reason enough for careful search for undetected neoplastic or systemic disease.

Surgeons have long held the impression that major, time-consuming abdominal operations, especially those involving great blood loss or those producing hypotension, are more liable to be followed by venous complications than are the more superficial or shorter operative procedures. Acutely ill medical patients appear to be more susceptible than do many chronic invalids. Bed rest is certainly not the only precipitating cause, as evidenced by the extremely low incidence of thrombotic disease among chronically bedridden patients.

Partial obstruction to return flow from the lower limbs may result from tumors of the pelvis, unusual positioning during surgery, abdominal distention and pregnancy. Stagnation and thrombosis may result.

Sites of Thrombosis in Lower Extremities (Fig. 5). It has been supposed that thrombi originate predominantly in the smaller, deep veins of the calf. However, meticulous post-mortem dissections reveal the distribution of clots to be extremely widespread and their location appears to bear little relationship to ante-mortem local symptoms. In some 40 per cent of the patients, thrombi occur bilaterally in the lower extremities. The deep femoral venous system of the thigh contains thrombi oftener than does the superficial femoral venous system in the thigh and the calf, including the so-called deep veins of the calf. The internal iliac veins contain thrombi in only 6 per cent of the subjects. Thus it would appear that phlebothrombosis actually is more common in the deep femoral vein branches of the thigh than in the calf veins, although clinical symptoms are more readily detectable when it is in the calf.

It has been suggested that thrombi in the legs begin during surgery, although they may not become clinically evident for several days, or perhaps not at all.

Incidence. Despite all the therapeutic and diagnostic advances in recent years, the incidence of phlebothrombosis, thrombophlebitis and thromboembolism has not changed ap-

preciably. Failure to recognize a bland thrombus until embolism occurs has no doubt kept the incidence of embolism virtually constant. A review of reports from all over the world involving over three million operations showed an incidence of fatal pulmonary embolism ranging from 0.1 to 0.87 per cent, averaging 0.14 per cent, with remarkably little change over the past fifty years. When statistics were based upon autopsy findings, the incidence of death from pulmonary embolism varied from 0.2 to 23 per cent, with an average of 2.8 per cent. In these long range statistics, there appeared an interesting but unexplained wavelike periodicity, even in the same institution. On a shorter range basis, thromboembolism appears to be more prevalent in the spring and autumn months in temperate climates. Since 95 per cent of all fatal pulmonary emboli are said to originate in the lower extremities, this anatomic site has naturally attracted the most attention for diagnosis and prophylactic treatment.

Among hospitalized patients, sixty of every

where stagnation is maximal—in the cul-de-sacs formed by the proximal surfaces of venous valves. As the clot grows and becomes organized, this localization becomes less and less obvious because of propagation and involvement of the entire contiguous vein wall.

Changes in the coagulative properties of the blood have been found postoperatively in some patients, but studies on blood fibrinogen, antithrombin, fibrinolysin and platelet counts have been unfruitful. Under certain circumstances, such as following splenectomy, increased platelet counts do parallel an increased tendency to thrombosis.

Many clinical conditions seem to predispose to venous thrombosis. These include surgical operations, injuries, burns, infectious diseases, cancer, especially pulmonary and pancreatic, dehydration, shock, heart failure, myocardial infarction, polycythemia vera, anemia, advancing age, bed rest, obesity, pregnancy and the puerperium. A perusal of this list reveals that slowed circulation or stagnation is common to most of the conditions, that hypoxia prevails in others and that perhaps some enzymatic change in the cir-

culating protein moieties of the blood may be held responsible in certain instances, as in carcinoma of the pancreas and lung.

Bland thrombosis usually originates in the deep veins of the legs, although occasionally other sites may be involved. The more inflammatory types of thrombophlebitis, which may vary from low-grade nonbacterial inflammation of the vein to full-blown suppurative lesion, are best known to occur in superficial veins of the legs, in pelvic veins, in the appendiceal vein (pyelephlebitis) and in veins accompanying the arteries in thromboangiitis obliterans (Buerger's disease).

Microscopic examination of the site of clinically bland phlebothrombosis reveals that after forty-eight to seventy-two hours this lesion is indistinguishable from actual thrombophlebitis (Fig 4). Thus, strictly speaking, the term phlebothrombosis applies only to lesions of perhaps less than four days' duration.

Suppurative thrombophlebitis may occasionally follow postpartum or postabortal sepsis. So-called migratory thrombophlebitis usually involves only the superficial veins and

thigh and foot. This examination should be done with only moderate pressure between the bellies of the gastrocnemius muscle, in the popliteal space and along the medial and posterior aspects of the thigh. The knee is moderately flexed during palpation. The examiner must learn to distinguish between the response to abnormal degrees of pain on the one hand, and the discomfort produced by too strenuous palpation on the other. This sign is not very reliable, since other causes for calf tenderness may confuse the picture.

5. *Homan's sign*, or dorsiflexion test. This maneuver consists of dorsiflexing the foot of the patient while the knee is extended. If dorsiflexion of the foot elicits pain in the calf or popliteal area, the reaction to the test is positive. However, as in the palpation maneuver, the test is not pathognomonic for thrombosis.

6. *Sphygmomanometer cuff pain test* (Lovenberg). The pneumatic cuff of the sphygmomanometer is placed about the calf or thigh and slowly inflated. Normally patients do not register discomfort at pressures below 150 mm. Hg on the calf or thigh. In the presence of thrombosis, the patient complains bitterly of pain at a pressure significantly below the normal. At this point the cuff is immediately deflated and the test is repeated on the other calf. The patient should not be alerted to the possibility of pain but should be watched for alteration of facial expression or a withdrawal reaction, such as flexing the thigh. This test appears to be the most sensitive and perhaps the most valuable of the diagnostic procedures available today to detect early bland thrombosis in the legs.

7. *Elicitation of pain on calf muscle rocking*. This is an acceptable clinical test, perhaps somewhat more sensitive than the palpation test, but not as reliable as the cuff test. The knee is slightly bent with the heel resting on the bed. The calf muscle group is rocked back and forth in its relaxed state. Severe pain or discomfort is suggestive of thrombosis.

8. *The cough-pain test* (Lawrence). The reaction to this test may occasionally be suggestive of thrombosis. Local pain on coughing has been claimed to be of some value especially in acute thrombophlebitis.

9. Search for other local signs, such as superficial venous congestion, dilated pretibial veins, etc.

may be present when the sign is pronounced, but as

a rule they are absent in most patients with early, bland phlebothrombosis.

Prognosis of Thrombophlebitis of Lower Extremities. Thrombophlebitis may progress along one of four lines: eventually no residual detectable sign of the original disease may be found, chronic venous insufficiency of the involved leg may give symptoms for life, death from pulmonary embolism may occur, pulmonary infarction may follow nonfatal pulmonary embolism.

No residual, detectable lesion. Probably in the majority of the milder cases of thrombophlebitis of the lower extremities the disease subsides completely in due time, in some cases because of good treatment, in others without adequate treatment. In the latter group are perhaps many originally unrecognized cases. In many patients mild residual edema of one extremity, with or without pain, will eventually subside completely. It must be remembered, however, that one attack predisposes to another, particularly after another surgical operation or injury or recurrent illness, such as heart failure. Consequently, a painstakingly careful history regarding leg symptoms after previous surgical procedures or illnesses is mandatory. Only by such screening can prophylactic measures be properly instituted.

Chronic venous insufficiency (postphlebitic syndrome). In a large percentage of patients the first indication of postpartum or postoperative thrombosis is the development of a pale, swollen, painful leg as ambulation is resumed postoperatively. This type of limb

Figure 7. Phlegmasia alba dolens (milk leg).

Figure 6 Some useful maneuvers to detect phlebothrombosis. A, Circumferential measurements using fixed sites on limbs. B, Palpation for tenderness between bellies of gastrocnemius muscle and popliteal area. C, Homans' sign or dorsiflexion test. D, Sphygmomanometer cuff pain test (Lowenberg) on calf or thigh.

100 patients with pulmonary embolism are on medical services, the remaining forty coming from surgical services. In 20 to 25 per cent of the patients, the first embolus is the fatal one. From 53 to 94 per cent of patients who die of pulmonary embolism, or who exhibit pulmonary embolism at post-mortem examination, were not known to have had any thromboembolic disease. In one series, the first signs of thrombosis were recognized in 74 per cent of patients only after massive pulmonary embolism.

It is obvious from these figures that significant numbers of patients have thrombotic disease without its being recognized. Therefore the true incidence of phlebothrombosis is not known. More important is the obvious inability on the part of the clinician to diagnose the condition early enough.

Clinical Picture of Phlebothrombosis and Thrombophlebitis. Superficial thrombophlebitis is ordinarily easy to diagnose because of the readily observed local signs, such as redness, local heat and subjective pain, supplemented by the usual systemic signs of inflammation, such as fever, tachycardia, rapid sedimentation rate and leukocytosis. The systemic signs vary in degree according to the amount of inflammation.

The diagnosis of deep vein thrombosis of the lower extremities is much more elusive and, as mentioned, the lesion often goes unrecognized. The diagnosis can sometimes be derived inferentially by an otherwise unexplained occurrence of the systemic signs

listed above for thrombophlebitis. When such signs appear they are usually soon supported by the detection of local signs of venous thrombosis or by those of pulmonary embolism.

The incidence of phlebothrombosis in a given institution is usually proportional to the diligence with which the condition is searched for. If daily examination of the leg is carefully carried out on both the surgical and medical services, the number of detected cases will be higher than if such examinations are not done.

The routine examination for silent deep vein thrombosis includes the following (Fig 6):

1. Precise questioning about soreness or discomfort in the legs. Unless specifically questioned along these lines, at least half of all postoperative patients fail to mention spontaneously aches in the calf muscles or other comparable minor symptoms.

2. Inspection of legs for slight changes in color. Incipient cyanosis of the skin may not be obvious unless the legs are dependent, as in sitting or standing. Comparison of one leg with the other makes for more accurate judgment than examining each leg separately. This test is not reliable in the earliest cases of bland thrombosis.

3. Measurement of the circumference of the legs at given points in the thigh, calf and ankle and, most important, comparison with preoperative measurements.

4. Palpation for tenderness in the calf,

thigh and foot. This examination should be done with only moderate pressure between the bellies of the gastrocnemius muscle, in the popliteal space and along the medial and posterior aspects of the thigh. The knee is moderately flexed during palpation. The examiner must learn to distinguish between the response to abnormal degrees of pain on the one hand, and the discomfort produced by too strenuous palpation on the other. This sign is not very reliable, since other causes for calf tenderness may confuse the picture.

5 Homans' sign, or dorsiflexion test. This maneuver consists of dorsiflexing the foot of the patient while the knee is extended. If dorsiflexion of the foot elicits pain in the calf or popliteal area, the reaction to the test is positive. However, as in the palpation maneuver, the test is not pathognomonic for thrombosis.

6 Sphygmomanometer cuff pain test (Lowenberg). The pneumatic cuff of the sphygmomanometer is placed about the calf or thigh and slowly inflated. Normally patients do not register discomfort at pressures below 150 mm. Hg on the calf or thigh. In the presence of thrombosis, the patient complains bitterly of pain at a pressure significantly below the normal. At this point the cuff is immediately deflated and the test is repeated on the other calf. The patient should not be alerted to the possibility of pain but should be watched for alteration of facial expression or a withdrawal reaction, such as flexing the thigh. This test appears to be the most sensitive and perhaps the most valuable of the diagnostic procedures available today to detect early bland thrombosis in the legs.

7. Elicitation of pain on calf muscle rocking. This is an acceptable clinical test, perhaps somewhat more sensitive than the palpation test, but not as reliable as the cuff test. The knee is slightly bent with the heel resting on the bed. The calf muscle group is rocked back and forth in its relaxed state. Severe pain or discomfort is suggestive of thrombosis.

8 The cough-pain test (Lawrence). The reaction to this test may occasionally be suggestive of thrombosis. Local pain on coughing has been claimed to be of some value especially in acute thrombophlebitis.

9 Search for other local signs, such as superficial venous congestion, dilated pretibial veins, increased local heat, redness and swelling, cyanotic mottling and other similar indications. These may be present when the inflammatory element is pronounced, but as

a rule they are absent in most patients with early, bland phlebothrombosis.

Prognosis of Thrombophlebitis of Lower Extremities. Thrombophlebitis may progress along one of four lines: eventually no residual detectable sign of the original disease may be found, chronic venous insufficiency of the involved leg may give symptoms for life; death from pulmonary embolism may occur, pulmonary infarction may follow nonfatal pulmonary embolism.

No residual, detectable lesion. Probably in the majority of the milder cases of thrombophlebitis of the lower extremities the disease subsides completely in due time, in some cases because of good treatment, in others without adequate treatment. In the latter group are perhaps many originally unrecognized cases. In many patients mild residual edema of one extremity, with or without pain, will eventually subside completely. It must be remembered, however, that one attack predisposes to another, particularly after another surgical operation or injury or recurrent illness, such as heart failure. Consequently, a painstakingly careful history regarding leg symptoms after previous surgical procedures or illnesses is mandatory. Only by such screening can prophylactic measures be properly instituted.

Chronic venous insufficiency (postphlebotic syndrome). In a large percentage of patients the first indication of postpartum or postoperative thrombosis is the development of a pale, swollen, painful leg as ambulation is resumed postoperatively. This type of limb

Figure 7 Phlegmasia alba dolens (milk leg).

Figure 8 Some sequelae of deep vein thrombosis. A, Chronic swelling with discoloration of skin of lower third of leg B, Parchment-like appearance of skin C, Ulceration D, Secondary varicosities and temporarily healed ulcer

has been referred to as *phlegmasia alba dolens*, or, more commonly, milk leg (Fig. 7). The lowered surface temperature of such a limb is apparently due to reflex arteriospasm which commonly accompanies venous occlusion. This condition may gradually spontaneously subside or it may persist for life.

If the condition progresses, the venous blockage results in development of other more serious sequelae (Fig. 8). Secondary varicosities are usually the result of shunting of the major portion of the venous return to the superficial leg veins. As a rule, this is more often the result of incompetency of the valvular system of the deep veins than of persistent blockage. As the deep vein thrombus becomes organized, the vein wall and its valves become an integral, inseparable part of the conglomerate thrombus. In due time, recanalization occurs, often with multiple channels, but the blood in the new channels is no longer aided along its course by valves. As a consequence, a high degree of stasis develops in the lower third of the leg. The skin and underlying tissues become poorly oxygenated, stasis thrombi form in small subcutaneous veins and the skin about the malleoli loses its normal color and consistency. It may become shiny and thinned.

Induration may begin in a small area overlying a perforated vein and involve skin and underlying fat. Fibrosis of the underlying fat either accompanies or follows induration of the skin. The skin gives the appearance of parchment paper under which the fatty layer is atrophic and hard.

The least trauma may result in chronic ulceration. Episodes of acute cellulitis or infected dermatitis may supervene. When associated lymphatic thrombi occur, the skin becomes thickened and leathery and in extreme instances elephantiasis may develop.

The patient unfortunate enough to suffer from chronic venous insufficiency with the manifestations mentioned usually must be resigned to lifelong care of the limb.

In decreasing order of frequency, the post-phlebotic leg exhibits edema, pigmentation, secondary varicosities, pain, dermatitis, induration and ulceration. Most of these sequelae can be obviated if proper early treatment is instituted and good care is taken of the leg afterward.

Pulmonary thromboembolism. While death from pulmonary embolism occurs in an extremely small percentage of patients with thrombotic disease of the lower extremities, it is likely to follow bland phlebothrombosis. Since, as stated, phlebothrombosis often goes unrecognized, pulmonary embolism usually occurs without warning. As mentioned previously, an overwhelming proportion of patients who die of pulmonary embolism are not known to have had clinically demonstrable thromboembolic disease, nor did they show signs or symptoms requiring therapy prior to the fatal embolism. Not all large pulmonary emboli are fatal. Some of them, particularly smaller pulmonary emboli, may produce pulmonary infarction. However, in 20 to 25 per cent of cases, the first embolus is the fatal one.

Animal experimentation has demonstrated that nonfatal pulmonary emboli do not invariably produce infarcts. Pulmonary infarction following pulmonary embolism is apparently dependent on the presence of other factors, such as diminished aeration, interference with blood supply and infection. If none of these factors is present, an embolus may organize in the pulmonary vessels and produce no demonstrable effects.

Certain concepts have been developed from the search for factors which may precipitate the embolization of a thrombus. For example, in the presence of anemia, clot retraction following coagulation is known to be greater than normal and is therefore

possible that exaggerated clot retraction, if it occurs following thrombosis, might tend to draw the clot away from contact with the vessel walls and permit it to be dislodged by the passing stream of blood. Excessive clot retraction occurs in either chronic anemia or in the anemia following acute blood loss from surgery.

Another concept of embolization is based on the nature of thrombus propagation. The oldest portion of the clot adheres to the intima, while the clot propagates by adding a soft "tail" of freshly clotted blood elements. The tail is only loosely attached over a small area to the adherent portion, but its largest surface area, exposed as it is to the stream of venous blood, makes ready ground for deposition of circulating platelets, cells and other clotting elements. The tail of a thrombus may later become attached to the vessel wall. But any sudden increase in venous pressure, as may accompany coughing, sudden motion, straining at a stool, or any other physical expression of the Valsalva maneuver, may easily cause the tail to break from its mooring and become an embolus. Similarly, if the tail of the thrombus extends past a branching vessel which brings blood from a neighboring part, the current from the branch may sweep off a portion of the soft clot.

The classical clinical picture of pulmonary embolism is the sudden onset of constricting chest pain, painful breathing, anxiety, shock and cyanosis. In a few patients, hemoptysis or cough with frothy pink sputum may occur. Rib cage tenderness, pleural friction rub and an x-ray shadow suggestive of infarction in the presence of these symptoms are *prima facie* evidence of pulmonary infarction. Tachycardia, fever and leukocytosis are later sequential phenomena. Early clinical differentiation from acute coronary occlusion may be difficult.

Pulmonary embolism may cause death within a few moments; however, several hours may elapse with the patient in a state of shock, with or without loss of consciousness, before death supervenes. It is in such patients that certain therapeutic measures may be attempted.

Electrocardiographic findings immediately after an attack are not easily differentiated from those due to posterior coronary vessel occlusion. Later, the changes of acute cor pulmonale are usually demonstrable.

In general, it can be said that a massive pulmonary embolism is usually lethal, smaller emboli usually result in infarction with

pleuritis, often with effusion; many smaller emboli result in no demonstrable pulmonary pathologic process, provided the lung is not previously diseased.

A "paradoxical" arterial embolism occurs when a venous embolism passes through a patent foramen ovale, from the right to the left side of the heart, and into the arterial system. Such an embolus may lodge in a femoral vessel, cerebral vessel or other peripheral artery.

Treatment. *Prophylaxis of venous thrombosis.* No known test or method can accurately foretell whether a patient will or will not have venous thrombosis. The recently introduced antithrombin and heparin tolerance tests have not proved reliable. Nonetheless, there are some measures which can be undertaken to reduce the risk. Also, the realization that thromboembolism may occur under certain circumstances should serve to alert the surgeon to identify and treat phlebothrombosis, if possible.

Since early recognition of thrombosis is the only hope of preventing embolism, daily examination of the legs, as previously outlined, in all postoperative patients and in severely ill medical patients, is mandatory.

Prophylactic measures during surgery include prevention of shock and maintenance of effective circulating blood volume when blood loss is great. Postoperatively, venous stasis in the legs may be discouraged by such measures as prevention of excessive abdominal distention, avoidance of tight abdominal binders and by not permitting prolonged periods of immobility or dependency of the legs.

Elastic stockings or bandages compress the superficial veins and thus tend to cause more rapid flow of venous blood through the deep veins. As a result, this measure is excellent prophylaxis against deep vein thrombosis. If elastic bandages are used, they must be applied carefully and reapplied daily. Elastic compression is particularly useful in patients with varicosities. The elastic stockings or bandages can be applied prior to surgery and worn by the patient during and after surgery. Of course, in the presence of inflammation or ischemia, elastic compression cannot be tolerated by the patient because of the local pain.

Early ambulation after surgery is undoubtedly a highly important preventive measure against thromboembolism. If ambulation cannot be carried out for any reason, a definite routine of gentle leg massage, leg exercises, and periodic deep breathing may be insti-

tuted. All such measures are aimed at preventing venous stasis in the legs.

The prophylactic postoperative use of anticoagulant drugs, such as heparin or bishydroxycoumarin (Dicumarol), has its adherents and its opponents. Those who favor this therapy apply it to all patients with a past history of thrombosis or embolism. In order not to risk hemorrhage, the anticoagulant effect is not instituted until forty-eight to seventy-two hours after surgery. The opponents claim that application of the method may risk hemorrhage and is probably not practical, since the onset of thrombosis usually occurs during surgery or within twenty-four hours afterward, hence they claim the late institution of anticoagulant therapy does not actually prevent the formation of thrombi and that after cessation of therapy embolization may still occur.

Active treatment. Inasmuch as the two outstanding features of thrombosis are pulmonary embolism and disability due to postphlebotic syndrome, therapy is aimed at prevention of each of these complications, once the thrombosis is discovered.

If the diagnosis is *deep vein phlebothrombosis* or *thrombophlebitis*, it is customary to wrap the legs in elastic bandages from toes to groin and immediately institute anticoagulant therapy. At this time the legs are neither elevated nor lowered but are kept flat in bed. Jack-knifing the patient to a full sitting position is to be avoided since this may encourage venous pooling or stagnation at the hip level.

Anticoagulant therapy is begun with heparin for immediate response and at the same time a coumarin derivative is administered orally. The latter drug usually takes forty-eight hours for full effect upon the prothrombin. When prothrombin levels reach therapeutic ranges the heparin is withdrawn. Careful check on both coagulation time and prothrombin time is made each day. Anticoagulant therapy is carried on somewhat longer than the week of bed rest. Therapy may cover a period of ten to fourteen days. In some instances, anticoagulants are continued up to three weeks.

If embolic phenomena occur despite the treatment outlined above, bilateral femoral vein ligation below the saphenofemoral junction is carried out with the patient under local anesthesia. If a thrombus is found at the site of proposed ligation, it may be necessary to do a thrombectomy, or occasionally a vena cava ligation. For a number of years in certain institutions, bilateral femoral vein liga-

tion was carried out as the initial procedure upon discovery of thrombosis in the legs. Later comparison of results, however, indicated no significant difference between the incidence of embolism in these patients and that in patients given anticoagulant therapy. Hence the procedure is now reserved for patients who show signs of embolic phenomena despite anticoagulant therapy. The operation is usually done without restoring normal coagulation.

When a patient with deep vein thrombosis is allowed to become ambulatory, he is fitted with elastic stockings from toes to knees to minimize the edema.

If the diagnosis is *acute inflammatory thrombophlebitis* of the deep or superficial veins of the leg, initial treatment is similar to that outlined above, except that elastic bandages cannot be used immediately because of the discomfort they cause. Curiously, in the acute stages, such patients usually require much larger doses of anticoagulant drug than the usual ones in order to elevate their coagulation time to therapeutic ranges. Another useful measure in the presence of severe pain, usually due to distention of veins in spasm, is to block the sympathetic impulses to the legs. If this is done by paravertebral sympathetic ganglionic block, it is best to begin the block before instituting anticoagulant therapy. Other methods of blocking the sympathetics include continuous caudal block and the use of parenteral ganglionic blocking agents, such as hexamethonium or related compounds. Antibiotics have been used empirically, together with anticoagulants, but their role remains to be evaluated since most of these lesions are not caused by bacterial invasion. If only superficial veins are involved, the affected segments may be excised once the early, acute inflammatory stage has subsided. Pulmonary embolism is not a common sequel to this lesion.

Ambulation is usually not attempted before a week or ten days or as soon as it is possible to wear elastic stockings.

Massive venous occlusion. In rare instances, massive thrombosis occludes practically all the veins of the leg, including the main stems. When this occurs the entire leg up to mid thigh becomes deeply cyanotic and extremely painful and swollen within a few hours. A patient with such a lesion may go into shock from blood loss into the extremity. Treatment consists of elevation, with knee bent, immediate anticoagulant therapy and intravenous administration of fluids and

blood to treat the shock, if it is present. Such treatment may be rewarded by gradual return of almost normal color to the skin within hours. In an occasional patient, the limb may become gangrenous and require amputation despite good treatment. Sympathetic block is usually to no avail in these patients.

Chronic venous insufficiency (postphlebotic syndrome). The chronic sequelae of thrombophlebitis present one of the most difficult therapeutic problems in surgery.

For patients whose skin is not ulcerated but whose main symptoms are pain on standing, and edema with or without skin discoloration, certain precautions must be taken. These individuals are instructed to avoid even minor trauma to the area of the ankles and lower legs; not to stand for a long time, when sitting for long periods, to keep the legs elevated; when walking, to wear elastic stockings, not to rub the skin of the legs too vigorously when drying after bathing, to apply lanolin ointment to the skin of the ankles before retiring at night, and if obese, to go on a strict weight-reduction regimen.

If varicosities are present, the great saphenous vein, and short saphenous if indicated, should be stripped and individual clusters of veins excised. The rationale for this procedure in the presence of chronic deep vein insufficiency is based on the supposition that venous return from the legs will be hastened through deep, uninvolved veins as well as recanalized veins, if the stagnant superficial system is removed.

If ulceration occurs, treatment depends upon the extent of tissue destruction. Superficial, small ulcers (Fig. 9) usually heal with a few days of bed rest with elevation and sterile saline dressings. However, as ambulation is resumed, the ulcers may recur unless the superficial venous system is stripped or proper elastic compression is applied.

Deep, infected ulcers often present a serious problem in therapy. Local application of antibiotic preparations is usually to no avail unless the basic principles of elevation, compression and clean care are applied. Purulent, pseudomembranous granulation tissue can usually be converted into clean, red, flat surfaces without the use of antibiotics, enzymatic debriding agents or other chemical means. In some patients a split-thickness skin graft can be applied to such healthy granulations. In others, surgical excision of the ulcerous area and neighboring poor tissue, often including the underlying fascia, may be necessary after attempts to clean the ulcer base have been carried out. It is known that

granulation tissue which appears healthy grossly is most receptive to grafting when its pH is over 7.4.

Occasionally the skin continues to break down repeatedly after healing with or without a graft, despite the measures outlined. Various modes of treatment have been prescribed for such patients, including sympathectomy, ligation of the popliteal vein or femoral vein and extensive excision of all superficial veins of the leg through long flap incisions. These measures have yielded good results in some patients.

The largest percentage of milder ulcers can be healed while the patient is ambulatory by means of weekly or semiweekly application of Unna's paste boot after painting the ulcer with gentian violet or a similar dye. The rationale for this treatment is one of compression, protection and maintenance of moisture and softness in the area. The boot consists of wrapping the leg, from the base of the toes to the knee, with gauze impregnated with a zinc oxide-gelatin-glycerin mixture. The method permits healing over a number of weeks or months. It has been replaced by and large by the more direct, shorter-term treatments mentioned above.

Infected dermatitis pursuant to chronic venous insufficiency is usually best treated by identification and eradication of sec-

Figure 9. Postphlebotic syndrome. Appearance of skin of leg immediately after healing of ulcer. Wrinkles in skin denote reduction in edema. Note tissue-paper thinness (parchment appearance) of skin.

ondary factors, such as epidermophytosis, sensitization to various allergens, secretions, medication or bacterial invasion. As stated, most patients, nonetheless, will respond to elevation, clean care and, later, compression.

It is important to impress upon the patient that despite the success of specific immediate therapy, lifelong care of the limb is mandatory.

Thromboembolism. Death from massive pulmonary embolism often supervenes within seconds of the embolization. Some patients may survive several hours or even days. In roughly 50 per cent of patients so afflicted, there is time to apply one or more of the emergency measures.

Since the first of these measures is immediate administration of oxygen by mask, it is always best to have oxygen readily available on surgical wards. The subcutaneous injection of atropine sulfate, $\frac{1}{50}$ gram, is advised to overcome reflex vagal effects if they are

present. The intravenous or subcutaneous administration of papavarine, $\frac{1}{2}$ gram, has been recommended to overcome bronchial spasm and to counteract ventricular fibrillation. Immediate heparinization is also advised.

Because one cannot predict which patients will survive, no valid statistics are available as to the efficacy of this form of treatment.

In a few centers in the world, pulmonary embolectomy has been successfully carried out. Obviously the results are better in the slowly fatal type in which there is time to perform thoracotomy, expose the pulmonary artery and remove all its contained blood clot. With the proper selection of patients, such drastic surgical measures may save an occasional life.

THROMBOSIS OF THE UPPER EXTREMITIES

Thrombophlebitis of the superficial veins, especially the antecubital vein, commonly

Figure 10. Venogram showing thrombosis of axillary vein. Note collateral channels t area of occlusion

It may be due to the solution, or to the solution from the needle.

As a rule, the area is painful and tender. The overlying skin is red and warm. The vein usually can be palpated as a firm cord under the skin. Moist hot packs usually cause the condition to subside in a few days.

Thrombosis of the axillary and subclavian vein may arise from a variety of causes. Direct trauma and prolonged compression are known etiologic factors. So-called effort thrombosis usually follows some unusual physical exertion involving compression of the vein by the subclavian muscle tendon or by the scalenus anticus muscle. In addition, fractures, hematomas, tumor growths and postoperative mastectomy compression have been responsible for axillary vein thrombosis. The axillary vein may also become involved in phlebitis migrans.

Symptoms are usually ushered in with pain at the site of thrombosis. In twenty-four to forty-eight hours the arm appears somewhat swollen and the skin assumes a burgundy color. Cyanosis of the deep blue variety may occur. Superficial veins become dilated. The arm feels heavy and full to the patient.

Strangely, the incidence of pulmonary embolism following upper extremity venous thrombosis is extremely low. Collateral channels about the axilla and shoulder are rich and soon assume the added burden of venous circulation, becoming visibly dilated.

A diagnostic aid is the injection of radiopaque medium into an arm vein in order to visualize the site of the occlusion on an x-ray film (Fig. 10). This should not be done for at least forty-eight hours in order not to dislodge the clot. Diagnosis without venography is preferred.

Treatment depends upon the location of the thrombosis and the severity of the symptoms. If symptoms are minimal, simple elevation of the arm and anticoagulant therapy for seven to ten days may suffice. Sympa-

thetic and stellate ganglionic blocks with 1 per cent procaine solution may be carried out to minimize spasm. If the vein occlusion is at the level of the scalenus anticus muscle, scalenotomy may be done as a late procedure, provided recanalization has been unsatisfactory. Thrombectomy is only rarely necessary. If symptoms persist after many months, sympathectomy may be performed to alleviate both arterial and venous spasm.

The Arteries

By HARRIS B. SHUMACKER, JR., M.D.

HARRIS B. SHUMACKER, JR., is a Mississippian who was educated at the University of Chattanooga, Vanderbilt University and Johns Hopkins University Medical School. From Yale University, he returned to Hopkins, then back to Yale, and now he is the Professor of Surgery at the Indiana University Medical School. His interest in vascular surgery is evidenced by his basic contributions to that field.

The arteries and arterioles serve as conduits for the transport of blood from the heart to the capillaries, where certain constituents of the blood are released into the surrounding tissue spaces and certain metabolites pass across the capillary membrane into the blood. They are also of importance in the regulation of blood pressure.

Normal arteries are not rigid tubes but are capable of wide variation in caliber. Spasm or constriction of these vessels may occur as the result of reflex sympathetic response or from certain direct stimuli such as trauma and cold. Though all sizes of arteries are capable of such alterations, the smaller arteries and arterioles undergo more pronounced changes as a consequence of sympathetic stimulation or paralysis than do larger arteries. Furthermore, the arteries supplying the skin, subcutaneous tissue, small muscles and viscera appear to undergo wider changes with sympathetic activity or paralysis than do those supplying large muscle masses. These variations in the tone of arteries and arterioles are of importance not only in determining blood flow into a given part of the body, but also in regulating central blood pressure. The sympathetic control of blood vessel tonus provides us with one of the most useful tools for dealing with ischemic disorders, namely, sympathetic paralysis by infiltration anesthesia, or operative denervation.

Most of the problems relating to the arteries concern difficulties with flow of blood into extremities. The various disorders can ordinarily be sorted out with considerable accuracy by carefully obtaining a history and carrying out a complete physical examination. A family history of diabetes, hypertension or arteriosclerosis is important. One must

inquire into the patient's history for symptoms suggestive of diabetes, hypertension, cardiac disorders and local cold injury. The use of tobacco and the character of the patient's work are of interest. One should try to determine whether the patient has had high, low or average vascular tonus. The description of the present illness should be obtained in an orderly sequential fashion. Circumstances under which symptoms are present should be noted, for example, whether at exercise or at rest. Any variations observed with changes in environmental circumstances are of importance. The common vasospastic disorders may produce symptoms more or less continuously, as is true of acrocyanosis, or, as in Raynaud's disease, episodically. The common symptoms are coldness of the hands or feet, color changes such as pallor or cyanosis, hyperhidrosis and, on occasion, numbness and tingling. Digital ulceration and areas of superficial gangrene may occur, but extensive gangrene is rare. The chronic obliterative diseases produce symptoms both at rest and with exercise. One of the commonest complaints is intermittent claudication, which is the onset of muscle fatigue or aching after walking a given distance, with prompt relief of symptoms after a momentary period of rest, and return of symptoms again after the same amount of exercise. In any case, intermittent claudication occurs sooner after walking rapidly, uphill or against the wind for a shorter distance. The walking distance is greater when patients walk slowly or downhill. Patients may also complain of numbness of the feet after exercise. At rest, the patient may notice coldness of the feet or hands, pallor or pain. The pain is particularly apt to be present when the patient is recumbent.

and the beneficial effects of gravity are not at play. Edema is likely to develop in ischemic limbs kept dependent and inactive for long periods.

The examination should include a careful general survey. It is important to evaluate the cardiac status, determine the blood pressure and carry out funduscopic study of the retinal vessels. The extremities should be inspected thoroughly. Any atrophy of muscles or atrophic changes in nails, hair or skin should be noted. It is important to observe whether the skin is dry, normally moist or excessively wet. The presence of normal color, pallor or rubor is important. Pallor on elevation above heart level and rubor in the dependent position are indicative of occlusive arterial disease. The degree of filling of the superficial veins of the hands and feet is important, as is the rapidity or slowness with which these vessels fill when the extremity is made dependent after a period of elevation (venous filling time). Fissures, calluses, ulcers and areas of superficial or deep gangrene must be noted. Superficial phlebitis and other venous abnormalities may be of importance. One should determine whether the extremities are normally warm, excessively hot, or cool and whether any asymmetry with regard to temperature exists. The environmental circumstances under which the examination is conducted are of great importance with respect to color, temperature, sweating and the quality of the pulses. All the peripheral pulses should be felt. It is not sufficient to palpate the radial and dorsal pedal pulses. The brachial, ulnar, abdominal aortic, iliac, femoral, popliteal and posterior tibial pulses must be examined as well. In a small percentage of normal individuals, dorsal pedal pulses are not felt, but the posterior tibial pulses are always normally present. The ulnar pulses are more commonly obliterated by disease than are the radial. It is important to note whether the arteries palpated are soft and compressible or firm, hard and beaded. One should detect aneurysmal dilatation if present and, when aneurysm, arteriovenous fistula, dilatation or partial constriction of an artery is suspected, one should feel for a thrill and listen for a bruit.

The degree of vascular tonus, the presence of vascular spasm and the capacity for vasodilatation can be estimated in a variety of ways. Changes noted in a warm and cold environment are of importance. A varying degree of release of vascular constriction and induction of vasodilatation may be noted when the patient is placed in a warm envi-

ronment, given a general or spinal anesthetic, subjected to immersion of one or more extremities in warm water, given diathermy over the abdomen and pelvis, treated by the administration of an autonomic blocking agent or subjected to a somatic peripheral nerve block with procaine or to procaine infiltration of the regional sympathetic chain. These measures vary in their effectiveness in blocking vasoconstriction and inducing vasodilatation. The most reliable method is the carrying out of an effective sympathetic block with procaine. Another good method is the blockade with procaine of a somatic nerve such as the ulnar or posterior tibial. Vasodilatation is associated with better warmth, venous filling and color. When sympathetic blockade is effected, sweating ceases and the cutaneous resistance increases. Tests carried out in order to determine the capacity for vasodilatation should be performed in a cool environment. In evaluating the possible effect of sympathectomy upon pain by procaine sympathetic block, the patient should be subjected, as soon as an effective injection is carried out, to those circumstances most conducive of pain in the case under study—lying down, walking or exposure to cold.

Reactive hyperemia, or the response to a period of deprivation of arterial circulation, is a simple test which gives one some insight into the adequacy of capillary circulation. It is usually performed by excluding the blood flow into the forearm or leg for a period of from three to five minutes with a sphygmomanometric cuff. After release of the pressure from the cuff, one notes the brilliance, extent, and rapidity of appearance of the resultant flush. In patients with good capillary blood flow, the flush is full and extends rapidly to the tips of the digits. A slow or incomplete flush indicates poor capillary circulation. The test can be carried out with the extremity horizontal or elevated a certain number of degrees above the heart level. The higher the elevation at which an adequate flush is observed, the better the circulation. The same test can be modified to study collateral blood flow about a given segment of a major arterial stem (the Matas test). This is of value in patients with aneurysm or arteriovenous fistula or in any in whom a contemplated operation may entail ligation of a major artery. The test is carried out in the usual manner except that the artery in question is carefully and completely occluded by digital pressure during the latter part of the period of exclusion of arterial inflow and for several min-

utes afterward. If, under these circumstances, a good full flush develops in less than two minutes, one has reason to assume that the collateral circulation is adequate. Since, in patients with *obliterative occlusion* of a radial or ulnar artery, the collateral circulation is ordinarily limited, a simple type of hyperemia test usually serves to confirm or disprove suspected absence of blood flow through a radial or ulnar artery (Allen's test). After both the radial and ulnar pulses are shut off by digital pressure, the patient squeezes the blood from his hand by making a tight fist. The digital pressure is released from the artery in question. If it is not patent, a flush fails to develop or is inadequate. If it is patent, a good flush occurs during continued compression of the other artery.

Rarely are special instruments or tests required in order to establish the diagnosis or outline a proper course of management. The oscillometer gives one some objective measure of the quality of pulsations in the main stem arteries. It serves largely to confirm conclusions reached from careful palpation of pulses. The magnitude of pulsations in the digits can be recorded by the digital plethysmograph or by impedance plethysmography. Thermocouples can be used to determine exactly the temperature of the skin, but one can train himself to judge temperature fairly accurately by palpation. Venous occlusion plethysmography permits reasonably good estimation of blood flow into a part. The rapidity with which radioactive sodium disappears from the site of its subcutaneous or intramuscular injection is related to the blood flow through the area. Arteriograms give a pictorial outline of the arterial tree (Fig 11). They are of particular value in demonstrating the lower limit of a segmental occlusion and in establishing the adequacy of the distal arterial bed. These and other precise methods are of especial importance in investigative studies and in clinical evaluation of certain unusual or difficult cases. The trained observer can do a good job in the majority of cases without such special equipment and tests.

The management of the ischemic extremity is very important. When the circulation to an extremity is markedly impaired, the comfort of the patient and, indeed, the survival or

Figure 11. Femoral arteriogram showing segmental obstruction of superficial femoral artery.

pendent to the heart level. Everything should be done to protect the ischemic hand or foot against injury. The pressure of bed clothes across the toes of a foot with markedly impaired circulation may be sufficient to initiate gangrene. The simplest and most effective way to obviate this difficulty is by use of a footboard so that the bed clothes do not press upon the feet. In general, it is wise to keep the toes separated by the use of cotton or thin layers of gauze. This is essential if there is maceration or if interdigital ulceration is present. Under certain circumstances, for example, acute arterial embolism, it may be advisable to use the anticoagulant drugs, heparin and the coumarin agents. One should avoid use of local heat. Hot water bottles, for example, may initiate gangrene and bring about the necessity for amputation.

Theoretically, use of local cooling might aid in saving limbs threatened with gangrene, since local cooling of a part does decrease the metabolic requirements. Unfortunately, local cooling also brings about still further reduction in arterial circulation since cold is one of the most effective stimuli for inducing vasoconstriction. Cold acts both directly and in a reflex manner to produce

is badly impaired, it may be adequate when the limb is in a position horizontal to or above the level of the heart. Under such circumstances it should be made de-

vasospasm, and cold of significant degree or duration induces marked vasoconstriction even in extremities from which the sympathetic nerve supply has been removed.

Since it is impossible when cooling an extremity to be certain that the local metabolic requirements are being reduced proportionately more than the arterial inflow of blood into the limb, and since, indeed, the reverse may be true, local cooling is not recommended as a measure for saving the ischemic extremity. Local refrigeration is an extremely useful tool for employment prior to amputation in patients in whom infection is present. If a limb is packed in ice or placed in a special refrigerating unit, it soon becomes quite comfortable, a tourniquet can be placed tightly about it and, for all purposes, a physiologic guillotine amputation is accomplished. The general effects of the local infection disappear rapidly. Control of diabetes becomes remarkably easy and, when the amputation is performed several days later, it can be carried out with much greater likelihood of primary healing. As long as there is any possibility of saving the ischemic limb, every effort should be made to improve the circulation to the part.

Obviously, the most effective method of restoring good blood flow into the limb is to relieve any mechanical block of a main-stem artery which may be present. In the case of arterial embolus, it is possible to remove the obstructing embolus. In segmental thrombosis, either as the result of trauma or arterial disease, one can often re-establish blood flow through the obstructed artery by thromboendarterectomy or a grafting procedure (see Fig. 17). When one is not dealing with segmental occlusion of a main-stem artery, the most effective method for increasing the flow of blood into the hand or foot is to carry out a regional sympathetic denervation. Sympathetic denervation brings about permanent localized maximal, or near maximal, vasodilatation and thus the best possible blood flow through the patent arteries. The effectiveness of sympathectomy in relieving ischemia depends upon the number of patent arteries in the extremity and their capacity to undergo vasodilatation. Sympathectomy also produces anhidrosis in the area denervated (Fig. 12). Altogether this effect is a beneficial one in circulatory disorders. Active sweating contributes to loss of heat from the extremity by evaporation and thus to the need for greater circulation. Its elimination, therefore, somewhat reduces the circulatory requirements. Furthermore, excessive sweat-

ing promotes maceration of tissues in some instances and may eventuate in ulceration or infection, which may lead to the necessity for amputation. The dry skin of the sympathetomized extremity is ordinarily easy to manage. It can generally be kept in good condition by the application of lanolin to the dry areas each day. A third consequence of sympathetic denervation, the relief of reflex pain, is useful primarily not in diseases of the arteries, but in those painful reflex disorders which follow trauma or inflammation.

Evidence obtained from carefully performed studies would indicate that the autonomic blocking agents, such as Priscoline and tetraethylammonium bromide, have no part in the management of the severely ischemic extremity, although such drugs are of considerable help in vasospastic disorders, particularly the mild ones, and are invaluable in the management of hypertensive disease. When an extremity is without adequate blood flow as the result of an obstructive lesion, such general blocking agents tend to produce vasodilatation in the other extremities in which there is no need for improve-

Figure 12. Drawings indicating the expected area of anhidrosis. A, Following removal of the second and third lumbar sympathetic ganglia. B, The first, second and third lumbar ganglia. C, Following preganglionic upper dorsal sympathectomy (Shumacker, H. B. Surgery, vol 13).

ment of circulation and they are apt to produce trivial, if any, improvement of circulation in the affected limb. Indeed, not infrequently blood flow into the ischemic limb itself becomes worse as vasodilatation takes place in the normal or near-normal extremities. The concomitant fall in blood pressure which sometimes takes place also tends to reduce the effectiveness of blood flow into the ischemic limb. Buerger's exercises may be of some help. They entail elevation of the hand or foot well above heart level until pallor is evident, followed by lowering the extremity below heart level until a flush develops. This maneuver is repeated a number of times and, when the limb is dependent, the digits, foot and ankle or the hand and wrist are exercised.

Wounds of Large Arteries. Wounds of

arteries are, of the injured limb, and maintenance or restoration of as adequate circulation as is possible.

Bleeding should be brought under control without delay. The method will vary from case to case. Every effort should be made to stop the hemorrhage by some method which does not entail the use of a tourniquet. Digital compression is an ideal method, but unfortunately can be used for only a relatively short time. Application of a firm compression dressing is sometimes effectual. On occasions it may be necessary to pack the wound itself with sterile gauze or, preferably, with some hemostatic absorbable material such as Oxycel gauze or Gelfoam. When packing is used, it should not be removed except under circumstances when the bleeding vessel can be dealt with in a definitive way and blood loss be replaced adequately in case hemorrhage recurs. An effective method for handling injured vessels of relatively little importance in the nutrition of the extremity is direct clamping with a hemostat. Clamping a main-stem artery, however, has the disadvantage that the local injury to the blood vessel may be increased. A tourniquet should be employed only when other methods cannot be utilized. For a tourniquet to be effective in stopping hemorrhage, the extremity distal to the tourniquet is rendered entirely ischemic. Once applied, a tourniquet should never be released except by a physician prepared to replace immediately any blood that may be lost and to deal with the local vascular injury so as to prevent exsanguinating hemorrhage. When a tourniquet is left in place for a number of hours, the extremity may be

irreparably damaged by the prolonged ischemia and re-establishment of satisfactory blood flow may be impossible because of resultant thrombosis in the arterial tree. Release of the tourniquet after a long period may be attended by massive loss of fluids into the limb with the onset of tourniquet shock. If a tourniquet is used in a hopeless situation in which amputation obviously will be required, it should be placed as far distally as possible.

Simultaneously with efforts to control hemorrhage, treatment for blood loss should be carried out with the aim to prevent shock or to treat it if already established. It is preferable to use whole blood for replacement and, if blood is not available, plasma or a plasma expander such as dextran. If none is obtainable, glucose or saline solution may be of help for a time in maintaining adequate circulation. If shock is present, any narcotic required for the relief of pain should be given intravenously rather than subcutaneously.

The initial efforts to control the bleeding and replace blood loss should be carried out immediately. At the same time, plans should be made to expedite definitive treatment of the blood vessel injury. The treatment of the vascular injury depends upon the specific artery involved and the nature of the damage to it, the presence or absence of continued or recurrent bleeding, the presence or absence of ischemia and the character of any associated injury to the extremity. Large arteries tend to bleed more persistently than small arteries. Clean injuries without significant contusion of surrounding tissue favor continued bleeding. Hemorrhage tends to be greater if there is a ready route for escape of blood to the exterior. Arteries having incomplete lacerations are prone to continue to bleed, while completely divided arteries not infrequently cease to bleed with retraction and thrombosis of the divided ends. Blood loss is sometimes minimal when there is a concomitant injury of an adjacent vein into which the lacerated artery may bleed with the formation of an arteriovenous communication. When bleeding ceases spontaneously or as the result of first-aid treatment and the limb is not ischemic, definitive treatment can be deferred for a reasonable time. When the limb is ischemic or when bleeding continues or recurs, treatment must be carried out without any waste of time. If the injured artery is ligated rather than repaired, it is safer to divide the artery between ligatures than to ligate it in continuity. Every

effort, however, should be made to preserve or restore the continuity of the damaged artery and this is ordinarily possible. Depending upon the nature of the injury, lateral suture of the lacerated artery, end-to-end anastomosis or replacement of the excised damaged portion by a vascular graft may be the treatment of choice (Figs. 13 to 15). At

the same time, adequate débridement must, of course, be accomplished in all patients in whom there is contusion of tissues.

The Vasospastic Disorders. Normal individuals vary considerably in vascular tonus. Some have an unusually low vasomotor tonus. Their extremities tend to remain warm and to cool slowly in a cold environment. Others have a high vasomotor tone; their hands and feet tend to be cool and to lose temperature rapidly upon exposure to a cold atmosphere. In between these extremes is another group of individuals with moderate vascular tonus. The distinction between normal individuals with high vasomotor tonus and individuals suffering from a true vasospastic disorder is sometimes difficult. Evidences of vasoconstriction in the former group are looked upon as a personal peculiarity and perhaps somewhat of a nuisance. In the latter, they constitute the basis for real complaints. There are a wide variety of vasospastic disorders.

Raynaud's disease is characterized by episodes of spasm of the digital arteries. It affects

second or third decades of life, it may have its onset, however, in older individuals. It tends to affect the digits of the upper extremities predominantly, although the lower extremities may be affected as well, and, more rarely, the nose and ears. The disorder tends to be symmetrical. Under ordinary environmental conditions, the circulation in the affected extremities is usually quite normal, although some individuals tend to have some coolness and hyperhidrosis of their extremities under most circumstances. The attacks occur as the response to cold and, in some, upon emotional excitation. Characteristically, the affected digits turn either white or blue during an attack and become quite numb. Upon return to a warm environment, the attack ceases, the digits become deep red in color and then normal color returns. As the part rewarms and color returns to normal, the patient complains of uncomfortable paresthesias. The thumb is less commonly affected than are the fingers. Usually only the distal two phalanges are involved. The temperature which initiates attacks varies from patient to patient. Some develop attacks only upon exposure to intense cold, while others develop attacks in a moderately cool, or even in a slightly cool, environment. The disorder may remain rather stationary for a period of years, but it tends to get progressively worse.

Figure 13 A, Technique for performing lateral anastomosis B, End-to-end anastomosis by use of interrupted everting mattress sutures (Shumacker, H B: JAMA, vol. 151).

Figure 14 A useful method for end-to-end anastomosis when branches fix one segment of the artery so it cannot be rotated freely. This is essentially the technique utilized by Blalock for subclavian-pulmonary artery anastomosis (Shumacker, H B: JAMA, vol. 151).

Figure 15 Technique for interpolation of vascular graft V (Shumacker, H B: JAMA, vol. 151).

Figure 16 Chart showing common digital temperature responses to procaine anesthetization of the sympathetic chain in a patient with Raynaud's disease, and in patients with obliterative arterial disease with and without significant vasospasm (redrawn from Shumacker, H. B., *Surgery*, vol. 13).

Rarely is spontaneous improvement noted. As time passes, the patient is apt to develop painful digital ulcers, superficial necrosis of tissue takes place and, if healing occurs, some of the substance of the tip of the digit is lost. Rarely does more extensive gangrene develop. In some individuals, scleroderma occurs in association with Raynaud's disease. The scleroderma may be progressive and disabling.

On examination in a warm environment the circulation usually is found to be perfectly normal. The major peripheral pulses are present. The hands and feet tend to be warm and normally moist, though in some individuals they may be somewhat cooler than normal and have excessive sweating. Characteristically, the tips of the fingers become tapered and may be further deformed by the loss of tissue as a consequence of digital ulceration. Scleroderma may or may not be present. Attacks often cannot be reproduced by immersion of the affected hands or feet in ice water. They can invariably be reproduced by general body chilling. An effective method for bringing this about is the taking of a cold shower.

Entirely similar attacks are sometimes noted early in childhood and are known as hereditary cold fingers. In contrast to true Raynaud's disease, patients with hereditary cold fingers tend to get better as they grow into adult life.

A disorder otherwise quite like idiopathic

Raynaud's disease sometimes follows the use of vibrating tools and seemingly is caused by the use of such equipment.

Raynaud's phenomena, identical in every respect to the attacks which characterize Raynaud's disease, also are noted as a manifestation of obliterative arterial disease and in association with arterial compression syndromes. For this reason, in any individual having attacks of this sort it is important to rule out the presence of obliterative arterial disease such as arteriosclerosis, thromboangitis obliterans or some compression syndrome such as may be due to a cervical rib or a tight anterior scalene muscle. The most difficult diagnostic problem is the differentiation between Raynaud's disease and non-specific obliterative arteritis, which also has a predilection for young women and for involvement of the upper extremities and is commonly associated with Raynaud-like attacks. Figure 16 shows digital temperatures in these processes.

Another relatively common vasospastic disorder is known as *acrocyanosis*. This, too, tends to occur primarily in women, especially young women. Unlike Raynaud's disease, *acrocyanosis* constitutes a relatively persistent complaint. The hands and sometimes the feet are affected. They tend to remain cold, excessively wet and cyanotic. The coldness and cyanosis are aggravated by exposure to a cold environment but are usually evident even in a warm atmosphere. Only under cir-

circumstances conducive to extreme vasodilatation do the affected extremities become warm and normally colored.

Livedo reticularis occurs in both males and females and in all age groups. It is characterized by a peculiar reticular bluish mottling of the skin. The legs and feet are commonly affected, occasionally the upper extremities are affected as well. The mottling tends to be persistent. It is exaggerated by exposure to cold and by dependency. It tends to clear somewhat in a very warm atmosphere and, more particularly, after exercise. Under no circumstances does it disappear completely. It may be associated with ulceration of the skin. It is usually accompanied by vasospasm.

A great many individuals suffer from an ill-defined vasospastic condition. Both males and females in all age groups are affected, though it is more common in the young than in the old. Common complaints are coldness and hyperhidrosis of the extremities. Sometimes numbness is present, particularly in cold weather. Occasionally some cyanosis is noted. Hyperhidrosis may be extreme. In some instances, the hyperhidrosis may be associated with a foul odor. This condition is known as *bromhidrosis*.

Patients with vasospastic disorders should be persuaded to abstain from tobacco and should dress warmly in cool weather. The milder vasospastic disorders sometimes are helped remarkably by the autonomic blocking agents. When these difficulties are severe and progressive and fail to respond to such measures, they are best treated by sympathetic denervation. Altogether the results are quite good. They are excellent in the ill-defined group of vasospastic difficulties and in acrocyanosis. The discoloration and the associated vasoconstriction which are evident in patients with *livedo reticularis* are remarkably improved. The limbs remain warm and dry and the bluish mottling is replaced by a faint pink reticular mottling which is not nearly so conspicuous. Ulcerated areas tend to heal. The results are excellent in cases of acrocyanosis. Raynaud's attacks usually disappear or recur much less commonly and only after a more severe cold stimulus than was formerly required to produce them. Attacks never are initiated by emotional excitation in sympathectomized extremities. Digital ulcers tend to heal and not to recur. Rarely is any improvement noted in scleroderma and in some instances the sclerodermatous process continues to become progressively worse.

A very serious acute vasospastic difficulty is known as *arterial stupor*, or segmental arterial spasm. In this condition a segment of a major arterial stem becomes so constricted as a result of spasm that it fails to transmit blood through its lumen. It occurs as a consequence of trauma in the vicinity of the artery. Sometimes the trauma is surgically induced. Varying degrees of ischemia result, depending upon the intensity of the spasm, the completeness of the obstruction of blood flow through the main artery and the location of the segment involved. Segmental spasm of the femoral artery may, for example, be associated with complete ischemia of the entire leg and foot almost up to the knee. If unrelieved, gangrene may develop. Sometimes, segmental arterial spasm responds dramatically to regional sympathetic procaine blockade or to spinal, caudal or general anesthesia. Unfortunately, not all the patients respond to such measures. If the affected artery must be exposed under any circumstances because of the associated injury, or if other measures have failed to relieve the spasm, the affected portion of the artery should be stripped of its gross adventitia, bathed in procaine solution and irrigated with warm saline solution. If these measures do not relieve the spasm, one may try the injection into the proximal artery of procaine solution, Prostigmin, or one of the autonomic blocking agents. In an occasional patient, all efforts fail to relieve the spasm.

Organic Obstruction of Arteries. The most dramatic of the acute occlusive disorders is *arterial embolus*. The etiologic factors for such emboli are rheumatic valvular heart disease, myocardial infarction with mural thrombi, and thrombi developing upon an arteriosclerotic plaque in the aorta or some large artery or within an aneurysmal sac. Thrombi in the heart are especially apt to become dislodged during episodes of atrial fibrillation or upon conversion of atrial fibrillation to normal sinus rhythm. The patient suddenly experiences pain, coldness, numbness and paresis. The ischemic part rapidly becomes pale, cyanotic, cold, hypesthetic or anesthetic, paretic or paralyzed. Generally the diagnosis is easy. Occasionally it may be difficult to distinguish this condition from acute arterial thrombosis, rarely from segmental arterial spasm or acute venous thrombosis with marked vasospasm. The localization of the obstruction usually presents no problem. Emboli tend to lodge where the artery suddenly becomes reduced in caliber and ordinarily at points of bifurcation or

compression—the end of the aorta, the division of the common iliac into external iliac and hypogastric, the bifurcation of the common femoral artery, the level at which the superficial femoral passes under the adductor tendon, the branching of the popliteal into anterior and posterior tibial arteries. If one observes the most distal pulse palpable, the level of coldness, discoloration and numbness, and the parts paralyzed or weak, he can determine the level of occlusion with remarkable accuracy. In patients with saddle embolus to the terminal aorta, for example, the iliac and femoral pulses are absent. Hip movements are present, but knee, ankle and toe movements are weak or absent. The level of coldness, pallor and sensory loss is near the groin. The findings are essentially the same but limited to one side when the common iliac artery is suddenly obstructed. The cold level may be a little more distal. When the common femoral artery is occluded, the last palpable pulse is just below the inguinal ligament. Knee movements are present, but not ankle or toe motion. The cold level is below the knee. In distal femoral or popliteal occlusion, pulsation is felt down to the adductor tendon or to the lower part of the popliteal space. The cold and sensory-change level is above the ankle. Only toe movements are lost. Unusually good collateral circulation or collateral circulation impaired by pre-existing occlusive disease may make the affected level lower or higher than one would ordinarily anticipate.

Effective therapy depends upon prompt recognition and the earliest possible treatment. As soon as the diagnosis is made, heparin should be administered, the ischemic extremity made dependent and protected from injury and preparations begun for definitive treatment. If an artery important in the nourishment of the limb is occluded, embolectomy should be carried out immediately, except in the most unusual circumstances. This is a simple procedure. Most embolectomies, for example those in the femoral artery, can be accomplished painlessly with the patient under local anesthesia. Little or no risk is entailed. In contrast, the risk of amputation in neglected patients is relatively high. Once the embolus is removed and the small arteriotomy incision closed, the patient experiences relief of symptoms and good circulation is evident in the previously ischemic extremity.

The key to success is the performance of embolectomy before thrombosis has occurred distal to the site of the embolus. Prior to em-

bolectomy, everything possible should be done to decrease the likelihood of such distal arterial thrombosis. In general, the chance for a good outcome is directly related to the *shortness of the interval between occlusion by the embolism and embolectomy*. Time is important, however, primarily in view of the fact that the briefer the interval the more likely the distal arterial tree is to be patent, and the longer the interval the more likely it is to be obstructed by thrombosis. Occasionally the entire distal arterial tree is clotted within a few hours. In contrast, it may remain open and successful embolectomy may be performed as long as forty-eight hours or more after the embolus has become lodged in the vessel. The better preserved the circulation in the affected extremity, the more certain one can be of a good result from embolectomy. Hence, preservation of some circulation should not influence one to elect nonsurgical treatment but should, on the other hand, prompt one to proceed with operative removal of the obstruction. After embolism has been treated, everything possible should be done to prevent recurrence. All too often a second or third embolus has proved fatal. If no specific therapy directed at the primary cause is applicable, prolonged anticoagulant treatment may be helpful. In patients with mitral stenosis, commissurotomy should be carried out. If the patient has had fibrillation, conversion should later be attempted.

Acute arterial thrombosis is similar in symptoms and signs but often of more gradual onset. The signs are not so consistently clear cut for any given level of obstruction, though the site of occlusion is generally evident from careful examination. It is hoped that such patients treated early will prove suitable for thrombectomy or by-pass grafting procedures. Often sympathetic denervation brings about remarkable improvement when the thrombosis is believed to be of too long duration to justify immediate direct operative attack upon the thrombosed artery. Not infrequently, patients having acute thrombosis who survive without gangrene can be treated later by by-passing procedures (Fig 17).

The commonest of all arterial disorders are the chronic obliterative arterial diseases and by far the commonest of these is *arteriosclerosis obliterans*. This occurs more commonly in men than in women and in the elderly rather than in the young. Though it is usually seen in individuals forty years or more in age, it is occasionally observed in younger people, particularly in those with

diabetes. Among diabetics, females are affected about as commonly as males. In many individuals, the arteriosclerotic process is a diffuse one affecting arteries throughout the body. In other individuals, it may be a very localized disease affecting only a relatively small segment of some arterial stem. Superficial migratory phlebitis, such as occurs in thromboangiitis obliterans, is not observed in arteriosclerosis. The lower extremities are affected predominantly and only rarely the upper extremities.

Thrombotic obstruction may take place in the terminal aorta, producing *Leriche's syndrome*. In this condition, the patient complains of intermittent claudication in the hips and frequently of impotence. When the iliac arteries are obstructed, the intermittent claudication is in the hips and thighs. When the femoral or popliteal arteries are occluded, intermittent claudication is felt in the calves. In rare circumstances in which the occlusive process affects the smaller arteries of the leg, the intermittent claudication may be noted in the feet. In addition to intermittent claudication, which is a very common complaint, rest pain may be present. This may be quite severe. It is usually experienced when the patient is in bed at night and is relieved to a certain extent by making the feet dependent. In patients with marked ischemia, the feet may be cold and numb. Ulceration of the toes or foot and superficial or deep gangrene may be present. In rare patients with occlusion of only the small arteries of the foot, ul-

ceration or even gangrene of toes may be present with good pulses in the major arteries of the lower extremity and no intermittent claudication.

On examination, one usually observes absent or weak pulsations in one or more of the major arteries of the extremity. The foot is apt to be cool and somewhat pale. The skin may have an atrophic, glossy appearance. Growth of hair may be poor and the nails may be deformed. The foot is likely to show pallor on elevation and rubor in the dependent position. Venous filling may be slow and incomplete. X-ray study of the soft tissues may reveal calcification of arteries.

Thromboangiitis obliterans occurs far less commonly than obliterative arteriosclerosis. Indeed, in most communities, thromboangiitis obliterans is a rare disease. The diagnosis is made far more commonly than the incidence of the disease warrants. It occurs predominantly in young individuals under the age of forty and almost exclusively in males. Though the lower extremities are primarily affected, the upper extremities may be involved as well and are diseased in a higher percentage of patients than is true of arteriosclerosis. There is a history of superficial migratory phlebitis in a substantial percentage of patients with thromboangiitis obliterans. Vessels in any part of the body may be affected, but the occlusive inflammatory process tends to be segmental. Microscopically there is evidence of nonsuppurative panarteritis or panphlebitis associated with prolifera-

Figure 17. Methods for dealing with segmental arterial occlusion. A, By thromboendarterectomy. B, Excision and end-to-end interpolation of graft. C, End-to-side by-pass with graft.

tion of intimal cells and cellular infiltration, particularly about the vasa vasorum in the adventitial layer, and a highly organized obstructing thrombus. As is true in patients with obliterative arteriosclerosis, patients with thromboangitis obliterans tend to have intermittent claudication, may have severe rest pain and are subject to ulceration of the toes and feet and to superficial and deep gangrene. In general, ulcerations due to thromboangitis obliterans are more painful than comparable lesions due to arteriosclerosis. In general, too, the collateral circulation about obstructed lesions in patients with thromboangitis obliterans is better than around similarly obstructed areas in patients having arteriosclerosis. Nevertheless, collateral circulation is not infrequently totally deficient, leading to extensive gangrene and necessitating amputation.

The chronic obliterative arterial diseases demand very careful treatment. Abstinence from tobacco should be advised and this is absolutely mandatory in patients with thromboangitis obliterans. Patients should be taught to take extraordinarily good care of the skin of their feet, to trim their nails carefully and in such a way as to minimize the hazard of developing ingrowing toenails. They should consult physicians for minor difficulties rather than apply home remedies. Seemingly trivial lesions such as calluses, fissures, vesicles and superficial ulcers may lead to loss of limb. Patients with intermittent claudication should be advised to cease walking and rest for a moment just short of the distance which brings on pain or fatigue, rather than to stop and rest after the onset of such claudication. They should understand that the walking distance can be increased by slowing the speed of walking. Existing diabetes should be kept under rigid control. Whenever annoying or disabling claudication is present, special study may be warranted in order to determine whether one is dealing with a segmental occlusion of a major arterial stem.

Distal arteriography is especially helpful. One can almost always determine the level of proximal obstruction. It is important to find out the extent of the obstruction and whether the distal arterial tree is open and adequate or whether it is diseased and insufficient. When a segmental occlusion is present with an open distal pathway, there is an excellent possibility of being able to restore relatively normal circulation to the extremity and to eliminate intermittent claudication by thromboendarterectomy or a grafting procedure.

In general, by-pass grafting procedures are the most effectual. The likelihood of a segmental block is suggested by the presence of intermittent claudication with relatively good circulation at rest. It is more apt to be present in the young than in the old, in individuals who have unilateral rather than bilateral difficulty, in the absence of demonstrable extensive calcification of vessels and in instances in which the arterial block is proximally rather than distally situated. Unfortunately, all too often, when the occlusive process begins in the femoral artery, it may extend down through the entire popliteal artery and involve its branches in the calf. Under such circumstances, there is no effective way of reopening the occluded arteries.

In these patients, the best method for improving the circulation is by means of sympathectomy. This may bring about complete relief of intermittent claudication in those rare instances in which it is felt solely in the small muscles of the foot. In the vast majority of patients, in whom the claudication is felt in the calf, thigh or hips, sympathectomy cannot be counted upon to bring about any significant increase in walking distance. Many patients cannot walk any further after sympathectomy has been performed than they could before. When some improvement is noted, it is usually of small degree. Sympathetic denervation does, however, often bring about remarkable improvement in the general circulation to the extremity. A previously cold foot may become quite warm. The patient may be relieved of agonizing rest pain, numbness of the foot and toes may disappear and areas of superficial ulceration may heal.

If well-developed deep gangrene is present in a patient with obliterative arteriosclerosis, the chances of avoiding amputation are slight, even though the gangrene may be limited to a toe. Toe amputations are rarely followed by healing when performed in elderly individuals with arteriosclerosis. Occasionally transmetatarsal amputations may be successful. Quite commonly good healing follows amputation carried out below the knee even when the popliteal, femoral and iliac pulses are not palpable. The more conserva-

litanous,

If pain limited to the distal portions of the foot persists after sympathetic denervation, it can sometimes be abolished by crushing appropriate sensory nerves in the leg. Such procedures are ly effectual if

the pain is diffuse and, at best, are not entirely satisfactory since the patient trades a painful foot for a numb one. On occasion it may be necessary to perform chordotomy in order to relieve pain. This is a justifiable procedure if severe pain persists in spite of more conservative measures, such as sympathetic denervation, and if the circulation is sufficiently good so that there is no real threat of loss of limb.

Aneurysms. An aneurysm is a hollow sac filled with blood and connected directly with the lumen of an artery. Aneurysms are classified into two types. *True aneurysms* are those which result from expansion of the arterial wall and in which the wall of the parent artery enters into the composition of the sac. *False aneurysms*, in contrast, result from the organization of pulsating hematomas which follow traumatic or infectious disruption of the wall of the artery. The sac of such aneurysms is formed entirely anew from perivascular tissues. Aneurysms may be further classified into traumatic, mycotic, erosion and congenital aneurysms, aneurysms which develop distal to areas of partial constriction or stenosis of arteries, and aneurysms resulting from disease of the arterial wall. A special variety of the latter type of aneurysm is the dissecting aneurysm. Aneurysms are further classified according to shape as fusiform or saccular lesions. True aneurysms may be fusiform or saccular. Most traumatic, mycotic, erosion and congenital aneurysms are saccular.

When an aneurysm develops as a consequence of traumatic perforation or rupture of an artery, the first stage is that of the pulsating hematoma. Blood extravasates through the opening in the arterial wall into adjacent tissues. The size and shape of the pulsating hematoma are determined by the nature of the surrounding tissues, the caliber of the injured artery and of the rent in its wall and by such factors as arterial blood pressure and the efficiency of the clotting mechanism. The major portion of the blood tends to clot quickly, but as time passes the thrombus becomes compressed, thinned out in its peripheral portions, and a sac of dense fibrous tissue forms. The central space communicating freely with the lumen of the artery becomes lined with a smooth endothelial-like layer. Mycotic and erosion aneurysms develop in a similar fashion, except that the causative factor is infection rather than injury. In some instances, mycotic aneurysms develop from the lodging of an infected embolus in the lumen of the artery. Presumably

the infection spreads into the wall of the artery and finally brings about thrombosis of its blood supply and ischemic erosion. In other instances, mycotic aneurysms result from the plugging up by small infected emboli of the vasa vasorum with resultant ischemic necrosis of the arterial wall. An infection outside the arterial wall may lead to infection, ischemia and disruption of the wall of the artery. These are erosion aneurysms.

Aneurysms may develop in arteries just beyond an area of partial constriction. One example is the aneurysm which develops in the subclavian artery distal to a point of compression by a tight anterior scalene muscle or a cervical rib. Another example is the aneurysm which develops beyond an area of coarctation of the aorta. The causative mechanism is thought to be the action of hydraulic forces. Blood passes through the constricted area with increased velocity and, distal to the point of stenosis, meets a mass of more slowly moving blood. Here, there is eddying of blood and increased lateral pressure. The clash of opposing streams and the increased lateral pressure result in structural fatigue and distention of the wall.

Congenital aneurysms result from intrinsic weakness of the wall of the artery. The weak wall gradually or suddenly gives way and expands into a saccular aneurysm.

Aneurysms due to arterial disease, such as arteriosclerosis or syphilis, also result from the gradual or sudden giving way of the arterial wall. This may be the result of a progressive dilatation and stretching of the diseased and weakened wall or a more or less localized disruption of the inner coats with ballooning out of the weaker portion of the wall. If the entire circumference of the artery is involved, a fusiform lesion develops. If only a portion of the wall is involved, a saccular aneurysm arises. Dissecting aneurysms develop as the result of medionecrosis. The rent occurs in the intima and media and blood extravasates into the potential space in the medial portion of the arterial wall. The dissection may extend a variable distance along the course of the vessel and may rupture back into the lumen of the artery at some other point, or perforate through the outer layer with resultant hemorrhage.

The majority of aneurysms of the ascending aorta are syphilitic in origin, although some develop as a result of arteriosclerosis and a few from trauma. Most of the aneurysms of the arch and descending thoracic aorta and almost all aneurysms of the abdominal aorta are arteriosclerotic. Peripheral ar-

terial aneurysms may be traumatic, syphilitic, arteriosclerotic or the result of medionecrosis. The peripheral and visceral arteries are the common sites for mycotic and erosion aneurysms. Intracranial aneurysms are thought to be primarily congenital, although some develop from inflammatory arteritis.

Symptoms caused by aneurysms vary with the location, size and structure of the lesion. Sometimes patients are unaware of the presence of aneurysms. In other instances a recognized mass or abnormal pulsation directs the patient's attention to the aneurysm. The chief symptoms arise from compression of adjacent structures, from rupture or from thrombosis. Aneurysms in the extremities may cause a sense of fullness or throbbing. They may be associated with paralysis of nerves or occlusion of veins as the result of compression. Sometimes they interfere with joint function. The thrombus within the sac may increase in size and bring about obstruction of blood flow into the distal artery with resultant ischemia. On occasion, a portion of the intraluminal thrombus may become dislodged and pass into the distal artery as an embolus. Aneurysms within the thorax may cause pain from vertebral erosion or compression of nerve roots. They may bring about partial or complete obstruction of the trachea, bronchi or esophagus and they may be associated with vagal paralysis. Intra-abdominal aneurysms may be similarly associated with root pain. They sometimes cause gastrointestinal dysfunction and, on occasion, obstruction of the ureters or vesicle neck. In the cranial cavity, aneurysms often cause headache and localized neurologic signs such as ophthalmoplegia. Regardless of their situation, aneurysms may perforate with serious consequences. An aneurysm in the extremity may rupture through the overlying skin, particularly if there is a thin, poorly healed wound, and fatal exsanguination may take place. When an aneurysm of an extremity perforates without external bleeding, adjacent blood vessels may be occluded by compression, with resultant ischemia. Intracranial rupture of an aneurysm near the surface of the brain results in the classical picture of subarachnoid hemorrhage. Rupture of aneurysms situated within the substance of the brain brings about variable signs and symptoms, depending upon their location and the extent of the hemorrhage. The rupture of an intrathoracic or abdominal aortic aneurysm usually leads to death, though prompt treatment may avert this disaster.

Aneurysms which are accessible to palpa-

Figure 18. Photograph showing thrombosed axillary aneurysm which required excision because of pressure paralysis of radial, ulnar and median nerves (Shumacker, H. B., and Wayson, E. E., *Am. J. Surg.*, vol. 79).

tion and auscultation can be recognized by the presence of a mass with intrinsic pulsation, a systolic thrill and a systolic bruit. A systolic bruit is heard in most aneurysms of the extremities but is not infrequently absent in intrathoracic and intra-abdominal lesions. Intra-abdominal aneurysms can usually be recognized with relative ease by the presence of a pulsating mass. Those within the thoracic cavity can be identified by fluoroscopic and x-ray examination. The commonest mistake in diagnosis is made when one erroneously interprets a transmitted pulsation of a cystic or solid mass lying adjacent to a large artery as intrinsic pulsation of the mass itself.

Aneurysms rarely become obliterated by progressive thrombosis. Sometimes, when thrombosis occurs within an aneurysm, there is simultaneous occlusion of the distal artery and ischemia of the part. Even if an aneurysm becomes solidly thrombosed without obstruction of blood flow through the distal artery, the firm, clotted sac may persist as a tumor mass and require operative treatment because of its size or because it compresses adjacent structures, such as nerves (Fig. 18). Since aneurysms rarely undergo a satisfactory "spontaneous cure" and are associated with very real danger, they should be treated surgically.

Treatment of aneurysms depends upon their size and location. If the aneurysm is accessible to palpation, it is wise to carry out a test of the collateral circulation before undertaking operative treatment. Under all circumstances, aneurysms involving main arterial stems should be

in some way

Figure 19 Drawings indicating methods for maintaining or restoring continuity of affected artery in patients with aneurysms. A, By excision and lateral suture. A. Davis Company.)

so as to preserve or restore circulation through the affected artery (Figs. 19 and 20). In certain saccular aneurysms this can be accomplished by extirpating the lesion and closing the opening from the artery into the sac by lateral suture. In other instances it is possible to remove the aneurysm and unite the mobilized ends of the artery by direct anastomosis. Frequently, excision of an aneurysm necessitates interpolation of a graft. Preserved homologous aortic grafts

and grafts fashioned of certain plastic materials are suitable for aortic replacement. Plastic prostheses are more reliable than homografts and are therefore preferred. In the extremities, fresh autogenous veins also serve satisfactorily for bridging defects of arteries. Whenever aneurysms are treated surgically, it is important that adequate exposure be obtained and that one gain control of the affected artery proximally and distally. Large aneurysms in the extremity are sometimes approached best by opening the sac directly under tourniquet control. One can then deal with the openings of the artery into the sac by suture or transfixion according to the obliterative aneurysmorrhaphy technique of Matas. If a large artery is involved, however, it is preferable to bridge the defect by suture interpolation of a graft between the ends of the artery. Once this is accomplished, the major portion of the sac wall can usually be excised without damage to the collateral vessels. In recent years, a great advance has been made in the treatment of aneurysms by demonstration that the same principles which have been used for years in the surgical management of peripheral aneurysms can be utilized for the excisional cure of aneurysms of the aorta. When an aneurysm of a main-stem peripheral artery is not associated with adequate collateral circulation, the collateral circulation can often be improved by prolonged use

of intermittent proximal occlusion of the artery. Sympathetic denervation is a valuable adjunct in bringing about the development of good collateral circulation since, with sympathetic denervation, maximal blood flow through the collateral vessels is assured.

Arteriovenous Fistulae. Arteriovenous fistulae are abnormal, direct connections between arteries and veins. Most arteriovenous fistulae result from trauma, some are the result of a congenital derangement. Arteriovenous fistulae may be classified into several groups (Fig. 21): direct fistulous communications between arteries and veins, arteriovenous fistulae associated with aneurysms, curd aneurysms in which there are multiple communications and marked dilatation of arteries and veins in the vicinity of the lesion and arteriovenous fistulae in vascular tumors such as hemangiomas and hemangioendotheliomas.

Arteriovenous fistulae are not always associated with symptoms. Sometimes the lesion is first called to the attention of the patient by its discovery during the course of a physical examination. Occasionally the patients are aware of some difficulty because they hear or feel a buzzing sensation in the region of the fistula or because they palpate a thrill in its vicinity. Some patients seek help because they notice dilated veins in the region of the lesion or alteration of warmth

	Ballistocardiogram	Pulse Rate	Stroke Volume	Cardiac Index

and color of the affected hand or foot. Sometimes medical aid is sought only after the development of cardiac symptoms, such as palpitation, tachycardia, dyspnea or frank heart failure. In rare circumstances, the patient may first seek help because of chills and fever resulting from bacterial endarteritis in the fistula.

The diagnosis usually is simple. Characteristically, in the region of the lesion a continuous bruit is present, with a systolic accentuation and a continuous thrill. If the fistula is located so that it can be temporarily occluded by digital compression, one can demonstrate a slowing of the pulse rate during compression—the Nicoladoni-Branham phenomenon. Usually, at the same time, the systolic and diastolic pressures rise and the pulse pressure decreases (Figs. 22 and 23). Such changes are pathognomonic of arteriovenous fistulae. If one withdraws venous blood from the neighborhood of the fistula, he can demonstrate arterial oxygen—

saturation as compared with blood drawn from a similarly located vein in the contralateral extremity. One will commonly note evidences suggesting increased circulation. The hand or foot may be unusually warm and well colored. If the arteriovenous fistula has been present before completion of epiphyseal growth, some increase in the length of the extremity may have taken place. Not in all instances are arteriovenous fistulae associated with evidences of increased circulation to the extremity. Sometimes they are associated with coldness, pallor, cyanosis and hyperhidrosis and in a few instances ischemic ulceration may be present. Although the arterial pulsation is increased in the region of the arteriovenous communication, the pulses distally are characteristically weaker than in the contralateral extremity and the blood pressure distal to the lesion is reduced. The systemic blood pressure may be somewhat elevated and the pulse pressure is characteristically increased. If the pulse pressure is wide, a capillary pulsation may be demonstrated or a pistol-shot sound may be audible over large peripheral arteries. There may be evidence of cardiac enlargement or even of heart failure. In most instances of large arteriovenous fistulae, one can demonstrate an increase in total circulating blood volume.

The circulatory changes which occur on sudden occlusion of an arteriovenous fistula are a very interesting physiologic response. The slowing of the pulse rate can be abolished by administration of large doses of vagal blocking agents. Vagal blocking, however, does not abolish the blood pressure responses to the occlusion. The cardiac output undergoes a precipitous and significant decrease upon closing of the fistula. All of these changes occur with the very first beat of the heart after the fistula is compressed. It has been demonstrated experimentally that blood pressure and cardiac output alterations upon occlusion of an arteriovenous fistula occur after depriving the heart completely of its vagal and sympathetic nerve supply. They constitute mechanical responses to shutting off abruptly the parasitic circulation through the fistula.

The increased work load on the heart in patients with large arteriovenous fistulae gradually leads to dilatation of the heart and eventually, in some instances, to frank heart failure. This results from the increased blood volume and the recirculation of blood through the fistula and directly back to the heart. Cardiac strain can be judged in a

rough fashion by the magnitude of the pulse and blood pressure responses to digital occlusion of the fistula. Significant cardiac enlargement is likely to be found in patients with marked slowing of the pulse rate, considerable rise in systolic and diastolic pressure and marked decrease in pulse pressure. Cardiac enlargement is also directly related to the size of the artery involved, to the size of the fistulous communication and to the duration of the lesion. Fistulae in the abdomen, pelvis and lower extremities are more likely to result in significant cardiac enlargement than fistulae of the head, neck and upper extremities.

Arteriovenous fistulae rarely close spontaneously. They tend, with the passage of time, to be associated with progressive dilatation of the veins in the neighborhood of the lesion and with dilatation of the proximal artery. The blood volume increases and cardiac dilatation becomes more marked as time passes. Ultimately, heart failure may occur. In rare instances, subacute bacterial endarteritis may develop in the fistula, manifested by bacteremia, chills and fever. Because of these consequences, arteriovenous fistulae should be treated by surgical extirpation.

As in patients with peripheral aneurysms, it is wise, before undertaking operation upon an arteriovenous fistula, to determine, if possible, the status of the collateral circulation. Ample exposure of the arteriovenous fistula should be obtained and the main artery and vein should be isolated proximally and distally before approaching the region of the fistula itself. One should never carry out a proximal arterial ligation for an arteriovenous fistula except in the case of internal carotid-cavernous sinus fistula. In this instance, the internal carotid artery has no branches between the point of origin and the point of the fistula and ligation of the carotid artery, preferably with ligation of the concomitant vein, often results in cure. In general, however, proximal arterial ligation does not effect a cure and is quite likely to result in gangrene. With the proximal artery ligated, the collateral vessels tend to drain into the distal artery and back through the fistulous communication into the vein and, thus, to deprive the distal portions of the extremity of adequate circulation. Arteriovenous fistulae should never be treated by simple ligation of the fistulous tract, for recurrence takes place far too commonly after such procedures. The fistula must be divided or excised. If the lesion affects a

Figure 21 Diagrammatic representation of various types of arteriovenous fistulae and associated aneurysms. Symbols: A, artery, V, vein, S, sacular aneurysm (Shumacker, H B., and Wayson, E. E. *Am J Surg*, vol 70).

of intermittent proximal occlusion of the artery. Sympathetic denervation is a valuable adjunct in bringing about the development of good collateral circulation since, with sympathetic denervation, maximal blood flow through the collateral vessels is assured.

Arteriovenous Fistulae. Arteriovenous fistulae are abnormal, direct connections between arteries and veins. Most arteriovenous fistulae result from trauma; some are the result of a congenital derangement. Arteriovenous fistulae may be classified into several groups (Fig 21) direct fistulous communications between arteries and veins, arteriovenous fistulae associated with aneurysms, cirroid aneurysms in which there are multiple communications and marked dilatation of arteries and veins in the vicinity of the lesion and arteriovenous fistulae in vascular tumors such as hemangiomas and hemangio-endotheliomas.

Arteriovenous fistulae are not always associated with symptoms. Sometimes the lesion is first called to the attention of the patient by its discovery during the course of a physical examination. Occasionally the patients are aware of some difficulty because they hear or feel a buzzing sensation in the region of the fistula or because they palpate a thrill in its vicinity. Some patients seek help because they notice dilated veins in the region of the lesion or alteration of warmth

Figure 22. Ballistocardiographic tracings, pulse rate and estimated stroke volume and cardiac index changes with occlusion of human arteriovenous fistula before and after atropinization (Elkin, D. C., and Warren, J. V.: *J.A.M.A.*, vol 134).

Figure 23. Optically recorded Hamilton manometric measurements of change in blood pressure (A) upon occlusion and (B) upon release of pressure from experimentally produced femoral arteriovenous fistula in dog with total excision of extrinsic nerve supply to heart. Period of occlusion indicated by heavy line (Shumacker, H B., et al. *J Thoracic Surg*, vol. 20)

and color of the affected hand or foot. Sometimes medical aid is sought only after the development of cardiac symptoms, such as palpitation, tachycardia, dyspnea or frank heart failure. In rare circumstances, the patient may first seek help because of chills and fever resulting from bacterial endarteritis in the fistula.

The diagnosis usually is simple. Characteristically, in the region of the lesion a continuous bruit is present, with a systolic accentuation and a continuous thrill. If the fistula is located so that it can be temporarily occluded by digital compression, one can demonstrate a slowing of the pulse rate during compression—the Nicoladoni-Branham phenomenon. Usually, at the same time, the systolic and diastolic pressures rise and the pulse pressure decreases (Figs 22 and 23). Such changes are pathognomonic of arteriovenous fistulae. If one withdraws venous blood from the neighborhood of the fistula, he can demonstrate

saturation as compared with blood drawn from a similarly located vein in the contralateral extremity. One will commonly note evidences suggesting increased circulation. The hand or foot may be unusually warm and well colored. If the arteriovenous fistula has been present before completion of epiphyseal growth, some increase in the length of the extremity may have taken place. Not in all instances are arteriovenous fistulae associated with evidences of increased circulation to the extremity. Sometimes they are associated with coldness, pallor, cyanosis and hyperhidrosis and in a few instances ischemic ulceration may be present. Although the arterial pulsation is increased in the region of the arteriovenous communication, the pulses distally are characteristically weaker than in the contralateral extremity and the blood pressure distal to the lesion is reduced. The systemic blood pressure may be somewhat elevated and the pulse pressure is characteristically increased. If the pulse pressure is wide, a capillary pulsation may be demonstrated or a pistol-shot sound may be audible over large peripheral arteries. There may be evidence of cardiac enlargement or even of heart failure. In most instances of large arteriovenous fistulae, one can demonstrate an increase in total circulating blood volume.

The circulatory changes which occur on sudden occlusion of an arteriovenous fistula are a very interesting physiologic response. The slowing of the pulse rate can be abolished by administration of large doses of vagal blocking agents. Vagal blocking, however, does not abolish the blood pressure responses to the occlusion. The cardiac output undergoes a precipitous and significant decrease upon closing of the fistula. All of these changes occur with the very first beat of the heart after the fistula is compressed. It has been demonstrated experimentally that blood pressure and cardiac output alterations upon occlusion of an arteriovenous fistula occur after depriving the heart completely of its vagal and sympathetic nerve supply. They constitute mechanical responses to shutting off abruptly the parasitic circulation through the fistula.

The increased work load on the heart in patients with large arteriovenous fistulae gradually leads to dilatation of the heart and eventually, in some instances, to frank heart failure. This results from the increased blood volume and the recirculation of blood through the fistula and directly back to the heart. Cardiac strain can be judged in a

rough fashion by the magnitude of the pulse and blood pressure responses to digital occlusion of the fistula. Significant cardiac enlargement is likely to be found in patients with marked slowing of the pulse rate, considerable rise in systolic and diastolic pressure and marked decrease in pulse pressure. Cardiac enlargement is also directly related to the size of the artery involved, to the size of the fistulous communication and to the duration of the lesion. Fistulae in the abdomen, pelvis and lower extremities are more likely to result in significant cardiac enlargement than fistulae of the head, neck and upper extremities.

Arteriovenous fistulae rarely close spontaneously. They tend, with the passage of time, to be associated with progressive dilatation of the veins in the neighborhood of the lesion and with dilatation of the proximal artery. The blood volume increases and cardiac dilatation becomes more marked as time passes. Ultimately, heart failure may occur. In rare instances, subacute bacterial endarteritis may develop in the fistula, manifested by bacteremia, chills and fever. Because of these consequences, arteriovenous fistulae should be treated by surgical extirpation.

As in patients with peripheral aneurysms, it is wise, before undertaking operation upon an arteriovenous fistula, to determine, if possible, the status of the collateral circulation. Ample exposure of the arteriovenous fistula should be obtained and the main artery and vein should be isolated proximally and distally before approaching the region of the fistula itself. One should never carry out a proximal arterial ligation for an arteriovenous fistula except in the case of internal carotid-cavernous sinus fistula. In this instance, the internal carotid artery has no branches between the point of origin and the point of the fistula and ligation of the carotid artery, preferably with ligation of the concomitant vein, often results in cure. In general, however, proximal arterial ligation does not effect a cure and is quite likely to result in gangrene. With the proximal artery ligated, the collateral vessels tend to drain into the distal artery and back through the fistulous communication into the vein and, thus, to deprive the distal portions of the extremity of adequate circulation. Arteriovenous fistulae should never be treated by simple ligation of the fistulous tract, for recurrence takes place far too commonly after such procedures. The fistula must be divided or excised. If the lesion affects a

main-stem artery important in the nutrition of the extremity, every effort should be made to preserve or restore its continuity. This can ordinarily be accomplished, either by carefully dissecting out the fistula, dividing it and closing the defect in the artery by

lateral suture or, more commonly, by excising the fistulous tract, together with the affected portion of the artery and vein, and reconstituting the artery by end-to-end anastomosis or by interpolation of a vascular graft (Fig. 24). The results of treatment are

very satisfactory (Fig. 25). Any cardiac dilatation which may be present tends to disappear shortly after operation. Cardiac failure, if present, is dramatically relieved. The increased blood volume returns to normal.

The Lymphatics

By GERALD H. PRATT, M.D.

GERALD HILARY PRATT was educated at the Universities of Minnesota and Iowa and trained in surgery in the South and on the eastern seaboard. He had experience in both the Army and Navy Medical Corps during World War II and there developed his interest in the diseases of the vascular and lymphatic systems.

Definition. The lymphatic system is complex and consists of massive capillary combinations which carry the lymph from all tissues of the body to a large system of col-

lecting vessels. These latter graduate in size and eventually transmit the lymph substance into the veins. Its passageway is filtered at various points by lymph glands which also

contribute lymphocytes to the fluid. Lymph itself is a transparent white or yellow fluid of alkaline type which may be pink when it contains red blood corpuscles. A common fat content may make it opalescent. The lymph corpuscles are granular, similar to white blood cells and measure approximately $1/2500$ inch in diameter. The lymphatic vessels of the intestine are similar, but during digestion they contain chyle, a milky substance, and they are designated as lacteals. Certain organs are of lymphocytic origin. Examples of these are the spleen, bone marrow, thymus gland, mucous membrane follicles and the tonsils.

The blood circulatory system carries oxygenated blood to the organs and periphery from the central pump, the heart. This blood passes through the capillary bed and tissue spaces and is reaccumulated in the venule end of the capillaries and returned to the heart by the venous system. The circulatory system has another component—the lymphatic system. This system is a closed one, with its own conduits, its capillaries, collecting minute lymphatic vessels, and larger transporting channels to its final vessels, the thoracic duct and the right lymphatic duct. The lymph drainage carrying certain products of metabolism from the bowel joins these final channels through the cisterna chyli (receptaculum chyli). These empty into the venous system at the junction of the subclavian and jugular veins. This lymphatic system is an integral and important part of the circulation and its anatomy and function are complex.

Embryology. The lymphatic system develops embryologically like the rest of the arterial and vascular system. The lymphatic endothelium arises from the venous endothelium. There is no reason to believe that it arises from mesenchymal cells. The lymphatic endothelium forms paired and unpaired sacs. Of the former, the jugular lymph sacs are derived from the jugular veins and then extend to the head, neck, thorax and arms. The other paired sacs arise from the iliac veins, where they unite with the cardinal veins. These spread to the abdominal wall, the pelvis and the legs. These lymphatic vessels join the cisterna chyli and vary from others in that they are not connected with veins. The unpaired lymphatics develop from the vena cava and mesonephric veins to form the retroperitoneal lymph sac. These lose their vein connections and join the cisterna chyli. Veins from the wolffian

bodies form sprouts to develop as the cisterna chyli.

The lymph nodes primarily develop in capillary plexuses at the third month of fetal life. The lymphocytes are already present and these probably form lymph masses and the lymphoid nodules. The mesenchyma forms a connecting tissue capsule. Trabeculae grow from this. The capillaries arise first, from which larger vessels lead to other vessels or nodes. The deeper plexuses develop first, both throughout the body and in the intestines, and gradually the superficial thoracic vessels are formed. All the lymph sacs except the cisterna chyli are divided by connective tissue bridges, which help to form the lymph glands. The cisterna chyli in the lower part becomes a gland, but its upper portion remains as a conduit or cisterna.

Anatomy. For descriptive purposes, the lymphatic system may be divided into four parts: the lymphatic fluid, the capillaries, the collecting vessels including the thoracic ducts, and the lymph glands (Fig. 26).

Lymph is a clear yellow substance, similar to but more dilute than blood plasma. It has a specific gravity of approximately 1.015. Its contents are lymphocytes and red blood corpuscles. The lymph probably accumulates by an osmosis-diffusion-filtration process from the tissue fluids. It is not the same as tissue fluid, however.

The *capillaries* are lined by flat endothelial cells, which lie in connective tissue regions throughout the body in areas bathed by intracellular tissue fluids. These lymphatic capillaries anastomose widely and they do not have a set size or form. Many of these capillaries have blind ends. The plexuses have both superficial and deep layers, the superficial one being the smaller. In the skin, lymphatic capillaries are found in the dermis. The epidermis is without lymphatic capillaries, which is of surgical interest. The subcutaneous tissue normally does not have any capillaries. Muscles, tendons, their sheaths, the periosteum and the joints all have lymphatic capillaries in abundance. The periosteum, the peritoneum, the pericardium and the pleura also have rich lymphatic components. In the digestive tract, just below the epithelium, are both superficial and deep lymphatic plexuses. The papillae appear to extend in blind-end formations into the villi of the small intestine. The lacteals arise in the lymphatic spaces in the intestinal villi.

Figure 26 Diagrammatic drawing of the lymphatic drainage of the body.

contribute lymphocytes to the fluid. Lymph itself is a transparent white or yellow fluid of alkaline type which may be pink when it contains red blood corpuscles. A common fat content may make it opalescent. The lymph corpuscles are granular, similar to white blood cells and measure approximately $1/2500$ inch in diameter. Examples of these are the spleen, bone marrow, thymus gland, mucous membrane follicles and the tonsils.

The blood circulatory system carries oxygenated blood to the organs and periphery from the central pump, the heart. Thus blood passes through the capillary bed and tissue spaces and is reaccumulated in the venule end of the capillaries and returned to the heart by the venous system. The circulatory system has another component—the lymphatic system. This system is a closed one, with its own conduits, its capillaries, collecting minute lymphatic vessels, and larger transporting channels to its final vessels, the thoracic duct and the right lymphatic duct. The lymph drainage carrying certain products of metabolism from the bowel joins these final channels through the cisterna chyli (receptaculum chyli). These empty into the venous system at the junction of the subclavian and jugular veins. This lymphatic system is an integral and important part of the circulation and its anatomy and function are complex.

Embryology. The lymphatic system develops embryologically like the rest of the arterial and vascular system. The lymphatic endothelium arises from the venous endothelium. There is no reason to believe that it arises from mesenchymal cells. The lymphatic endothelium forms paired and unpaired sacs. Of the former, the jugular lymph sacs are derived from the jugular veins and then extend to the head, neck, thorax and arms. The other paired sacs arise from the iliac veins, where they unite with the cardinal veins. These spread to the abdominal wall, the pelvis and the legs. These lymphatic vessels join the cisterna chyli and vary from others in that they are not connected with veins. The unpaired lymphatics develop from the vena cava and mesonephric veins to form the retroperitoneal lymph sac. These lose their vein connections and join the cisterna chyli. Veins from the wolffian

bodies form sprouts to develop as the cisterna chyli.

The lymph nodes primarily develop in capillary plexuses at the third month of fetal life. The lymphocytes are already present and these probably form lymph masses and the lymphoid nodules. The mesenchyma forms a connecting tissue capsule. Trabeculae grow from this. The capillaries arise first, from which larger vessels lead to other vessels or nodes. The deeper plexuses develop first, both throughout the body and in the intestines, and gradually the superficial thoracic vessels are formed. All the lymph sacs except the cisterna chyli are divided by connective tissue bridges, which help to form the lymph glands. The cisterna chyli in the lower part becomes a gland, but its upper portion remains as a conduit or cisterna.

Anatomy. For descriptive purposes, the lymphatic system may be divided into four parts: the lymphatic fluid, the capillaries, the collecting vessels including the thoracic ducts, and the lymph glands (Fig. 26).

Lymph is a clear yellow substance, similar to but more dilute than blood plasma. It has a specific gravity of approximately 1.015. Its contents are lymphocytes and red blood corpuscles. The lymph probably accumulates by an osmosis-diffusion-filtration process from the tissue fluids. It is not the same as tissue fluid, however.

The *capillaries* are lined by flat endothelial cells, which lie in connective tissue regions throughout the body in areas bathed by intracellular tissue fluids. These lymphatic capillaries anastomose widely and they do not have a set size or form. Many of these capillaries have blind ends. The plexuses have both superficial and deep layers, the superficial one being the smaller. In the skin, lymphatic capillaries are found in the dermis. The epidermis is without lymphatic capillaries, which is of surgical interest. The subcutaneous tissue normally does not have any capillaries. Muscles, tendons, their sheaths, the periosteum and the joints all have lymphatic capillaries in abundance. The periosteum, the peritoneum, the pericardium and the pleura also have rich lymphatic components. In the digestive tract, just below the epithelium, are both superficial and deep lymphatic plexuses. The papillae appear to extend in blind-end formations into the villi of the small intestine. The lacteals arise in the lymphatic spaces in the intestinal villi.

Figure 26 Diagrammatic drawing of the lymphatic drainage of the body.

contribute lymphocytes to the fluid. Lymph itself is a transparent white or yellow fluid of alkaline type which may be pink when it contains red blood corpuscles. A common fat content may make it opalescent. The lymph corpuscles are granular, similar to white blood cells and measure approximately $\frac{1}{2500}$ inch in diameter. The lymphatic vessels of the intestine are similar, but during digestion they contain chyle, a milky substance, and they are designated as lacteals. Certain organs are of lymphocytic origin. Examples of these are the spleen, bone marrow, thymus gland, mucous membrane follicles and the tonsils.

The blood circulatory system carries oxygenated blood to the organs and periphery from the central pump, the heart. This blood passes through the capillary bed and tissue spaces and is reaccumulated in the venule end of the capillaries and returned to the heart by the venous system. The circulatory system has another component—the lymphatic system. This system is a closed one, with its own conduits, its capillaries, collecting minute lymphatic vessels, and larger transporting channels to its final vessels, the thoracic duct and the right lymphatic duct. The lymph drainage carrying certain products of metabolism from the bowel joins these final channels through the *cisterna chyli* (*receptaculum chyli*). These empty into the venous system at the junction of the subclavian and jugular veins. This lymphatic system is an integral and important part of the circulation and its anatomy and function are complex.

Embryology. The lymphatic system develops embryologically like the rest of the arterial and vascular system. The lymphatic endothelium arises from the venous endothelium. There is no reason to believe that it arises from mesenchymal cells. The lymphatic endothelium forms paired and unpaired sacs. Of the former, the jugular lymph sacs are derived from the jugular veins and then extend to the head, neck, thorax and arms. The other paired sacs arise from the iliac veins, where they unite with the cardinal veins. These spread to the abdominal wall, the pelvis and the legs. These lymphatic vessels join the *cisterna chyli* and vary from others in that they are not connected with veins. The unpaired lymphatics develop from the vena cava and mesonephric veins to form the retroperitoneal lymph sac. These lose their vein connections and join the *cisterna chyli*. Veins from the wolffian

bodies form sprouts to develop as the *cisterna chyli*.

The lymph nodes primarily develop in capillary plexuses at the third month of fetal life. The lymphocytes are already present and these probably form lymph masses and the lymphoid nodules. The mesenchyma forms a connecting tissue capsule. Trabeculae grow from this. The capillaries arise first, from which larger vessels lead to other vessels or nodes. The deeper plexuses develop first, both throughout the body and in the intestines, and gradually the superficial thoracic vessels are formed. All the lymph sacs except the *cisterna chyli* are divided by connective tissue bridges, which help to form the lymph glands. The *cisterna chyli* in the lower part becomes a gland, but its upper portion remains as a conduit or *cisterna*.

Anatomy. For descriptive purposes, the lymphatic system may be divided into four parts: the lymphatic fluid, the capillaries, the collecting vessels including the thoracic ducts, and the lymph glands (Fig. 26).

Lymph is a clear yellow substance, similar to but more dilute than blood plasma. It has a specific gravity of approximately 1.015. Its contents are lymphocytes and red blood corpuscles. The lymph probably accumulates by an osmosis-diffusion-filtration process from the tissue fluids. It is not the same as tissue fluid, however.

The *capillaries* are lined by flat endothelial cells, which lie in connective tissue regions throughout the body in areas bathed by intracellular tissue fluids. These lymphatic capillaries anastomose widely and they do not have a set size or form. Many of these capillaries have blind ends. The plexuses have both superficial and deep layers, the superficial one being the smaller. In the skin, lymphatic capillaries are found in the dermis. The epidermis is without lymphatic capillaries, which is of surgical interest. The subcutaneous tissue normally does not have any capillaries. Muscles, tendons, their sheaths, the periosteum and the joints all have lymphatic capillaries in abundance. The periosteum, the peritoneum, the pericardium and the pleura also have rich lymphatic components. In the digestive tract, just below the epithelium, are both superficial and deep lymphatic plexuses. The papillae appear to extend in blind-end formations into the villi of the small intestine. The lacteals arise in the lymphatic spaces in the intestinal villi.

Figure 26. Diagrammatic drawing of the lymphatic drainage of the body

The salivary glands, the liver, the spleen, the adrenals and the kidney have large supplies of lymphatic capillaries. The nasal, tracheal and bronchial trees have a wide distribution of lymphatics within them. The bladder, the prostate, testes, ovaries and uterus all have a wealth of plexuses. The heart is also abundantly supplied with lymphatics, which lie beneath the endocardium and throughout the myocardium. Lymphatics are not seen in the bone marrow or in cartilage. The central nervous system is not supplied with lymphatics. Other tissues without lymphatic capillaries are the liver lobule, the meninges, the eye, the internal ear, most striated muscle, the spleen pulp, kidney, bone marrow, cartilage and epidermis.

The *lymphatic vessels* collect the fluid from the lymphatic capillaries. All parts of the body, with the exception of the non-vascular areas, contain lymph vessels. These exceptions are the hair, nails, cuticles and cartilages. The lymph vessels have an internal, a middle and an external coat. The *internal coat* is a layer of elongated endothelial cells, supported by an elastic membrane. The middle coat is of smooth muscle, except in the smaller vessels. The external coat has some muscle fibers, but there is mainly a connective tissue covering which becomes firmer as the vessels increase in size. In construction, the thoracic duct, with a subendothelial layer of muscle and elastic fibers, is more like a blood than a lymphatic vessel. The blood and nerve supplies to the lymphatics enter into the outer and middle coats.

The valves of the lymphatic vessels originate from the fibrous tissues that have an endothelial covering similar to that of veins. These valves are of a semilunar type and they are placed much closer together than are the valves of the vein. The number of valves increases as one approaches a lymph gland. They are fewer in number in the lower extremity as compared to the upper extremity or the head and neck. The vessels pouch above the valves and when distended they appear knotted in shape.

The superficial lymph vessels accompany the veins, with which they perforate the deep fascia. They lie in the submucosal fatty tissue throughout the digestive, respiratory and genitourinary tracts, and in the thoracic and abdominal walls just below the serosa.

The lymphatic vessels are plexiform networks, these networks being larger than those of the capillary plexus. They form

small vessels which pass to a neighboring gland or from a larger lymphatic trunk. The deep lymphatic vessels are larger but fewer in number and they also accompany the blood vessels. The lymphatic vessels are *more numerous than veins, but are smaller in size*. The vessels with which they anastomose are frequently of the same size.

The *cisterna chyli* is formed from the intestinal trunk which drains the lymphatics from the stomach and intestine, the pancreas, spleen and from the lower and forward part of the liver. It is joined by the right and left lumbar lymphatic trunks formed by the vessels from the aortic lymph nodes and the lower limbs and the walls of the pelvis, kidneys and adrenal glands. The lymphatics of the abdominal wall also open in this area.

Through the *thoracic duct* the lymph and chyle are carried from the tissues and organs into the blood stream. It is a final collecting place for all of the lymph in the body except that from the right side of the head, neck and thorax, from the right arm, right lung, right side of the heart and the convex side of the liver. It begins at the second lumbar vertebra, to the right of and behind the aorta. There is a descending trunk from the posterior intercostal lymph glands, a trunk which drains the upper lumbar lymphatic glands, and a trunk from the posterior mediastinal lymph glands and the intercostal lymph glands of the lower and upper intercostal spaces which join the thoracic duct just above the cisterna chyli. The thoracic duct passes through the diaphragm with the aorta and ascends between the aorta and the azygos vein. At the level of the fifth thoracic vertebra, it passes to the left and ascends behind the aortic arch and the left subclavian artery between the esophagus and the left pleura. The left jugular and left subclavian trunks also join the thoracic duct, as may the left bronchomediastinal trunks. In the neck, the duct arches to approximately 3 cm. above the clavicle and crosses in front of the subclavian artery, the vertebral artery and vein and the thyrocervical trunk and opens into the left subclavian vein at its junction with the left internal jugular vein.

The *right lymphatic duct* drains the areas on the right already described and opens into the right subclavian vein at its junction with the right internal jugular vein.

The *lymph nodes or glands* are oval or round structures spaced in the channels of the lymph vessels. Their size varies between that of a bean and that of an olive. The afferent lymph vessels enter at various parts

of the periphery. The efferent vessels leave at the hilum, which is the same site through which blood vessels and nerves enter and leave. The gland is made of packed lymphocytes massed between trabeculae from the capsule. Reticular fibers from the trabeculae further divide the gland into sinuses. The efferent vessels open into the subcapsular sinuses and the efferent arise from the medullary sinuses. The germ centers where the lymphocytes increase by division are in the center of the cortical sinuses.

Modern surgery, in its effort to control infection and malignant disease, requires the knowledge of the lymphatic drainage from specific parts and organs. Upon such knowledge depend the possibilities of cure and sometimes life or death.

Lymphatic supply of upper extremity. The lymphatics of the upper extremity are both superficial and deep and in general follow the course of the veins. The superficial lymph glands normally are few in

number. There are some supratrochlear glands above the medial epicondyle of the humerus which drain the third, fourth and fifth fingers, the medial side of the hand and ulnar side of the forearm afferently to the deeper vessels. There are some deltoid pectoral nodes near the cephalic nodes which also drain superficially.

The deep glands may have a few scattered nodes along the radial, ulnar and brachial arteries. The main deep nodes are the axillary nodes which are large and are twenty to thirty in number. They consist of five groups: (1) The anterior or pectoral consists of four or five nodes around the lateral thoracic artery at the lower border of the pectoralis minor muscle. They drain the anterior and lateral chest wall and the lateral and middle part of the breast efferently to the subclavicular group. (2) The posterior or subscapular glands follow the subscapular artery. They drain the skin and muscles of the back of the neck and thorax

Figure 27. Lymph drainage of the axilla. Arrows indicate direction of flow. Note the five groups of lymph nodes and their vessels. Drainage to the lymphatic ducts to the neck and mediastinum makes eradication of malignant disease difficult once it has extended to the glands.

The salivary glands, the liver, the spleen, the adrenals and the kidney have large supplies of lymphatic capillaries. The nasal, tracheal and bronchial trees have a wide distribution of lymphatics within them. The bladder, the prostate, testes, ovaries and uterus all have a wealth of plexuses. The heart is also abundantly supplied with lymphatics, which lie beneath the endocardium and throughout the myocardium. Lymphatics are not seen in the bone marrow or in cartilage. The central nervous system is not supplied with lymphatics. Other tissues without lymphatic capillaries are the liver lobule, the meninges, the eye, the internal ear, most striated muscle, the spleen pulp, kidney, bone marrow, cartilage and epidermis.

The *lymphatic vessels* collect the fluid from the lymphatic capillaries. All parts of the body, with the exception of the non-vascular areas, contain lymph vessels. These exceptions are the hair, nails, cuticles and cartilages. The lymph vessels have an internal, a middle and an external coat. The internal coat is a layer of elongated endothelial cells, supported by an elastic membrane. The middle coat is of smooth muscle, except in the smaller vessels. The external coat has some muscle fibers, but there is mainly a connective tissue covering which becomes firmer as the vessels increase in size. In construction, the thoracic duct, with a subendothelial layer of muscle and elastic fibers, is more like a blood than a lymphatic vessel. The blood and nerve supplies to the lymphatics enter into the outer and middle coats.

The valves of the lymphatic vessels originate from the fibrous tissues that have an endothelial covering similar to that of veins. These valves are of a semilunar type and they are placed much closer together than are the valves of the vein. The number of valves increases as one approaches a lymph gland. They are fewer in number in the lower extremity as compared to the upper extremity or the head and neck. The vessels pouch above the valves and when distended they appear knotted in shape.

The superficial lymph vessels accompany the veins, with which they perforate the deep fascia. They lie in the submucosal fatty tissue throughout the digestive, respiratory and genitourinary tracts, and in the thoracic and abdominal walls just below the serosa.

The lymphatic vessels are plexiform networks, these networks being larger than those of the capillary plexus. They form

small vessels which pass to a neighboring gland or from a larger lymphatic trunk. The deep lymphatic vessels are larger but fewer in number and they also accompany the blood vessels. The lymphatic vessels are more numerous than veins, but are smaller in size. The vessels with which they anastomose are frequently of the same size.

The *cisterna chyli* is formed from the intestinal trunk which drains the lymphatics from the stomach and intestine, the pancreas, spleen and from the lower and forward part of the liver. It is joined by the right and left lumbar lymphatic trunks formed by the vessels from the aortic lymph nodes and the lower limbs and the walls of the pelvis, kidneys and adrenal glands. The lymphatics of the abdominal wall also open in this area.

Through the *thoracic duct* the lymph and chyle are carried from the tissues and organs into the blood stream. It is a final collecting place for all of the lymph in the body except that from the right side of the head, neck and thorax, from the right arm, right lung, right side of the heart and the convex side of the liver. It begins at the second lumbar vertebra, to the right of and behind the aorta. There is a descending trunk from the posterior intercostal lymph glands, a trunk which drains the upper lumbar lymphatic glands, and a trunk from the posterior mediastinal lymph glands and the intercostal lymph glands of the lower and upper intercostal spaces which join the thoracic duct just above the cisterna chyli. The thoracic duct passes through the diaphragm with the aorta and ascends between the aorta and the azygos vein. At the level of the fifth thoracic vertebra, it passes to the left and ascends behind the aortic arch and the left subclavian artery between the esophagus and the left pleura. The left jugular and left subclavian trunks also join the thoracic duct, as may the left bronchomediastinal trunks. In the neck, the duct arches to approximately 3 cm above the clavicle and crosses in front of the subclavian artery, the *vertebral artery* and vein and the thyrocervical trunk and opens into the left subclavian vein at its junction with the left internal jugular vein.

The *right lymphatic duct* drains the areas on the right already described and opens into the right subclavian vein at its junction with the right internal jugular vein.

The *lymph nodes or glands* are oval or round structures spaced in the channels of the lymph vessels. Their size varies between that of a bean and that of an olive. The afferent lymph vessels enter various parts

perior gastric nodes have upper nodes at the base of the left gastric artery, a lower part accompanying the branches of this artery along the lesser curvature between the layers of the omentum, and a paracardial group which resembles a chain of beads around the neck of the stomach. The inferior gastric nodes number from four to eight and lie between the layers of the greater omentum on the greater curvature near the pylorus. The hepatic glands have a hepatic group at the base of the hepatic artery and extend along the common bile duct in the lesser omentum. One node, called the cystic gland, is at the neck of the gallbladder. The subpyloric hepatic nodes number about five and are located at the superior and descending parts of the duodenum at the bifurcation of the gastroduodenal artery. These nodes drain the stomach, duodenum, liver and pancreas and drain into the preaortic

nodes. The pancreaticocolic glands are on the upper and posterior border of the pancreas in relation to the splenic artery. They drain the stomach, spleen and pancreas.

The *superior mesenteric glands* drain into the mesenteric, ileocolic and mesocolic lymph nodes. The mesenteric glands number from 100 to 150 and lie in three areas near the terminal branches of the mesenteric artery at the secondary vascular loops and also along the main artery supply.

The *ileocolic nodes*, which number from ten to twenty, surround the ileocolic artery. They are grouped near the duodenum and also at the trunk of the artery. They divide into those called ileal glands which are located at the ileal branch of the artery; the anterior is in the ileocolic fold by the wall of the cecum and the posterior glands lie behind the cecum near the ascending colon. There is a single or double node in the

Figure 28. Lymphatics of the pelvis and abdomen. The lymphatic drainage from both the male and female stomachs illustrates the difficulty of the cure of malignant disease.

to the central axillary nodes. (3) The five glands of the *lateral group* are located medially and behind the axillary vein. They drain the whole arm except the cephalic side and empty into the subclavicular axillary nodes and the inferior deep cervical nodes. (4) The *central or intermediate* three or four nodes are deep in the base of the axilla. These drain all of the other groups to the subclavicular nodes. (5) The *subclavicular or medial nodes* number from five to ten and are above and behind the pectoralis minor muscle. These glands drain all of the other axillary nodes. This makes them of utmost anatomic importance in cancer surgery, particularly of the breast. These glands drain the lymph conduits accompanying the cephalic vein and the upper and outer part of the breast. They unite to form a subclavian afferent vessel. This trunk may open directly into the subclavian and jugular veins or the jugular lymphatic trunk or, on the left, the thoracic duct (Fig. 27).

The *lymphatic vessels* of the upper extremity are of both the superficial and deep types. The superficial vessels form trunks which accompany the cephalic, median and basilic veins. A few vessels on the ulnar side drain to the supratrochlear nodes. The others drain to the lateral groups of axillary nodes. A few empty to the subclavicular axillary nodes or inferior cervical nodes by way of the deltoid-pectoral nodes. The deep lymphatic vessels of the upper extremity follow the deep blood vessels and, in general, drain to the lateral axillary glands.

Lymphatic supply of lower extremity. The glands are the anterior tibial, popliteal and inguinal nodes. The *anterior* lie in the interosseous membrane and are surgically unimportant. The *popliteal* glands are five to eight glands in close approximation to the popliteal blood vessels, they drain the part of the leg corresponding to the lesser saphenous and popliteal veins and also the knee joint. Most of these glands are on the sides of the popliteal vessels and drain the tissues supplied by the anterior and posterior tibial vessels. The *inguinal glands* number from twelve to twenty and are in the femoral triangle. The *superficial* inguinal glands are just below the inguinal ligament, above the saphenous vein, and they drain the integument of the penis, scrotum, perineum, buttock and abdominal wall below the umbilicus. The *subinguinal* glands lie below the saphenous vein and have superficial and deep components. The *superficial* subinguinal glands drain the superficial tissue of

the leg and some of the genital areas. The *deep subinguinal* glands are under the fascia lata, medial to the femoral vein, and they drain the penis, the clitoris and the superficial subinguinal glands.

The *lymphatic vessels* of the lower extremity are of surgical importance. They also are of both superficial and deep types. The superficial lymphatic vessels are composed of a *medial* larger group, in which the vessels pass up with the great saphenous vein and into the subinguinal group of superficial glands. The *lateral*, or fibular, group of vessels arise from the lateral side of the foot and accompany the small saphenous vein to enter the popliteal glands.

The deep lymphatic vessels are few in number and accompany the corresponding deep blood vessels to the popliteal glands. The gluteal and ischial regions are drained by lymphatics which follow the blood vessels of the same name.

Lymphatic drainage of abdomen and pelvis (Fig. 28). The lymphatics of the abdomen and pelvis are of extreme surgical importance in the care of diseases or new growths of this area. The glands consist of the parietal and visceral nodes. The *parietal glands* which lie behind the peritoneum have as their subdivisions the external and common iliac, epigastric, iliac circumflex, hypogastric, sacral and the lumbar or aortic glands. The iliac, the epigastric, the circumflex and the hypogastric glands drain the areas supplied by the arteries of the same name. These glands are lateral to, in front of and behind the aorta. The lateral aortic glands are in close approximation on the right to the inferior vena cava, the renal vein, the psoas muscle and the right crux of the diaphragm. On the left they follow the abdominal aorta and drain to the cisterna chyli. The *preaortic* glands, so important in the eradication of malignant disease, are the celiac and the superior and inferior mesenteric glands. These and the *retroaortic* glands likewise drain into the cisterna chyli. These glands are named for the vessels around which they drain and their names indicate their anatomic location. They drain the viscera supplied by the celiac, superior and inferior mesenteric vessels. The *visceral glands* are related to the branches of these vessels.

The celiac glands are the gastric, the hepatic and the pancreaticocolic groups. The *gastric glands* are divided into the superior and inferior groups and they drain to the celiac part of the preaortic glands. The su-

perior gastric nodes have upper nodes at the base of the left gastric artery, a lower part accompanying the branches of this artery along the lesser curvature between the layers of the omentum, and a paracardial group which resembles a chain of beads around the neck of the stomach. The inferior gastric nodes number from four to eight and lie between the layers of the greater omentum on the greater curvature near the pylorus. The hepatic glands have a hepatic group at the base of the hepatic artery and extend along the common bile duct in the lesser omentum. One node, called the cystic gland, is at the neck of the gallbladder. The subpyloric hepatic nodes number about five and are located at the superior and descending parts of the duodenum at the bifurcation of the gastroduodenal artery. These nodes drain the stomach, duodenum, liver and pancreas and drain into the preaortic

nodes. The pancreaticolienal glands are on the upper and posterior border of the pancreas in relation to the splenic artery. They drain the stomach, spleen and pancreas.

The *superior mesenteric glands* drain into the mesenteric, ileocolic and mesocolic lymph nodes. The mesenteric glands number from 100 to 150 and lie in three areas near the terminal branches of the mesenteric artery at the secondary vascular loops and also along the main artery supply.

The *ileocolic nodes*, which number from ten to twenty, surround the ileocolic artery. They are grouped near the duodenum and also at the trunk of the artery. They divide into those called ileal glands which are located at the ileal branch of the artery; the anterior is in the ileocolic fold by the wall of the cecum and the posterior glands lie behind the cecum near the ascending colon. There is a single or double node in the

Figure 28 Lymphatics of the pelvis and abdomen. The lymphatic drainage from both the male and female genitalia and pelvis, stomach, liver and colon. The lymphatic glands and the lymphatic drainage of the lymphatic system.

to the central axillary nodes. (3) The five glands of the lateral group are located medially and behind the axillary vein. They drain the whole arm except the cephalic side and empty into the subclavicular axillary nodes and the inferior deep cervical nodes. (4) The central or intermediate three or four nodes are deep in the base of the axilla. These drain all of the other groups to the subclavicular nodes. (5) The subclavicular or medial nodes number from five to ten and are above and behind the pectoralis minor muscle. These glands drain all of the other axillary nodes. This makes them of utmost anatomic importance in cancer surgery, particularly of the breast. These glands drain the lymph conduits accompanying the cephalic vein and the upper and outer part of the breast. They unite to form a subclavian afferent vessel. This trunk may open directly into the subclavian and jugular veins or the jugular lymphatic trunk or, on the left, the thoracic duct (Fig 27).

The lymphatic vessels of the upper extremity are of both the superficial and deep types. The superficial vessels form trunks which accompany the cephalic, median and basilic veins. A few vessels on the ulnar side drain to the supratrochlear nodes. The others drain to the lateral groups of axillary nodes. A few empty to the subclavicular axillary nodes or inferior cervical nodes by way of the deltoid-pectoral nodes. The deep lymphatic vessels of the upper extremity follow the deep blood vessels and, in general, drain to the lateral axillary glands.

Lymphatic supply of lower extremity. The glands are the anterior tibial, popliteal and inguinal nodes. The anterior lie in the interosseous membrane and are surgically unimportant. The popliteal glands are five to eight glands in close approximation to the popliteal blood vessels, they drain the part of the leg corresponding to the lesser saphenous and popliteal veins and also the knee joint. Most of these glands are on the sides of the popliteal vessels and drain the tissues supplied by the anterior and posterior tibial vessels. The inguinal glands number from twelve to twenty and are in the femoral triangle. The superficial inguinal glands are just below the inguinal ligament, above the saphenous vein, and they drain the integument of the penis, scrotum, perineum, buttock and abdominal wall below the umbilicus. The subinguinal glands lie below the saphenous vein and have superficial and deep components. The superficial subinguinal glands drain the superficial tissue of

the leg and some of the genital areas. The deep subinguinal glands are under the fascia lata, medial to the femoral vein, and they drain the penis, the clitoris and the superficial subinguinal glands.

The lymphatic vessels of the lower extremity are of surgical importance. They also are of both superficial and deep types. The superficial lymphatic vessels are composed of a medial larger group, in which the vessels pass up with the great saphenous vein and into the subinguinal group of superficial glands. The lateral, or fibular, group of vessels arise from the lateral side of the foot and accompany the small saphenous vein to enter the popliteal glands.

The deep lymphatic vessels are few in number and accompany the corresponding deep blood vessels to the popliteal glands. The gluteal and ischial regions are drained by lymphatics which follow the blood vessels of the same name.

Lymphatic drainage of abdomen and pelvis (Fig. 28). The lymphatics of the abdomen and pelvis are of extreme surgical importance in the care of diseases or new growths of this area. The glands consist of the parietal and visceral nodes. The parietal glands which lie behind the peritoneum have as their subdivisions the external and common iliac, epigastric, iliac circumflex, hypogastric, sacral and the lumbar or aortic glands. The iliac, the epigastric, the circumflex and the hypogastric glands drain the areas supplied by the arteries of the same name. These glands are lateral to, in front of and behind the aorta. The lateral aortic glands are in close approximation on the right to the inferior vena cava, the renal vein, the psoas muscle and the right crux of the diaphragm. On the left they follow the abdominal aorta and drain to the cisterna chyli. The preaortic glands, so important in the eradication of malignant disease, are the celiac and the superior and inferior mesenteric glands. These and the retroaortic glands likewise drain into the cisterna chyli. These glands are named for the vessels around which they drain and their names indicate their anatomic location. They drain the viscera supplied by the celiac, superior and inferior mesenteric vessels. The visceral glands are related to the branches of these vessels.

The celiac glands are the gastric, the hepatic and the pancreaticocolic groups. The gastric glands are divided into the superior and inferior groups and they drain to the celiac part of the

Lymph vessels of the *omentum* are large and have a complex anastomosis and many valves. They vary in size, depending upon the diseases to which the patient has been subject. The lymph vessels follow the arteries and veins.

The lymphatic vessels of the *urinary organs* are divided into those of the kidney, ureter, bladder, prostate and urethra. The lymphatics of the *kidney* are in three plexuses; one in the substance of the kidney, a second below its capsule and a third in the surrounding fat. The vessels from the kidney substance converge into trunks which pass through the hilum. They join the lymph vessels from the subcapsule plexus and follow the course of the renal vein to end in the lateral aortic glands. The perinephric lymph vessels also drain to these same glands. The direction of the lymphatic vessels of the ureter depends on the part of the ureter involved. The upper *ureter* drains into the efferent vessels of the kidney and also into the aortic glands. Those vessels from the lower portion, but above the brim of the pelvis, drain into the common iliac glands. The lymphatics from the lower or intrapelvic portion drain mainly into the hypogastric glands.

The lymphatic vessels of the *bladder* drain the lymph from the intramuscular and extramuscular tissues. The mucosa apparently does not have a lymphatic supply. The lymphatic vessels drain from the anterior surface of the bladder into the external iliac glands. These lymphatics have minute glands situated in their course which are called the anterior and lateral vesical glands. The lymphatic vessels from the back of the bladder pass to the hypogastric and external and common iliac glands.

The lymphatics of the *prostate* drain into the hypogastric and sacral glands. There is one vessel from the back of the prostate which drains to the external iliac nodes and one from the anterior part drains to the lymph vessel from the membranous urethra. The drainage, in part, is similar to that of the urethra. The lymph vessels of the *urethra* are accompanied by those from the glans penis and drain to the subinguinal as well as the external iliac glands. The membranous and prostatic portions of the urethra in the male, and the entire urethra in the female, are drained to the hypogastric glands.

The lymphatic vessels of the *testis* and *ovary* consist of both superficial and deep parts and are anatomically similar. These drain the tunica vaginalis and epididymis in

the male and the ovary in the female. The vessels form trunks which accompany the spermatic vein in the spermatic cord in the male, and the ovarian vessels in the female, to the lateral and preaortic lumbar glands. The lymphatic vessels of the *uterine tube* drain partly with the ovarian and partly with the uterine vessels.

The lymphatic vessels of the *uterus* consist of a superficial vessel under the peritoneum and a deeper one in the uterus itself. These lymphatics become greatly enlarged during pregnancy. They drain through the broad ligaments and are continued up to the ovarian vessels and then to the lateral and preaortic glands. A few vessels run to the external iliac and superficial inguinal glands. The lymphatics of the *cervix* drain to the external iliac glands, hypogastric glands and posteriorly to the common iliac glands.

The lymphatics of the *vagina* drain according to the part of the vagina involved. The vessels of the upper vagina lead to the external iliac glands, those of the middle part to the hypogastric glands, and those of the lower part to the common iliac glands. These lymphatic vessels anastomose with those of the cervix, the vulva and the rectum, but not with those of the bladder, a point which is important at times surgically. The lymphatics of the *vulva* drain to the superficial inguinal glands.

Lymphatic drainage of the thorax (Fig. 29). There are two types of lymphatic nodes in the thorax—the *parietal* and the *visceral*.

The *parietal glands* are composed of the sternal, intercostal and diaphragmatic nodes. The sternal glands are in the intercostal spaces in close approximation to the internal mammary artery. They drain, to some extent, the breast, the deep structures of the anterior upper abdominal wall and, in part, the upper surface of the liver. These glands may drain directly to the subclavian or internal jugular veins or the thoracic ducts. The intercostal glands are in intimate association with the intercostal vessels. They drain the deep lymphatics from the sides of the chest and their lymph channels form a descending trunk to the cisterna chyli or thoracic duct. The upper glands drain to the thoracic duct on one side and to the right lymphatic duct on the other side. The diaphragmatic glands have medial, anterior and posterior components. The anterior nodes are behind the base of the xiphoid. They drain the vessels from the upper part of the liver and the front part of the diaphragm and pass effer-

mesentery of the appendix as well as a few nodes, called the right colic glands, which lie medial to the ascending colon.

The *mesocolic nodes* are numerous and lie in the layers of the transverse mesocolon near the hepatic and splenic flexures. They drain into the preaortic nodes.

The *inferior mesenteric nodes* form one group on the branches of the left colic and sigmoid arteries. A second collection of nodes surrounds the superior hemorrhoidal artery in the sigmoid mesocolon. A third, or perirectal, group is in and around the muscular coat of the rectum. These glands drain the descending and sigmoid colons as well as the upper rectum and drain to the lower preaortic nodes.

Lymph vessels of the abdominal and pelvic viscera The lymphatic vessels of the digestive organs below the diaphragm drain to the preaortic glands, following the course of the blood vessels which supply these organs. They are important because of the part they play in the spread of cancer or infection.

The lymphatic vessels of the *stomach* join above with the vessels of the esophagus and below with those of the duodenum. Those near the left gastric artery drain to the superior gastric nodes. The fundus and body of the stomach to the left of a line projected by the esophageal junction drain to the pancreaticocolic nodes. The vessels to the right of this point as far as the pylorus drain to the inferior gastric nodes and thence to the subpyloric nodes. The pylorus is drained by lymph vessels to the superior gastric nodes by way of the hepatic and subpyloric nodes. From this complex lymph node and vessel distribution, the difficulty of eradicating malignant disease of the stomach, once it has extended, is evident.

The *duodenal* lymph vessels drain anteriorly and posteriorly to the pancreaticoduodenal nodes between the head of the pancreas and the duodenum and then to the hepatic and preaortic nodes.

The lymphatic vessels of the *jejunum* and *ileum* are familiar to all surgeons. During intestinal digestion they become distended with milklike lymph fluid. These vessels are termed lacteals. They arise in the lymphatic spaces in the intestinal villi. They then course between the layers of the mesentery of the small bowel and converge to the appropriate mesenteric nodes. These small bowel nodes drain efferently to the preaortic nodes and then to the cisterna chyli.

The appendix and cecum are drained by

multiple lymph vessels which end in the ileocolic chain. There may be some lymph nodes at the peritoneal fold. These vessels form an anterior and posterior group, the anterior going to the ileocolic nodes and the posterior passing over the back of the cecum.

The *right and transverse colon* lymph vessels pass through the right and transverse mesocolon to the mesocolic nodes. The *descending and sigmoid colon* vessels drain to the left colic and sigmoid nodes. They end in the preaortic lymph nodes.

The lymph vessels from the *rectum* pass through the perirectal glands to the sigmoid and mesocolon glands. From here they go to those preaortic nodes located near the inferior mesenteric artery. The *anal* lymphatic vessels drain to the superficial inguinal nodes. The anal canal lymphatic vessels, however, follow the middle and inferior hemorrhoidal arteries and terminate in the hypogastric nodes.

The *liver* is drained by both superficial and deep lymphatics. The superficial lymphatic vessel drainage from the liver divides itself naturally into a superior and inferior part corresponding to the convex and lower surfaces of the liver. Some lymph vessels on the upper surface of the right and left lobes form a trunk which passes through the diaphragm with the vena cava and ends in glands near that organ. A few vessels go through the esophageal opening in the diaphragm to the paracardial glands in the superior gastric nodes. Some vessels from this side end in the preaortic nodes near the celiac artery. Another trunk from the upper right and left lobes ends in the hepatic nodes. Some lymph vessels from the under-surface of the liver accompany the deep lymphatics to the hepatic nodes, while one vessel goes through the diaphragm to the vena cava nodes. The deep lymphatic vessels form ascending and descending trunks, the former draining to the inferior vena cava area and the latter to the hepatic nodes. The *gallbladder* drains to the hepatic nodes as does the bile duct. The latter may drain also to the pancreaticoduodenal nodes.

The lymph vessels of the *pancreas* drain mainly to the pancreaticocolic nodes, but a few end in pancreaticoduodenal and preaortic nodes.

The lymphatic vessels of the *spleen* pass to the pancreaticocolic glands. The *suprarenals* accompany the suprarenal veins to the lateral aortic nodes, but occasionally some vessels drain to the posterior mediastinum above the diaphragm.

The *superficial lymphatic vessels* of the wall of the thorax are situated just below the skin and converge at the axillary glands. Those over the muscles drain to the subscapular, the pectoral and the sternal glands. A few of the lymphatic vessels in the pectoral area drain to the supraclavicular cervical glands.

The lymphatic vessels of the *breast* arise in the interlobular spaces and on the walls of the milk ducts. A plexus is formed for those in the central part, directly below the areola and nipple, and these join and pass to the pectoral group of nodes in the axillary glands. The medial breast vessels pierce the chest wall and drain to the sternal glands or occasionally to the subclavicular glands. The lymph vessels of the lateral and medial parts of the breast drain to the subclavicular axillary glands. The upper and outer part of the breast also is drained to the subclavicular lymph nodes.

The *deep lymphatic vessels* of the thoracic wall are: the lymphatics of the muscles on the ribs, the intercostal lymphatic vessels and the lymphatic vessels of the diaphragm. The lymphatics of the muscles on the ribs drain to the axillary glands and a few to the sternal glands. The intercostal lymphatic vessels drain both the intercostal glands and parietal pleura and empty into the intercostal glands. The internal intercostal lymph vessels and those from the pleura drain to the sternal glands. The lymphatic vessels of the diaphragm form a thoracic and an abdominal plexus. The plexus on the thoracic side drains to the glands near the junction of the seventh rib and its costal cartilage. They then pass to the glands on the esophagus, to those nodes around the termination of the inferior vena cava and to the glands which surround the aorta. The lymph vessel plexus on the abdominal surface of the diaphragm is drained in two ways. The vessels from the right half of the diaphragm drain to the glands near the inferior phrenic artery and the right lateral aortic glands. Those from the left half of the plexus pass to the pre-aortic and lateral aortic glands and to glands at the terminal portion of the esophagus.

The lymphatic vessels of the *heart* are of the deep and superficial types, the deep being under the endocardium and the superficial close to the visceral pericardium. The deep and superficial plexuses form a right and left collecting trunk. The *left trunk* drains both ventricles and rises in the anterior longitudinal sulcus. It receives a diaphragmatic trunk at the coronary sulcus and

the single lymph vessel thus formed passes to the tracheobronchial nodes. The *right trunk* drains the right atrium and the diaphragmatic side of the right ventricle. It ascends the posterior longitudinal sulcus and the coronary sulcus to the tracheobronchial nodes.

The *lungs* similarly have a superficial and a deep lymph plexus and, unlike other plexuses, they do not anastomose to any great extent. This is of surgical importance. The superficial plexus is beneath the pleura and drains to the glands at the hilus of the lung. The deep plexus accompanies branches of the pulmonary vessels and the bronchi, either beneath the mucosa or around the bronchi. These vessels converge at the glands at the hilus and end efferently in the tracheobronchial glands. The alveolar walls of the lung have no lymph vessels.

The lymphatic vessels of the *pleura* drain the visceral part and end in the superficial efferents of the lung. The parietal pleura drains to the sternal glands, while the diaphragmatic part of the pleura is drained by the diaphragmatic chain. The lymph vessels of the mediastinal portion end in the posterior mediastinal glands.

The *thymus* lymph drains to the anterior mediastinal, tracheobronchial and sternal glands.

The lymphatic vessels of the *esophagus* form a plexus around this organ and drain into the posterior mediastinal glands.

Lymphatic supply of the head and neck. The *lymph glands of the neck* are in association with the salivary glands and the deep and superficial lymph plexuses. The *submaxillary nodes* vary in number from four to six. They are located in the submaxillary triangle and lie on the salivary glands of the same name. The middle node of Stahr is directly over the external maxillary artery at the mandible. The submaxillary nodes drain the cheek, the side of the nose, upper lip, side of the lower lip, the gums, the side of the tongue and the medial palpebral commissure. Lymph from the facial and submental nodes also drains to these glands. Efferently the lymph nodes drain to the upper deep cervical nodes. The *submental (suprahyoid) nodes* lie between the anterior bellies of the digastric muscles. They drain the lower lip, the floor of the mouth and the apex of the tongue. They drain to the submaxillary and deep cervical nodes. The *superficial cervical nodes* follow the external jugular vein. They drain the ear and parotid area to the superior deep cervical nodes.

Figure 29 Lymph drainage of the thorax, thoracic duct, neck and head. The early involvement of the thoracic glands by cancer of the lungs reduces the possibility of cure in this disease. The large thoracic duct may be injured in its abdominal or thoracic portions. This results in chyle peritoneum or chyle thorax.

ently to the sternal glands. The medial glands are alongside the phrenic opening in the diaphragm and on the right may be in the sac of the pericardium. They drain the lymph from the middle diaphragm and, on the right, from the upper part of the liver. The lymph drains from these to the posterior mediastinal glands. The posterior glands are on the back of the crux of the diaphragm and drain the vessels from the lumbar nodes and efferently go to the posterior mediastinal nodes.

The visceral lymph nodes are named for their sites. They are the anterior mediastinal, posterior mediastinal and tracheobronchial glands. The anterior mediastinal nodes lie in front of the aortic arch and are in close relation to the innominate veins. They drain the lymph from the thymus, pericardium and

the sternal glands. Their vessels form, with the tracheobronchial ones, the right and left bronchomediastinal trunks. The posterior mediastinal glands are behind the pericardium, close to the esophagus and the descending aorta. They drain afferently the esophagus, the posterior part of the pericardium, the diaphragm and the convex surface of the liver. Efferently they end in the thoracic duct or in the tracheomediastinal trunk. The tracheobronchial glands drain the lungs, the bronchi, the trachea and the heart and receive the drainage from the posterior mediastinal glands as well. Their lymph vessels join the internal mammary vessels and the anterior mediastinal glands to form the right and left bronchomediastinal trunks. They may drain into the thoracic ducts or directly into the subclavian or jugular veins.

the lymphatics and the part it plays in the spread or control of infection and malignant disease. In addition, specific diseases of the lymphatic system and obstruction of the lymphatic flow become surgically important. Functional failure of this lymph drainage creates lesions which are disabling and disfiguring. Many of these diseases are amenable to surgery.

The lymphatics from the ileum and jejunum, called lacteals, collect the products of fat digestion and, with the other intestinal lymphatic drainage, carry these into the receptaculum chyli. This flow, with the lymph from the rest of the body, then goes to the subclavian veins at their junction with the jugular veins, by means of the thoracic and right lymphatic ducts. This lymph presents a surgical problem when obstruction, new growth or injury interrupts it. An injury may occur to the main conduits as the result of trauma or as a complication of a surgical operation. Most often, serious injuries occur in the lower part of the neck and chest.

INJURIES TO THE LYMPH SYSTEM

The injuries to the lymph system may involve the glands or the lymph vessels. The latter injuries are the important ones. The large lymph ducts or the small lymphatic vessels may be the site of the injury.

Injuries to Thoracic and Lymphatic Ducts. The thoracic duct, which measures between 36 and 48 cm., runs from the second lumbar vertebra to the root of the neck. It is in intimate association with the vertebrae and from the fifth thoracic vertebra runs to the left side.

The duct may be injured by an open wound, an indirect bruising wound or, most often, by a crushing wound. In the latter wounds, the other associated injuries take precedence in treatment and the lymph duct injury may be masked. The duct may be severed in part or entirely during a surgical operation. An extensive lymph node excision may cause severe duct lacerations. Burns and rays may cause duct injuries. The anatomic position demonstrates well the possibility of injury from trauma and in operations on the pleura and lungs, esophagus, sympathetics and large vessels of the neck.

If the lymph wound is an open one, a lymph fistula occurs with lymphorrhea (lymphorrhagia). The chyle will escape freely with each respiration.

The diagnosis of chyle thorax is made from the history of trauma, the x-ray appearance

of fluid and pressure or displacement, and is confirmed by thoracentesis. Simple aspiration often will relieve the pressure and the laceration in the duct may close spontaneously.

The thoracic duct or the right lymphatic duct, if injured at the time of an operation, may be reanastomosed. In the case of the right duct, this repair may not be necessary and a simple ligature or suture will resolve the process. Many times a ligation has stopped the lymph flow from the thoracic duct itself, the duct continuing to carry the chyle through collateral lymph vessels or through a spontaneously created anastomosis. In crushing injuries, the treatment is directed to that of the other injuries. For the accumulation in the chest or abdomen, thoracentesis or paracentesis will relieve the chyle pressure. The damaged duct usually repairs itself as the other wounds heal. The chyle thorax may require operative intervention because of pressure on or displacement of the chest or mediastinal contents. If the fluid continues to reaccumulate or body depletion from its loss is threatened, it can be repaired surgically after thoracotomy. If this is impossible technically, the duct should be ligated. The collateral circulation usually will carry the chyle through the opposite duct. Most injuries to the abdominal portion of the duct will heal spontaneously, but if it continues to drain the duct may be ligated. One cannot overemphasize the damage done by the pressure of lymph in the thorax if unrelieved by aspiration.

Injuries to Small Lymphatic Vessels. The lymphatic vessels are injured with any laceration or incision. Usually extensive operations and especially lymph node dissections divide larger lymph vessels. Lymphedema occurs in these patients if a tissue space or cavity remains for lymph accumulation. External pressure will control most of these accumulations unless they are complicated by sepsis or unless the wound is drained. There is evidence that lymphatic collections and obstructions occur more often in drained than in undrained wounds.

Injuries to lymph vessels occur also from burns and rays from irradiation. The atomic explosions at Hiroshima and Nagasaki during World War II caused widespread damage to the lymphatics and the healing of the burns resulted in lymphedema and heavy keloids.

The fistulae caused by laceration of lymphatic channels of smaller size than the thoracic duct often close spontaneously. Lym-

The anterior cervical nodes have a superficial set which is on the anterior deep jugular vein and a deeper group which is in front of the larynx and trachea. These glands drain the larynx, thyroid node and upper trachea to the deep cervical nodes.

The large and numerous *deep cervical glands* follow the carotid sheath from the skull to the thorax, hugging the pharynx, trachea and esophagus. The superior group lies under the sternocleidomastoid muscle around the accessory nerve and the internal jugular vein. The superior deep cervical nodes drain the occipital scalp, the ear, the back of the neck, part of the tongue, the larynx, thyroid, trachea, the nasal cavities, the nasal pharynx, the palate and esophagus. They also drain all the other glands of the head and neck except the lower deep cervical nodes. Efferently they form a trunk with the inferior deep cervical nodes and so-called jugular trunk. The inferior deep cervical nodes are in the supraclavicular triangle lateral to the sternocleidomastoid muscle. They are close to the brachial plexus and the subclavian vein. These nodes drain the back of the head and neck, the pectoral region and part of the arm. They also occasionally drain the upper surface of the liver. They receive drainage from the superior deep nodes and drain to join with a trunk from the superior nodes to form the jugular trunk. This trunk ends on the right side in the subclavian vein and on the left in the thoracic duct.

The skin and muscles of the neck drain to the deep cervical nodes. The pharynx drains to the retropharyngeal and the lower deep cervical nodes. The larynx in its upper part drains through the hyothyroid membrane to the superior deep cervical nodes. The lower laryngeal vessels go to the pretracheal and prelaryngeal nodes and a few of them pass between the cricoid and the first tracheal ring to the lower deep cervical nodes. The thyroid node drains to both the upper deep cervical nodes and to the paratracheal nodes.

Physiology. The lymphatic system has two functions, the first of which aids in digestion by the collection of chyle from the intestines and the transportation of this chyle through the lymphatic system to the veins. Its second function is to collect and return lymph from the other organs and the extremities. The lymphatic system also is a part of the body's defense. It contains and retains infection and new growth for a certain time. When its defense nature is overwhelmed, it appears to pass on or even to accelerate the spread of sepsis or malignant disease. In this way it

simulates a sponge, absorbing until it no longer can hold more, at which time it appears to squeeze itself or to overflow. This saturation is not just a quantitative one, but is qualitative as well, depending on the type of organism or cell, its virulence or rapidity of growth or spread and the local defensive power of the lymphatics in the area involved.

The lymph system also collects foreign material. These substances are admitted to this closed system between the endothelial cells of the capillaries when these objects are pressed against the vessel surfaces. The muscular contractions motivate the lymph and this action is aided by the valvular system of the vessels. The degree of motion of the lymph stream varies with the individual's activities. Lymph will coagulate, but it clots only one-fourth as rapidly as blood because of the lack of platelets in the lymph substance. Thrombosis occurs in the lymphatic vessels similarly to the thrombosis that occurs in veins. The inflammation to which patients with lymphedema are subject destroys the valves of the lymphatics, again in a similar manner to the way in which the valves of the veins are destroyed in thrombophlebitis.

The lymph circulation consists of an elaborate system of collecting vessels which drain the lymphatic fluid from the capillary networks. This fluid is collected from nearly all the organs of the body and its tissues by lymph capillaries. The lymph then passes to ever-enlarging vessels until it eventually reaches the thoracic ducts, which carry it to the venous system. At various places in this dense network are located the lymph glands, or lymph nodes. The number of these glands depends upon the local lymphatic function and changes due to disease in which the lymphatic system plays a unique part. These are spaced in the path of the collecting vessels and appear to do two things: they filter out pathologic cells and organisms, passing on lymph fluid in a more purified state, and they add lymphocytes to this circulating fluid.

The function of the lymphatic system is to return lymph fluids from the tissues, organs and serous cavities and chyle from the alimentary tract to the general circulation. The central depository is the circulating blood. This transfer is made by a convergence of the lymphatic conduits into the thoracic duct on the left and the lymphatic duct on the right. The fluid is isotonic with blood. A surgical problem is posed: "the drainage of

nese during World War II, certain staging areas, the Samoan and Wallace Islands, for example, used for final training prior to the invasion of the islands had epidemic and endemic filariae-infected natives. The marines and sailors fraternized with the natives. In one year (1943), 6000 trained troops had to be evacuated because of filariasis of the legs or genitalia following lymphatic obstruction. Rigid quarantine dropped this number in one year to 10 per cent of that figure.

The tuberculosis and syphilitic organisms cause similar invasions, infections and reactions.

INFECTIOUS LYMPHEDEMA. The lymphatic system is both a block to and pathway for the spread of infection. The ordinary contaminant organisms such as the streptococci and staphylococci may increase in virulence and the host's defense may be overcome, these organisms then enter the lymph vessels. They locally inflame these vessels and spread to the regional lymph nodes. These nodes filter out the infection and retain it unless the sepsis overwhelms them. In the latter event, the organisms may pass on to other lymph vessels and eventually to the blood stream. Such infections usually cause localized lymphedema. If the infection is continued or recurrent, fibrosis and scarring within the lymphatics is the end result.

In their invasion, these organisms may cause sufficient inflammation to obstruct the lymphatics and destroy their valves.

Repeated infections invariably cause low-grade changes in the glands. These glands, in themselves, may keep the infection active or recurrent, similar to the situation in tonsillitis.

ALLERGIC LYMPHEDEMA. Some individuals are sensitive to certain pollens, proteins or environmental changes which affect the lymphatics and precipitate lymph blocks. An example is the allergic reaction to exposure to cold. A type of temporary block is due to massive hives. Such diathesis rarely is the cause of permanent lymphedema, but such reactions if extensive can produce lymphedema.

POST-THROMBOTIC LYMPHEDEMA. Thrombosis of the deep or superficial veins causes edema which throws an overload on the lymphatic component. There may be a damming back of the lymphatics, with permanent lymphedema. When the major venous vessels are clotted, rarely are there sufficient collaterals to return the fluid. Unless gravity drainage is utilized, a massive swelling must

Figure 30 Typical post-thrombotic lymphedema. Massive lymph stasis secondary to obstruction of the deep vein system. The original lymph stasis is a spastic obstruction, but after a time this becomes an organic obstruction with the destruction of the lymph vessel valves (Pratt, G. H.: J.A.M.A., vol. 151).

occur (Fig 30). This results in the post-phlebotic leg, or milk leg. Even if the veins recanalize at a later date, their valves are defective and they do not function adequately again. The fluid which has accumulated has created a space between the skin and fascia which, if not obliterated, becomes permanent. Fibrous trabeculae form in this space and, in the late stage, while elevation may drain some of the fluid, the heavy, thickened tissue space remains.

TRAUMATIC LYMPHEDEMA. Lacerations, thrombosis, burns, operation incisions, keloids and the scarring which results from roentgen, radium and radioactive isotope rays may destroy the continuity of the lymph channels. If the injuries are extensive enough, massive lymph collections follow because of the inability of the lymphatics to carry away the lymph fluid. The development of the fluid may be delayed until the scars have contracted, this final scarring obliterating the remaining collateral lymphatics.

CONGENITAL LYMPH COLLECTIONS. Many abnormal lymph collections have been reported. These may be due to lymph rests, cystic hygroma, simple lymph cysts, cavern-

phorrea may be stopped by a pressure dressing. This therapy applies to the lymph drainage after gland resections in the neck, groin or axilla. Often the accumulation is considered purulent erroneously and a surgeon may continue to drain this fluid, thus keeping its fistulous nature active. The best treatment is compression in the form of a bandage.

LYMPHEDEMA (LYMPH STASIS, ELEPHANTIASIS OR LYMPH OBSTRUCTION)

Lymphedema in the Lower Extremity. Since the lymphatic system is a closed one, with its own spaces, fluid, and vessels which begin as the lymph capillaries and end in the venous system, any obstruction to this system causes lymph accumulation. Such a collection, by its size and its complications, will cause increasing disability. Lymph obstruction always is accompanied by dilatation of the venous drainage system, which makes an effort to take over part of the fluid return from the involved tissues. The lymphatic obstruction, by its massive pressure, causes deleterious skin changes and distention or destruction in the other tissues, often with atrophy or even displacement of the muscles. The lymph vessels involved in lymphedema are those in the dermis, but not the epidermal layer of the skin, since the epidermis does not have lymphatics. The fluid collection extends into the subcutaneous fat and deep fascial layers. The muscle lymphatics usually do not become involved in this process because of their protected position.

The lymphatic drainage channels may be closed by a congenital defect or they may become obstructed secondarily by inflammation or internal or external pressure. Lymphedema may be localized, due to a block in the main lymphatics, or it may be generalized with all of the lymphatics of the part obstructed. When the extremity or part is elevated, the fluid will flow by gravity through the subcutaneous tissues to areas where there are no lymphatic blocks and the lymph then will be carried away. This method of drainage occurs only when there is elevation of the part. With dependency, the lymph reaccumulates, since there are no physical pathways for its removal. With failure of lymph drainage, the part becomes susceptible to inflammation caused by the usual contaminant organisms. Each inflammation causes further scarring and more lymph vessel obstruction. The path-

logic process thus becomes self-perpetuating.

Etiology. Any disease or trauma which directly or indirectly obstructs the lymphatic canals or destroys their valves may cause lymphedema. The causes of this condition thus are innumerable. A congenital or developmental failure of the lymph vessels or their valves may be responsible for the lesion. In some patients the lymph stasis seems to be due to an endocrine dysfunction. A specific or nonspecific infection in the lymphatic system, an injury, a burn and a primary or secondary new growth are the usual acquired causes. Thrombophlebitis, in addition to producing tissue space fluid accumulation, also causes lymphedema. The originating or precipitating factors in the development of lymphedema have been classified into eight types: specific lymphedema, infectious lymphedema, allergic lymphedema, post-thrombotic lymphedema, traumatic lymphedema, congenital lymph collections, malignant lymphedema and essential lymphedema.

SPECIFIC LYMPHEDEMA. Certain organisms have a predilection for invasion and inflammation of the lymphatic channels. Of these, the filarial worm (*Wuchereria bancrofti*), the tuberculosis organism (*Mycobacterium tuberculosis*) and the *Treponema pallidum*, which causes syphilis, are examples.

A mosquito, the *Stegomyia pseudoscutellaris*, or *Culex fatigans*, picks up the worm, the *Wuchereria bancrofti*. The larvae are deposited and injected by the penetration of the bite of the mosquito. Adult filariae live in the lymph channels and discharge embryos. The dead worms also may cause a lymphatic inflammation. Streptococci or other pyogens frequently cause an associated suppurative infection. The lymph vessels become filled by organisms and inflammatory cells and this causes secondary lymph collections in the tissues. The lymph glands are infected and enlarged. The filariae produce recurrent febrile attacks, each one resulting in an inflammatory reaction with more pathologic changes.

Lymphedema due to filarial worm invasion has had historical military implications. The Roman Legions fought natives in Africa who had these grotesque obstructions which caused disfigurement of the limbs and genitalia. The term "elephantiasis" originated in their reports on these natives. Not only the skin resembled that of the elephant with its thickening and wrinkling, but the affected parts were grotesquely large. In the Ameri-

the dependent medial areas. In some patients the collections are most irregular with overhanging masses of tissue which may obscure the normal contour of the extremities. In the enlargements of the upper extremity, the mass may have involved even the fingers. In some of the massive collections, the normal position of the bones may have been displaced.

The shiny skin may become thickened and roughened. It may resemble the skin of an elephant. The pores enlarge and develop a pigskin appearance. There is usually a pigment deposit, particularly in the lower extremity. The color varies from light yellow to all degrees of brown, purple and black. Ulcerations may be present because of the poor vascularity of the overdistended tissue. The associated venous involvement may be evidenced by large veins, dermatitis and ulcers. Dermatitis, especially of the fungus type, is often associated. Often there are weeping and eczematoid changes, particularly around the toes. The skin in such areas will be heaped up and frequently is

draining. The nails usually show curvature, irregularity and atrophy with associated fungus infection. There may be signs of repeated phlebitis.

The patients are subject to frequent attacks of sepsis. These bouts are characterized by high fever, chills, malaise and general upsets. The local reactions are similar to those of cellulitis, lymphangitis or erysipeloid reactions. The patient often gives a history of having had many attacks of "erysipelas." These reactions are due to lack of resistance of the part to the common skin contaminants, the streptococci and staphylococci. The limbs appear to lose their power to resist infection. Some patients have regularly recurring febrile attacks. There may be skip periods of freedom from fever and some patients may go for years without any septic attack. Such periods usually are associated with a time of excellent general health. Why some patients will have innumerable attacks and others none is not explainable. Each recurrence of the reaction increases the pathologic process, closing off

Figure 32 A, Extensive lymphedema of the Milroy type in a fifteen-year-old girl. Measurements: right calf, 27.4 cm., thigh, 56.0 cm., left calf, 56.0 cm., thigh, 66.6 cm. B, Postoperative view following operation. Scars can be covered by stocking or cosmetics.

ous lymph collections or lymphangiectasis. Abnormal lymph growths may interfere with obstetric delivery. Bizarre symptoms may develop, depending upon the location, size and extent of pressure.

MALIGNANT LYMPHEDEMA. Just as the lymphatics are the site of the spread of infection, they are a pathway for the spread of malignant disease, particularly carcinoma. The rate of spread varies in different types of growths and in different individuals and there seems to be an inverse ratio of spread to age. The growth spreads along the lymphatics to the regional nodes which contain extensions for a time. The localization does not appear related to the size of the spread, although it is related frequently to the length of time that the primary growth has existed. In some patients it appears that the regional nodes pass on the growth after their resistance has been overcome. The localization of growths in regional nodes varies greatly. The tumor may involve all of the nodes or only one or two. In some instances there is widespread dissemination with only minimal, or with no, involvement of the regional nodes and some groups of nodes may be "skipped" with involvement of the others.

Sarcoma may spread by the lymphatic pathway, although it most often extends by way of the blood stream. Melanoma frequently metastasizes by way of the blood stream. Sarcomas of the tonsil, thyroid or testicle are exceptions. The degree of involvement regionally often determines the size of the lymphedema. Secondary obstruction or overload of the venous drainage complicates the edema picture (Fig. 31).

Malignant tumors also may involve the lymphatics primarily, thus lymphosarcoma, Hodgkin's disease (malignant lymphoma) and lymphatic and leukocytic leukemia all may present lymphatic collections and secondary lymphedema.

ESSENTIAL LYMPHEDEMA. Some types of lymphedema are of unknown origin. These collections appear to be hereditary in nature, although most of them do not appear clinically until the time of puberty. The advent of the symptoms with this developmental changing time in life suggests that the maturing endocrine system, or some dysfunction of it, plays a part in precipitation of these lesions.

Some forms of congenital lymphedema also are known as Milroy's disease (Fig. 32), originally described as both a familial and congenital disease. Many of the patients in whom swelling of unknown origin

Figure 31 Malignant lymphedema secondary to liposarcoma of nine years' duration

appears at puberty do have a history of similar involvement occurring in other members of the family. Congenital lymphedema has been described as "simple" when the patient is the only one in the family so affected, and "hereditary" if other relatives are afflicted. There is some anatomic and physiologic defect in these patients from birth. It may be that a congenital swelling present from the day of birth is of such mild degree as to be not noticed until the time of more rapid growth. While the leg or legs are most often involved, the upper extremity may be affected as may the labia, scrotum and other male and female genitalia. The entire retroperitoneal space may be involved.

Symptoms. The symptoms of lymphedema vary, depending upon the degree of blockage, the age of the patient, the type of tissue involved, the secondary skin changes and whether the part has been subjected to repeated inflammations.

The usual picture is that of symmetrical enlargement of the extremity. In the leg, the swelling begins in the groin. It may be confined more to the upper or lower part of the limb, but usually both portions are involved as are the foot and toes. In the congenital type, it most often involves one extremity, both legs being implicated in only 25 per cent of the subjects. The skin is tight, tense and usually shiny. There may be wrinkled and lobular areas irregularly situated. The larger collectio ph are in

months, years or indefinitely to maintain the control of the sepsis, which is of great importance. This program of management of lymphedema due to infection is of help in the prevention of lymphedema due to other causes and has aided in controlling lymphedema seen after radical mastectomy, in which infection and not malignant metastasis is the cause. Allergic lymphedema sometimes responds to desensitization. Antihistamines may be helpful. Patients with lymphedema due to cold exposure may be come conditioned by exposure to slowly lowered temperatures. Obstructions due to burns or scars require surgical correction. Lymphedema following irradiation, in the absence of retained malignant disease, is due to burns. Excision of the burned area and various plastic procedures may be helpful.

Lymphedema which follows the post-thrombotic syndrome presents a complicated picture and its therapy is difficult. The treatment depends upon the stage of the disease which the patient presents. In the acute stage, spasm is the most likely causative factor. For the patient with incompetent veins, ligation and stripping of these veins may be helpful. In all these patients venograms and lymphangiograms should be obtained routinely to determine the actual venous involvement and the adequacy of the remaining veins and lymphatics. For causalgia and the reflex spastic problems, sympathectomy may be successful if paravertebral blocks produce a good clinical result.

In patients with mild residual lymph stasis, elevation of the part when the patient is not using it, and good support when the part is dependent, may be all that is necessary. Such therapy must be applied early and continued for as long as a year. Basically, this therapy is planned to remove and keep the lymph fluid from the leg until such time as other lymph collaterals are developed or the lymph spaces are closed. This regimen consists of elevating the limb sufficiently high for gravitational drainage. This should be done each night and every time during the day that the limb begins to swell as shown by a tightness and discomfort of the bandage. Adequate support requires even application of a well-fitted pressure bandage, reaching from the toes to as far as the swelling extends. The bandage must be removed and replaced each time that the part is elevated.

Massage, like exercise, will cause lymph flow within the lymph channels. It will also

aid in the motivation and movement of extraluminal lymph. The massage should be from the distal to the proximal end of the swelling and should not be traumatic.

To the above measures must be added antibiotic therapy, care of fungus infection, treatment of any allied ulcers and sympathetic nerve blocks or sympathectomy for those in whom there is a large reflex spastic element.

In the moderate types of lymphedema, especially when the post-thrombotic syndrome is an etiologic factor, sympathectomy may resolve the process. This operation should be selected as a treatment only if a sympathetic nerve block gives good laboratory and clinical evidence that some of the fluid collection results from a reflex spastic element. In some of the patients with venous involvement, this can be combined with resection of the pathologic veins. In other patients, in whom the lack of good early bandaging has left a residually enlarged leg, the surgical correction by wedge excision has been sufficient to give relief. In this operation, a medial section of skin, subcutaneous tissue, lymph, fat and deep fascia is excised. The width of the skin segment removed is sufficient to reduce the part to normal size, but a segment of subcutaneous and deep fascia wider than the skin segment is excised. The remaining superficial tissue is then mobilized and approximated with a plastic closure.

Surgical measures to develop lymph drainage to other nonblock areas have been tried for nearly as long as surgery has been performed. Originally, Handley placed silk sutures subcutaneously in hopes of developing new lymph channels. Drainage tubes of all types, sizes and materials have been constructed. Tissue bridges with large pedicle grafts have been formed, testifying to the ingenuity of their originators if not to their surgical success. Techniques using glass needle tubes and various types of metal wires as well as tissue bridges are advocated by some surgeons. Our observed results have been poor.

A therapeutic technique based on the original observation of Kondoleon, that lymphedema is confined to the tissues external to the muscles, has been employed. Kondoleon excised windows in the fascia, hoping that the lymph would flow internally and be absorbed by the muscle lymphatics. This procedure was extended by others and the technique consisted of undermining the skin and excising part, or all, of the subcu-

Figure 33. A, Photomicrograph of lymphedema showing avascular subepidermal layer and condensation; B, vascular infiltration in the dermis (Pratt, G. H.: Cardiovascular Surgery. Lea & Febiger).

more lymph channels. The febrile reactions, while violent, will respond to the antibiotics.

Patients who have specific infections such as syphilis, filariasis or tuberculosis will have the symptoms of these diseases. The symptoms of lymph collections due to trauma, allergy and malignant disease are self-evident. The symptoms of lymphedema due to the post-thrombotic syndrome include those of that syndrome. In addition to the enlargement of the part, there may be all the signs of thrombotic veins, depending upon the stage of the thrombosis and the recovery from it. Causalgia-like pain is not an uncommon symptom.

Pathology. The epidermis of the skin per se, although thickened, does not contain lymph stasis. The lymph accumulates in the dermis beginning at approximately $\frac{1}{16}$ inch in depth and shows great thickening. The papillae and sweat glands become obliterated. The edema is condensed and there may be avascularity due to pressure on the blood vessels from the fluid (Fig 33). The lymph collections within the spaces become enlarged. The pressure of this lymph increases in the subcutaneous and fascial spaces. The lymph walls may be fragmented and gross lymph will be found in the extralymphatic spaces. Some of the structure of the subcutaneous tissues, fascia and collagens may be broken up. The fat is compressed and may become necrotic. Some of it is replaced by lymph spaces. The lymph channels are fibrosed, although some of them may be widely dilated. The muscles, tendons and even bone will show the effect of pressure and atrophy. The lymph may spread to the fascia and it often involves the fat below the fascia and within the muscle or around blood vessels. Lymph nodes are enlarged

and many of them become chronically inflamed and fibrosed.

In the stage of acute inflammation, the organisms may directly invade the lymphatics or pass through the cellular lining if there is no open lesion. The organisms multiply. The lymph fluid and the vessels react with an increase in the cellular elements and spread proximally. The edema is a hard, brawny type which indents or pits with difficulty. In the more advanced stage of the affection, suppuration may occur.

With elevation, the lymph flows gravitationally. With dependency, it reaccumulates.

At a later stage, fibrous trabeculae form between the skin and deep layers. These form a skeleton-like framework which then maintains the space in which the lymph collects. The valves in the lymph channels are destroyed.

Treatment. The aim of the treatment is twofold—elimination of the cause of the condition and relief of the residual lymph stasis.

Active therapy for the primary cause of the specific lymphedemas is indicated. In filarial infections, evacuation from the area of infection and avoidance of reinfection usually are all that are required. Lymphangiography should be performed prior to treatment in all cases of doubtful etiology. If the lymphedema is due to secondary infections, cultures should be made from material taken from the inflamed or infected area and the sensitivity of any organism to standard antibiotics should be determined. Antibiotic therapy should be thorough. When febrile attacks have been recurrent, the time pattern of these attacks should be determined and antibiotics given prophylactically prior to the anticipated time of the fever. Such therapy may have to be continued for

Grafts of skin, or skin and subcutaneous tissues, have been pedicled so that their base is proximal to the lymphatic block. The results have not been good. The technical difficulties attending use of these large grafts and the discomfort entailed in their production, and subsequently, have made this type of operation obsolete.

Certain tissues of the body do not contain lymph. Among these is the epidermis. With the modern electric dermatomes one can remove skin so thin that only the epidermis is in the graft. All of the skin from the involved part is removed in long strips. Our best results have been obtained with skin 0.015 inch thick. Repeated biopsies show that the abnormal lymph collections begin approximately $\frac{1}{50}$ inch below the skin surface. After this thin skin excision is completed, all the rest of the skin, the lymph, the fat and subcutaneous and deep fascia are removed. Great care is exercised to remove all of the fatty tissue and fascia from the underlying muscles. After hemostasis is secured, the skin previously removed is placed directly onto the muscle. The operation is performed in stages, the front half of the leg from the groin to the toes being operated upon first, and the back half being operated upon when healing of the front graft is complete, approximately in three weeks (Figs. 34 and 35).

SECONDARY KELOIDS AND FUNGUS INFECTIONS Since the skin is poor, often diseased and subject to fungus infection, disfiguring keloids or fungus collections may appear. In such cases these should be surgically excised

down to red muscle, grafted and the area treated with x-ray beginning immediately after surgery to prevent recurrence.

Lymphedema of the Upper Extremity. Any of the etiologic factors detailed as a cause of lymphedema of the lower extremity may cause such an accumulation in the upper extremity. Most cases of lymphedema of the upper arm, however, follow operations for carcinoma of the breast (Fig. 36). One of the earliest suspected causes for lymphedema of the arm after an operation, namely, sepsis, often is a factor.

One of the last papers written by William Halsted was about the problem of lymphedema following radical mastectomy. He believed that the streptococcus was the cause. Most of his patients with this problem who were followed died of malignant disease and appraisal of the part that sepsis plays in the picture was neglected for some time. Swelling of the arm after mastectomy should be considered of possible malignant origin until proved otherwise. There remains, however, a sizable group of patients in whom lymphedema develops and annoyingly persists in the absence of carcinoma. It has been demonstrated not only that lymphedema follows infection, but that the elimination of this infection by antibiotics controls and sometimes corrects lymphedema.

If it is determined that there is no malignant or infectious cause for the lymphedema, surgical eradication of the lymphedema may be performed. The surgical treatment is similar to that for lymphedema of the lower extremity.

Figure 36. Lymphedema occurring seven years after radical mastectomy for carcinoma of the breast.

Figure 34. A, Massive lymphedema nine years after radical mastectomy and x-ray therapy; B, postoperative appearance. Patient had no recurrence of malignant disease thirteen years after original operation. Lymphedema has not recurred since the described operation was performed in 1954.

Figure 35. A, Massive lymphedema; B, postoperative appearance (Pratt, G. H. JAMA, vol 147)

taneous and deep fascia. The skin was replaced directly on the muscles. While reduction in size of the part resulted, lymphedema recurred in nearly all patients. The

value of the operation was temporary and consisted in plastic excisions of lymph-swollen tissues. This operation and its modifications have limited value.

of the blood is not to replace red blood cells. The transfusions are given to replace some defensive factor lacking, at least temporarily, in the patient so afflicted. This defensive factor when supplied by blood is used up rapidly and must be replaced regularly, approximately every two days. The regular repeated small blood transfusions have been decisive in overcoming infections of this type in innumerable cases. Abscesses should be drained wherever they occur. The original site, if it is a blister, broken nail or callus, should be incised only if there is localized suppuration. Surgical intervention in the presence of localized pus is imperative, but it is important to remember that, without such localization, the best treatment locally is surgical restraint. Such cutting in the absence of pus is bungling surgery and will be registered by increased morbidity and possibly mortality.

Chronic Lymphangitis. The usual septic organisms may cause chronic lymphangitis if their virulence is not too great or the defense of the host is high. Repeated attacks of acute lymphangitis may also result in chronic lymphangitis. In the absence of a septic cause for chronic lymphangitis, the specific types of infection may be the cause of chronic lymphangitis. The various fungus infections such as epidermophytosis, occasionally involve the lymphatics, usually in the form of the "tid." Most often the fungus infection is associated with a secondary invading organism. *Sporotrichosis*, a more rare mycotic disease caused by *Sporotrichum schenckii*, may be the cause. Carcinoma may spread through the lymphatics and cause signs and symptoms not unlike those of an inflammation. The possibility of malignant disease should always be ruled out in any patient with nonspecific lymphangitis.

In nonspecific chronic lymphangitis, there may be recurrent signs of redness and swelling. The degree of lymph obstruction varies from a mild block to lymphedema. The glands are enlarged and their physical size often adds to the lymph obstruction. In many cases, thrombophlebitis is associated. The skin changes depend upon the degree of lymph obstruction and the venous involvement. Often there is pigskin appearance with enlarged pores. There may be secondary dermatitis or ulcer formation. A dusky skin appears in the skin in the later stages of the disease. The edema is of the brawny type which pits with difficulty and persists longer than normal edema. In tuberculosis, the lymphatic channels are cordlike nodules which later break down, forming abscesses, and

may become secondarily infected. A similar type of nodular change occurs with syphilis, but the lesions are less likely to suppurate. The epitrochlear glands may be involved by both of these lesions.

In chronic lymphangitis secondary to sepsis, the initial site of infection may have to be excised. A small callus, infected nail bed, foreign body or an area of osteomyelitis may be responsible for continuance of the lymphangitis infection until the source is eliminated. Antibiotic drugs should be used and, if possible, the specific one for the organism cultured should be selected. Tuberculous lymphangitis may require general therapy for the disease. In such cases, the newer drugs such as streptomycin with para-aminosalicylic acid and isoniazid should be utilized. X-ray therapy has had some beneficial results in some cases. Excision of the involved lymph nodes often is necessary. In each case, the possibility of malignant disease should be considered and biopsies performed when doubt exists.

Lymphadenitis. The cause, course, symptoms and treatment of lymphadenitis in general are similar to those of lymphangitis, and the infections of the glands may be acute or chronic.

The glands enlarge and become tender when the invading organisms are septic in type. The degree of inflammation depends upon the virulence of the organism and the defense of the host. In tuberculosis, the glands enlarge rapidly, become firm and discrete nodules and then break down and caseate. The glands become fused together and suppuration and sinus formation take place. In syphilis, the nodes are universal but discrete. They are painless and do not tend to suppurate. In carcinoma, gland enlargement and secondary reaction depend upon the type of cell and extent of the spread as well as the therapy.

In the treatment of mild inflammation, correctly selected antibiotics may be all that is necessary. The organism should always be cultured and sensitivity to the routine antibiotics determined. Locally, warm packs may help to resolve the process. If suppuration occurs, surgical drainage is necessary. When doubt as to the cause of the enlarged gland exists, biopsy or excision is necessary and should not be delayed.

The glands most often involved in tuberculous adenitis are the mediastinal nodes which drain the lungs. These nodes may be fibrotic and heal with surrounding calcium deposits. Most individuals have such calcified nodes in their lungs or in the medias-

Figure 37. Massive lymphedema involving fingers, hand, forearm and part of the arm (Pratt, G. H.: Cardiovascular Surgery, Lea & Febiger)

Congenital lymphedema of the upper extremity. The cause for this condition is unknown. Some congenital rest, overactivity as in the Milroy's syndrome, or a glandular imbalance may be a factor. The lymphedema may involve the entire extremity or parts of it. Unfortunately, it often involves the digits,

and support. Some of the vasodilator drugs seem to be partially effective. Treatment of the patients with extensive lymphedema is unsatisfactory. The arm, forearm and hand can be treated effectively. The digits themselves pose a problem both from the general surgical and plastic standpoint. The viability of the graft must be obtained without sacrificing the mobility so necessary to tendon and joint motion. The fact that most of these patients are children adds to the difficulty, since patient cooperation is required for the necessary active motion. Each patient's problem must be individually assessed and the treatment planned specifically for him.

Lymphedema Scrotum; Lymphedema Labia. The cause for these lymphatic collections is unknown. The lymph stasis may be minimal in amount or it may develop into a tremendous and grotesque collection. The symptoms may vary from those in which the patient is aware of the enlargement only when tight-fitting clothing is worn, to that typified by the textbook picture of the East Indian sitting on his scrotum. When lymphorrhea is a complication, the problem may become most severe. Some patients must wear towels or rubber devices to collect the lymph. Secondary sepsis and dermatitis are common. In the female, pregnancy complicates the symptoms markedly.

The treatment of these lymph collections depends upon the extent of the lymph stasis.

In the mild cases, antibiotic therapy, hygienic care and elastic support to the genitalia may ameliorate the symptoms. In the extensive and advanced degree of lymphatic obstructions, surgical eradication may be necessary. In the patient with massive lymph labia, partial or complete vulvectomy may be necessary and at times curative. In lymph scrotum, treatment must be individualized. The lymph area may be excised. In others, a new scrotal covering must be constructed by grafts and the skin and all subcutaneous and lymph-bearing tissues surgically excised.

LYMPHATIC INFECTIONS

Acute Lymphangitis. The most common causative organisms of acute lymphangitis are the staphylococcus and streptococcus. Usually the infection gains entrance through some skin break caused by an injury. The entry point may appear innocuous. A small paronychia or an ingrown nail, fungus infection, skin break or puncture wound often is the site of entry and source of infection.

The small lymph vessels or capillaries may be first involved. Usually there is redness, some heat and tenderness with edema. The condition spreads proximally, involving first the lymph plexus and then the large lymph vessels. Once the main channels are involved, a red streak develops from the original site of infection to the focal nodes. In the arm, these may be the epitrochlears. The infection then goes to the axillary nodes or it may go directly to the axilla. In the lower extremity, the popliteal glands less often are involved. A red streak extending directly from the site of origin of the infection to the inguinal or axillary nodes is the most common. Often there are associated perilymphangitis and cellulitis. Once the glands are involved, there may be all degrees of sepsis from simple inflammation to suppuration and abscess formation. If the infection extends beyond the regional nodes, it invades the blood stream, producing bacteremia and septicopyemia. Abscesses then may occur in any part of the body.

An essential part of the treatment is rest and immobilization of the part. Local cultures and blood cultures should be obtained

doses. In the absence of a positive culture or until it is obtained, antibiotics can be given empirically. Massive wet dressings should be applied locally. Blood transfusions should augment the antibiotic therapy. The purpose

but there may be some discoloration due to venous pressure or venous involvement. Dilated blood vessels, especially the veins, often accompany these growths. They may occur at any place, but are often seen in the extremities. The head, face, neck, shoulders and chest are more unusual sites. They may develop a vesicular or keratotic appearance and in the latter instance they appear like warts. When this tumor occurs in combination with blood vessels, it is called *lymphangioma cavernosum* (Fig. 38). Such a tumor is red to blue in color and is livid. Many of them are considered birthmarks. When they occur around the mouth they are called *macroglomia* and around the lips they are named *macrocheilia*.

Grossly these tumors vary markedly. The large ones are compressible. Histologically they are found to arise from epithelial cells. The *lymphangioma simplex* has vesicles, and these distend the epidermis. The proliferation of the epidermis over the vesicles forms *keratosis*. The vesicles contain coagulated lymph and the interstitial connective tissue is edematous. The *cavernosum* type shows much larger sinuses and in these the epithelial lining is well formed.

In the small growths, electrocauterization has been effective. Carbon dioxide snow application will eradicate some of the superficial ones. The larger lesions should be excised surgically. These tumors do become malignant on occasion and this is a valid reason for their excision.

Lymphangioma Cysticum. *Lymphangioma cysticum* appears to be caused by germ rests. In some of the tumors, trauma or chronic inflammation is a contributing factor. They occur most often in the neck and sacrum. They have been seen frequently on the extremities and more rarely in the internal organs.

These cysts are large, not compressible and cause symptoms depending upon their site and size. They may cause distortion or pain by pressure. They are softer than xanthomas. Biopsies may be required for differentiation from other tumor masses.

The cysts are lined with endothelium. The fluid is serous or chylous. The surrounding sac is made of connective tissue and includes muscle fibers.

These tumors should be surgically excised. If they are removed without puncture, a complete cure will be obtained.

Other Lymphangiomas. These small tumors also may be in the form of congenital *lymphangectasis*. They may be in the skin

(*nevus lymphaticus*), the lips (*macrocheilia*), the tongue (*macroglomia*), the dorsum of the hand (*macrocheiria*) or the neck (*cystic hygroma*) or they may be lymphatic cysts or hydrocele of the neck, axilla or floor of the mouth. In the neck, the tumor is beneath the deep fascia and may protrude either anteriorly or posteriorly to the *sternocleidomastoid* muscle. The tumor may be of such size as to interfere with respiration or swallowing.

Surgical treatment is difficult and sometimes dangerous. If the cyst is not too large and does not interfere with swallowing or breathing, conservative therapy may be used. Sometimes the condition regresses spontaneously. X-ray therapy has been effective. Radium has been used. In some instances, a combination of radium and subsequent surgery has been effective with secondary plastic repair.

Lymphosarcoma. This is the most common of the malignant lymphomas. The tumor starts in the neck, the mediastinum or the axilla and grows rapidly with infiltration of the surrounding tissues. It also extends to and involves the skin. It may enlarge rapidly because of hemorrhage within it. The early signs may be those due to pressure on nerves or other vital structures. Secondary lymph stasis begins distal to the involved glands. Metastasis occurs by way of the blood stream, particularly to the lung and the liver. The condition must be differentiated from other primary and secondary tumors of the glands, particularly from Hodgkin's disease. *Lymphosarcoma* grows and spreads more rapidly (Fig. 39), usually occurs on one side of the body and has ulceration, whereas Hodgkin's disease rarely ulcerates and is slower in its extension.

Two distinct types of lymphosarcoma are recognized. These are a localized form and a generalized one called *lymphosarcomatosis*. In the localized form, the tumor may be composed of lymphoblasts (*lymphoblastoma*), which have large round cells. When the cells are small, the tumor is called *lymphocytoma*. When the tumor cells originate from the reticular cells, the growth is called a *reticulum cell sarcoma*.

In the generalized form, the sarcoma is in many different parts of the lymphatic system and metastasizes early by way of the blood stream. The tumor may be in the blood vessels or in the blood stream itself (*leukosarcoma*).

Surgical excision usually is indicated only for biopsy or to relieve unusual pressure.

tinum At other times, cold abscesses form with caseation. It is likely that from these latter abscesses develops miliary tuberculosis which is disseminated by the blood stream. Inflammation of these glands subsides when the primary disease abates.

Cervical tuberculous glands are visible and palpable and are important in differential diagnosis of cervical adenopathy. At the time of the biopsy, surgical excision is indicated. Most of these glands require excision. Their chronic draining sinuses will lead to secondary suppuration.

Syphilitic adenitis requires specific therapy and operation is indicated for biopsy only.

Repetitive Septic Adenitis. Suppurative adenitis in itself may continue bouts of sepsis. These glands chronically, subacutely and acutely reinfected become sources of the disease. Like repeated tonsillitis which results in frequent sore throat, these glands no longer are defensive. Their radical excision may help the patient. It must be recognized that these glands were placed by nature as a defense mechanism. When they have been reinvaded by organisms they are containers of, but not defenders from, infections. While their excision removes a natural barrier, this protection is no longer present and the patient often is better after radical surgery.

Lymphogranuloma Inguinale. This tropical disease also occurs in temperate climates. Adult male Negroes are most commonly affected. The etiologic factors are intracellular microorganisms called Donovan's bodies. They are passed from one person to another by contact.

Three to seven weeks after contact, the organisms cause a papule to develop on or near the genitalia. The involved area enlarges and breaks down and gives a thin white discharge which has a fetid odor. Other nodules may be secondarily affected. The regional lymph nodes are not enlarged in all cases but may be secondarily affected.

The diagnosis is made from the clinical appearance, the demonstration of the organisms, a typical pathologic section or reaction to the complement fixation test. There is no active surgical treatment, although surgery may be necessary for plastic repairs. Intravenous injections of tartar emetic have been effective and streptomycin may be of value.

TUMORS OF THE LYMPHATIC SYSTEM

Tumors of the lymphatic system are not too uncommon. Lumb divides the malignant

Figure 38. Lymphangioma cavernosum in a boy aged twelve years. There is massive involvement of the right lower extremity which includes both the lymphatics and the venous system.

ones into those having lymphocytic differentiation (lymphosarcomas, including lymphatic leukemia with lymph gland involvement), those with reticular cell characteristics, those with mixed cell types, such as Hodgkin's disease, and those with imperfect cell type differentiation. Benign lymphatic tumors may be primarily lymphatic or a mixture of lymphatic and blood vessel development.

Lymphangioma. Most lymphangiomas are of congenital origin. Some are noted in early life, but even these may have been present at birth but not noted. They are usually associated with other congenital anomalies. They have been seen in association with hemangiomas, neurofibromas and undescended testicles.

This type of tumor may develop as an individual growth called *lymphangioma simplex*. It may be any size from that of a minute nodule to as large as a baseball. These tumors are usually the color of skin,

and excessive connective tissue. The spleen is enlarged and has gray areas within it resembling lymph nodes. It has been called the "hard baked spleen." Lymph nodes also are found in the liver and bone marrow. The blood will show secondary anemia and leukopenia with relative lymphocytosis. Leukocytosis may occur terminally.

The disease has been grouped into the localized, the acute generalized; the Pel-Ebstein syndrome, characterized by alternate periods of fever and nonfever occurring at two-week intervals, and the typhoid type, because of its insidious onset, remittent fe-

ver and enlargement of the retroperitoneal and mediastinal glands.

The main lesion from which Hodgkin's disease must be differentiated is lymphosarcoma. Lymphosarcoma occurs on one side of the body primarily, grows more rapidly than does malignant lymphadenoma and tends to develop skin ulceration. Carcinoma normally has a primary source. Biopsy may be necessary to determine the correct diagnosis. Leukemia is differentiated by the blood count. In tuberculous lymphadenitis, the glands are irregularly nodular, coalesce and caseate. In syphilis the gland enlargement is general-

Figure 39 A, Lymphosarcoma arising from the periaortic lymph nodes. Note growth around and into the aorta; B, microscopic appearance of lymphosarcoma with massive infiltration of round cells (courtesy of Dr A. Rottino)

Radiation therapy has been used extensively and the results at first are good, but the tumor recurs. Regression can be maintained for some time with radiation therapy. Nitrogen mustard (mechlorethamine hydrochloride) and radiophosphorus have been effective in causing remissions. Mechlorethamine hydrochloride is thought to act by halting mitosis. This substance has been used in conjunction with radiation. If the lesion is localized, surgical excision may be tried and oc

pain. Often the enlargement begins in the glands of the neck and progresses in the direction of the lymph flow. The affected glands are discrete, variable in size and elastic. There is usually a high fever. The condition is progressive and fatal, but remissions have occurred.

Enlargement of the glands in the neck or thorax may cause coughing, shortness of breath and difficulty in swallowing. There may be inequality of the pupils and paralysis of the recurrent nerve. Edema of the arm or face with dilated veins occurs. Any type of neurologic symptoms may arise from intracranial or spinal cord pressure.

lymphomas and was described by Hodgkin in 1832. It was also called lymphadenoma without leukemia by Wunderlich, malignant lymphoma by Billroth and lymphogranuloma by Sternberg.

The cause of Hodgkin's disease is unknown. It attacks males more often than females and is seen in early adult life.

The lymph nodes rapidly enlarge without

All of the lymphoid tissue of the body may become involved. The affected glands are round, not adherent and encapsulated. On cut section they appear gray and non-necrotic. Microscopic examination reveals giant cells with three or four nuclei (lymphadenoma cells), increased endothelial cells having single nuclei (Fig. 40), an eosinophils

less fluid or are nearly empty so that their identification or injection made the problem of lymphangiography most complex. That the method has value in differentiation of the

causes and the treatment is obvious. Recently the technique has been standardized.

Lymphangiography of Leg and Thigh.

ized, but slight and positive reactions to serologic tests and a therapeutic test will differentiate this disease.

Patients with Hodgkin's disease live from two to four years after the condition becomes manifest. Those having remissions may live from five to ten years.

Surgery is indicated for biopsy and occasionally for relief of pressure. The glands respond to radiotherapy, but, unfortunately, this is only temporarily effective. Methyl-bis (β -chloroethyl) amine hydrochloride (mechlorethamine) has been used and there has been some fair response. This substance may be employed in conjunction with x-ray therapy. The radioactive isotopes, particularly phosphorus (P^{32}), are being used in some patients. Triethylenemelamine (TEM) was introduced in treatment in 1951. Rottino reported one patient with subsidence of massive nodes of the neck, axilla and mediastinum following this therapy. He also reported one patient with no recurrence nine years after excision of the nodes of the neck. Some patients have survived ten years after x-ray therapy. It is apparent that no one type of treatment should be tried to the exclusion of all others. With supportive and other therapy the patient can be made more comfortable and months or years may be added to his life.

Supervoltage ray therapy. More recently, tumors of the lymphatic system have been treated by supervoltage therapy. This can be given by x-ray or cobalt. This latter substance can be given in large dosages and can reach the site of the lesion more readily than roentgen therapy. In addition, the reaction of the patient to the treatment is much less. Both general and local response to supervoltage therapy as administered today is minimal.

Carcinoma. Since carcinoma is disseminated by the lymphatic stream, it is a frequent cause for tumors of the lymph glands. The primary focus usually is apparent. In certain parts of the body, such as the cervical nodes, the primary site may be difficult to demonstrate. Repeated biopsies of the tonsil, pharynx, thyroid gland or bronchus may be required when undifferentiated carcinoma is found in the cervical gland. The tendency of some carcinomas to skip certain local glands may add to the confusion.

Sarcoma. Sarcomas, other than those specific for the lymphatic system, may involve the glands. Unlike carcinoma, however, most of these tumors spread by way of the blood stream. The rapid enlargement of a tumor

in a gland may make one suspicious of sarcoma, as these tumors tend to have internal hemorrhages and increase suddenly in size.

Endothelioma. Endotheliomas arise within the endothelial linings of the lymph sinuses and the lymph glands and may metastasize. These tumors are rare and are differentiated by biopsy, particularly from secondary carcinoma.

Chloroma. Chloroma has been described as a sarcoma of the blood-forming organs. It involves the lymph nodes and spleen. The greenish color, indicated by its name, is thought to be due to blood pigment or the products of fatty cell metabolism. The disease affects young males and is rapidly fatal.

Lymphatic Leukemia. This is a disease of the blood characterized by a marked increase in the number of circulating lymphocytes. The lymph glands as well as other lymphoid tissue throughout the body enlarge. Lymphatic leukemia may go through an aleukemic stage at which time diagnosis may be difficult. The relative lymphocytosis and the clinical course suggest the diagnosis even in this phase. Children are usually affected by the acute form, which is rapidly fatal. Their glands enlarge, but are soft and discrete. High fever and weakness as well as the blood picture are characteristic. The chronic form occurs in older persons. The glands are generally enlarged. The nodes are gray and homogeneous. On section, the reticulum is seen to be packed with lymphocytes. Often the larger the lymphocytes, the more rapidly growing is the tumor. There is no surgical treatment for leukemia. Biopsy is indicated. Nitrogen mustard administered intravenously, urethan, ACTH and cortisone have been tried. X-ray therapy will relieve some of the symptoms and P^{32} has given equivocal results.

LYMPHANGIOGRAPHY

Despite the fact that arteriography and venography have been in use for over twenty years, the application of similar techniques to the lymphatic system (Fig. 41) was difficult and was delayed until recent years. The early work was of an indirect type and began approximately in 1931 with efforts in this direction by dos Santos. Identification of both lymph vessels and nodes was made in dogs and rabbits. More recently, Kinmonth has refined the technique sufficiently for it to be of clinical value and surgical use. To some extent, techniques used today are much like those described by Homans years ago.

Lymph vessels are so small, contain color-

tibia and there is also a lateral group. A third group which follows the lesser saphenous is of less clinical significance. Since the superficial lymphatics are the ones involved most often in lymphedema, their delineation is most important. These lymphatics follow the greater and lesser saphenous veins to the superficial lymph nodes. Under normal circumstances they are thin (about 1 mm. in size), wavy and parallel. Most of them are on the medial side of the leg and thigh.

Diffusible dye (patent blue, patent blue violet or patent blue V) is injected into the subcutaneous tissue and is picked up by the superficial lymphatics. This solution is made in an isotonic solution, 11 per cent, in distilled water and is sterilized by autoclaving. This dye delineates the lymphatics. A total of 2 to 4 ml is injected in the subcutaneous tissue between the toes (0.5 ml. in each toe web) and massaged with gauze for half a minute. It usually does not diffuse retrogradely. This dye is nontoxic but will run into the blood system and cause the patient to become blue.

In a bloodless field an incision is made in the foot proximal to the injection site. By means of pressure the lymph trunk is distended with dye. A radiopaque solution of 70 per cent iodopyracet or 50 per cent sodium diatrizoate is injected through a no. 18 needle. From 1 to 10 ml. is injected and radiographs of it are made as soon as possible. Fluoroscopic films of the extremities and screen films for the pelvis are suggested. Serial films give the best results and should be timed. Sites of blocks may be determined. Both benign and malignant causes of blocks may be indicated.

In *lymphedema* the lymph vessels become tortuous and dilated.

In lymphedema associated with *iliofemoral venous thrombosis* spasm of both the veins and lymphatics plays a part. In the acute stage permanent obstruction does not occur.

In *chronic venous insufficiency thrombosis* of the protein-rich lymphatics may cause a permanent edema state. Repeated bouts of febrile reactions of lymphangitis or cellulitis may cause fibrosis and scarring.

Recently, a technique to demonstrate venograms has been done by direct bone marrow injection. It has been found that such venograms delineate lymph glands. This is of importance in malignancy and may indicate the site of metastasis better than any gross exploration. In addition, massive metastasis

may be demonstrated and indicate that any surgical procedure is contraindicated. Twenty cc. of 25 per cent iodopyracet or 76 per cent sodium methylglucamine diatrizoate is used.

the closed cavity characteristics of the head.

Cranioerebral injuries may be caused by direct forces acting upon the head, such as a moving object striking the head. Indirect forces may also act upon the head as when a moving body contacts a nonmoving or slower moving object. As a result of direct and indirect forces, the head may undergo acceleration, deceleration or compression (indenting of the skull). In many accidents, the sudden setting of the head into motion (acceleration) and compression coexists, also a sudden stoppage of the head (deceleration) and compression may coexist. Indirect forces include falls upon the lower portions of the body and the buttocks resulting in a downward thrust of the head toward the spine. Whip-lash injuries may cause a sudden lagging behind of the head in relation to the body, which is projected forward, as the neck is first hyperextended, then flexed.

As a result of these various forces acting upon the head, various changes may occur—deformation of the skull, increase in intracranial pressure, mass movements of intracranial contents, distortion of the skull and dural septa; shearing of a portion of the head and contents, without increase in intracranial pressure, shearing and severe increased intracranial pressure, such as with wounds by bullet or shell fragments, or a combination of two or more of these changes.

Deformation (compression) of the skull, if sufficiently severe, results in a fracture of the skull. A depressed or perforated fracture may occur if the injuring force is of high velocity, whereas a linear fracture may be caused by a blow of lesser velocity.

A sudden increase in intracranial pressure occurs at the time of the impact. This may be due in part to the deformation of the skull and in part to the acceleration or deceleration of the head. If there is extensive tearing of the tissue, including scalp, skull and brain, the phenomenon of increased intracranial pressure may not involve the cranial contents, since the closed cranial cavity state, under the circumstances of an open wound, may not then obtain. In experimental studies 15 to 100 pounds per square inch (450 to 5000 mm. Hg pressure) results in convulsive effects. The time duration of the increase in intracranial pressure is directly proportional to the effects upon the brain. The records suggest positive and negative phases of pressure with elevations at the origin of the blow and negative pressures at an area opposite the region of the blow. In this connection it may be noted that the craniospinal junction

constitutes a region of pressure gradients between the cranial cavity and the spinal canal. Brain stem involvement is more possible if the closed cavity dynamics of the head obtains when the energy of a major blow is dissipated.

Mass movements of the intracranial contents also may occur. This has been shown, by cinephotographic studies, to take place with impact injuries. Mass movements result in tearing of tissues, particularly when brain and irregularly placed cranial bony structures are apposed. This is true in the neighborhood of the frontotemporal junction and the anterior and middle fossae. Many contusions and lacerations of the brain surface occur in this region, resulting from mass movements with abutment of the brain against the sharp edges of the lesser wing of the sphenoid and the irregular surfaces of the floors of the anterior fossae.

Distortion of the skull and the dural septa may occur in cranioerebral trauma with heavy forces acting upon the head with little or no velocity. This is particularly true in injuries to the newborn in the birth canal with forces being applied to the head by the contraction of the uterus and the resistance of the birth canal. Distortions may also occur in the adult as a result of low velocity heavy forces. Such distortions tear and bruise the brain, the dural sinuses and other intracranial blood vessels.

Shearing of a portion of the head and contents may occur without increase in the intracranial pressure at the time of impact, as illustrated by a puncture wound made by a sharp object.

As a result of these forces, fracture, concussion, contusion, laceration and hemorrhage may occur. Contusions and lacerations of the brain may occur as a result of mass movements of the brain against rough and sharp bony structures, such as the lesser

the blow, with fracture and depression at this site, negative pressures in deceleration and acceleration injuries due to "cavitation," or the distortion of bony and dural prominences may tear the adjacent brain.

Small hemorrhages may occur in the path of the injuring force or larger hemorrhages may result from tears of larger vessels. There may be pressure gradients between the cranial cavity proper and the craniospinal junction, thus causing hemorrhages in the brain stem. Distortions may result in tears of connecting veins on the surface of the brain.

NERVOUS SYSTEM

Craniocerebral Injuries

By ELISHA S. GURDJIAN, M.D.,
and JOHN E. WEBSTER, M.D.

ELISHA STEPHENS GURDJIAN was born in Smyrna, Asia Minor, now Turkey, and received his Doctor of Philosophy degree and medical education at the University of Michigan

JOHN ELLIOTT WEBSTER, the son of a pharmacist, received his education in Michigan, where he was born. He is a product of the University of Michigan and Wayne State University College of Medicine.

The investigations of Doctors Gurdjian and Webster upon the forces of stress and strain produced in craniocerebral injuries have added considerable knowledge to an understanding of the many factors involved in these injuries.

In 1957, over 94,000 persons in the United States were killed as a result of accidents. Among these accidental deaths, head injuries played a prominent role. Thirty-eight thousand and five hundred deaths were the result of motor vehicle accidents. In and about the home, 27,000 lives were lost as a result of injuries. Deaths caused by industry numbered 14,500, while public accidents other than those involving motor vehicles took about 16,500 lives. In individuals under the age of twenty-one years, accidents were an important cause of death. For the entire population, they were the fourth most common cause. Many accidents involving head injuries occur in and about the home, the result of falls down steps, off ladders and from

porches. Among the adult population, home and vehicular accidents are often associated with the consumption of alcoholic beverages, carelessness and fatigue.

Mechanism of Injury. For a good understanding of the mechanism of the head injury, the importance of the structural characteristics of the skull and contents must be recognized. The skull is a spheroid structure containing semiliquid contents—brain, blood and cerebrospinal fluid. In injuries, the craniospinal junction presents an avenue for pressure gradients to occur between the head cavity and the spinal canal. The "closed cavity" feature of the head may be disturbed by certain types of trauma. In other instances, severe injuries may depend upon

the closed cavity characteristics of the head.

Craniocerebral injuries may be caused by direct forces acting upon the head, such as a moving object striking the head. Indirect forces may also act upon the head as when a moving body contacts a nonmoving or slower moving object. As a result of direct and indirect forces, the head may undergo acceleration, deceleration or compression (inbending of the skull). In many accidents, the sudden setting of the head into motion (acceleration) and compression coexists; also a sudden stoppage of the head (deceleration) and compression may coexist. Indirect forces include falls upon the lower portions of the body and the buttocks resulting in a downward thrust of the head toward the spine. Whip-lash injuries may cause a sudden lagging behind of the head in relation to the body, which is projected forward, as the neck is first hyperextended, then flexed.

As a result of these various forces acting upon the head, various changes may occur—deformation of the skull; increase in intracranial pressure; mass movements of intracranial contents; distortion of the skull and dural septa; shearing of a portion of the head and contents, without increase in intracranial pressure; shearing and severe increased intracranial pressure, such as with wounds by bullet or shell fragments, or a combination of two or more of these changes.

Deformation (compression) of the skull, if sufficiently severe, results in a fracture of the skull. A depressed or perforated fracture may occur if the injuring force is of high velocity, whereas a linear fracture may be caused by a blow of lesser velocity.

A sudden increase in intracranial pressure occurs at the time of the impact. This may be due in part to the deformation of the skull and in part to the acceleration or deceleration of the head. If there is extensive tearing of the tissue, including scalp, skull and brain, the phenomenon of increased intracranial pressure may not involve the cranial contents, since the closed cranial cavity state, under the circumstances of an open wound, may not then obtain. In experimental studies 15 to 100 pounds per square inch (450 to 5000 mm. Hg pressure) results in concussive effects. The time duration of the increase in intracranial pressure is directly proportional to the effects upon the brain. The records suggest positive and negative phases of pressure with elevations at the origin of the blow and negative pressures at an area opposite the region of the blow. In this connection it may be noted that the craniospinal junction

constitutes a region of pressure gradients between the cranial cavity and the spinal canal. Brain stem involvement is more possible if the closed cavity dynamics of the head obtains when the energy of a major blow is dissipated.

Mass movements of the intracranial contents also may occur. This has been shown, by cinephotographic studies, to take place with impact injuries. Mass movements result in tearing of tissues, particularly when brain and irregularly placed cranial bony structures are apposed. This is true in the neighborhood of the frontotemporal junction and the anterior and middle fossae. Many contusions and lacerations of the brain surface occur in this region, resulting from mass movements with abutment of the brain against the sharp edges of the lesser wing of the sphenoid and the irregular surfaces of the floors of the anterior fossae.

Distortion of the skull and the dural septa may occur in craniocerebral trauma with heavy forces acting upon the head with little or no velocity. This is particularly true in injuries to the newborn in the birth canal with forces being applied to the head by the contraction of the uterus and the resistance of the birth canal. Distortions may also occur in the adult as a result of low velocity heavy forces. Such distortions tear and bruise the brain, the dural sinuses and other intracranial blood vessels.

Shearing of a portion of the head and contents may occur without increase in the intracranial pressure at the time of impact, as illustrated by a puncture wound made by a sharp object.

As a result of these forces, fracture, concussion, contusion, laceration and hemorrhage may occur. Contusions and lacerations of the brain may occur as a result of mass movements of the brain against rough and sharp bony structures, such as the lesser wing of the sphenoid and the floors of the anterior fossae; inbending of the skull at the point of the blow, with fracture and depression at this site, negative pressures in deceleration and acceleration injuries due to "cavitation," or the distortion of bony and dural prominences may tear the adjacent brain.

Small hemorrhages may occur in the path of the injuring force or larger hemorrhages may result from tears of larger vessels. There may be pressure gradients between the cranial cavity proper and the craniospinal junction, thus causing hemorrhages in the brain stem. Distortions may result in tears of connecting veins on the surface of the brain.

Figure 1. Contusions of the temporal and frontal tips in a patient with an occipital fracture.

Figure 2 Deep contusion of the left fronto-temporal region with petechial hemorrhages surrounding the area of contusion. If the patient survives for several days, such an area will soften and become infarcted and may constitute an intracerebral hematoma with severe tissue loss.

With fractures of the skull there may be tears of the dural lining with hemorrhages due to laceration of the meningeal vessels. Subdural hemorrhages and intracerebral hemorrhages may take place by the mechanical disruption of veins. Laceration of the arachnoid and of the brain may occur. The effect of sudden compression of the chest upon intracranial structures is not well understood. Indirect involvement of the brain by such forces may be produced when the chest is suddenly decelerated by a steering wheel.

Pathology. The terms *concussion*, *contusion* and *laceration* of the brain should not be used in a manner to suggest prognostic evaluation and the degree of severity of

Figure 3. In the cross section of the brain above, compression of the upper brain stem by a left-sided uncal herniation is noted. Below, marked swelling of the centrum ovale on the left side is seen. Such swelling of the white matter extends all the way into the brain stem.

injury. Concussion is defined as a post-traumatic state due to an involvement of the upper brain stem centers, resulting in unconsciousness with low pulse rate and a cold clammy skin associated with a shocklike state. Contusions (Figs. 1 and 2) and lacerations of the brain may accompany concussion, but not necessarily. Lacerations and contusions may occur without associated involvement of brain stem centers causing a concussion.

Increased intracranial pressure and edema of the brain in acute head injury are important pathologic entities. Increased intracranial pressure may result from edema and swelling of the brain (Fig. 3), hemorrhage into the intracranial contents and increased intracranial blood volume due to trauma. It is agreed that hemorrhage into the intracranial contents causes increased intracranial pressure. This is due to an actual increase of the volume of intracranial contents caused by the escape of blood, particularly into the subarachnoid space. Blood in the subdural and subarachnoid spaces on the brain surface may result in a high osmotic pressure and consequently may attract a collection of tissue fluids and cerebrospinal fluid in the area of the bleeding. In the subarachnoid space, actual increase in the amount of fluid may occur because of the osmotic

pressure of the cerebrospinal fluid. Traumatic contusions of the brain, bloody extravasations, small thrombi and areas of necrosis may cause edema. Collections of fluid and swelling in these areas of tears and bruises are similar to edema about a traumatic lesion elsewhere in the body.

The presence of edema without an appreciable amount of bleeding into the tissues is difficult to explain. Many years ago, vasomotor paralysis of cerebral vessels by the trauma, with subsequent venous stasis and tissue waterlogging due to increased permeability of the capillaries, was thought to be a cause for the brain swelling. Recently, the same opinion has been restated by neuropathologists.

Other explanations of increased intracranial pressure are increased activity of the choroid plexus due to irritation and stimulation by the injury, resulting in increased cerebrospinal fluid formation; a lowering of the rate of absorption of the cerebrospinal fluid due to venous stasis with venous pressure elevated well above that of the cerebrospinal fluid. Increased protein content in the cerebrospinal fluid due to blood retards its absorption and, since bloody cerebrospinal fluid is quite common in head injury, increased intracranial pressure may then be due in part to a deficient absorption of the cerebrospinal fluid.

That edema and swelling of the brain occur is unquestioned. That this can take place in the absence of large mass lesions in the cranial cavity is also well substantiated. Figure 4 shows a contusion of the left temporo-

parietal region of the brain associated with marked edema on the affected side with actual herniation of the cingulate gyrus across the midline. Swelling and edema of the brain may also result in tentorial herniation of the uncus and brain stem as well as herniation of the medulla and cerebellar tonsils into the foramen magnum. Swelling of the white matter under a mass lesion may extend into the brain stem.

Clinical Manifestations. The clinical manifestations of acute head injuries depend mainly upon the degree of involvement of the brain. The gravity is indicated, in part, by the length of unconsciousness following trauma. It should be pointed out, however, that a certain number of apparently serious open wounds of the cranial cavity may be unassociated with initial unconsciousness or may be associated with a very short period of unconsciousness. On the other hand, many closed injuries of the head may be associated with severe derangement of the conscious state for many days.

The older classifications of patients with head injury have emphasized the terms concussion, contusion and laceration, the first-named representing a usually mild injury; the last two indicating injury of a more severe grade. Recent evidence indicates that some patients with brain laceration may not have an initial unconscious state, whereas others with no laceration or contusions may have a fatal outcome with only a so-called concussive effect and little evidence of microscopic damage to the nervous system. Consequently, a present-day classification of head injury recognizes the fact that patients who have initial unconsciousness following the trauma have brain stem involvement. However, patients without initial unconsciousness may have extensive brain damage without involvement of the brain stem. Patients with brain stem syndromes present post-traumatic unconsciousness, their pulse is slow and the pallor of their skin suggests a shocklike state. The brain stem dysfunction may be of varying intensity involving both reversible and irreversible states. The reversible state may result in complete recovery. Head injuries without a brain stem syndrome are common. Open wounds of the head without initial unconsciousness are examples. The utilization of energy resulting in the open wound leaves little or no energy to involve the brain stem centers.

Another group consists of patients having a combination of a brain stem syndrome with a severe wound of the nervous system. It

The clinical manifestations of head injury may be grouped as states of consciousness and their alterations, changes in the vital functions, headaches, dizziness, vomiting, the neurologic status of the patient, convulsions, the cerebrospinal fluid findings and the associated injuries elsewhere in the body.

States of consciousness and their alterations. A normal state of consciousness is a favorable sign in the patient with an acute head injury. This state is a contraindication for any operative intervention except in patients having defects of the skull such as open wounds. Progressive return of consciousness is also a favorable sign and is almost always a contraindication for surgical treatment. On the other hand, progressive drowsiness and periods of consciousness alternating with periods of drowsiness and disorientation may signify that a dynamic lesion exists necessitating surgical intervention. A lucid or conscious interval followed by drowsiness and semiconsciousness or unconsciousness is an important syndrome, often, but not always, signifying an intracranial mass lesion. At times, localized areas of bruising and contusions of the brain with swelling of the tissue, particularly over the

turbed conscious state may return to normal. Middle meningeal hemorrhage, subdural hemorrhage, subdural accumulation of cerebrospinal fluid, intracerebral hematomas and edema of the brain may be associated with a lucid interval. In a certain number of head injury patients, extreme disorientation alternating with periods of semiconsciousness and psychotic manifestations are seen. In this group, an injury in the temporal tip may be present, resulting in this agitated state. Area 44, which is at the junction of the frontal and temporal lobes, may be injured in severe craniocerebral trauma, the result of mass movements of the brain. Unilateral or bilateral contusions of this region may occur. Acute psychotic states usually tend to resolve, but personality derangements may exist for a long time.

In general, patients who remain unconscious for many days return to consciousness through a transitional state of semiconsciousness with disorientation and confusion. Occasionally the return to normalcy is quite prompt, but more often it is prolonged. Neurotic and psychotic manifestations associated with head injury are difficult to evaluate in respect to cause-and-effect relationship. Psy-

should also be pointed out that in the course of time a patient who may begin with no evidences of brain stem dysfunction may, through edema of the brain or intracranial hemorrhage, develop evidences of involvement in this region. These secondary manifestations of brain stem derangement are, of course, quite common in head injury. If we are to use the term "concussion," it should be defined as post-traumatic unconsciousness following impact, due to functional or anatomic derangement of the upper brain stem. Concussion may occur with or without brain contusion or laceration, or with or without a skull fracture and vice versa.

choneurotic manifestations seen several months or years after a head injury from which the patient apparently has made a satisfactory physical recovery are probably not related to the head injury per se, but to the experience of stress upon an abnormal pretraumatic personality. A proper evaluation should include a careful consideration of the patient's psychiatric background, his ability to tolerate stress and his reactions to environmental experiences. In some patients, mental deterioration following a severe head injury with no improvement in the intellect can undoubtedly be ascribed to the total devastating effect of the trauma upon the central nervous system. Among the patients with this class of injury, adolescents and children rehabilitate better than do adults. The latter may remain in a vegetative state for weeks or months following a severe head injury. In these patients, the condition appears to be related to cortical brain damage with or without a major degree of brain stem injury.

Amnesia following head injury is quite common. Usually the patient remembers neither the accident nor activities immediately preceding the accident. Sometimes the amnesic state may be present in patients who appear normal. Such patients may have a short period of post-traumatic unconsciousness or may be merely dazed for several seconds. Nearly 80 per cent have complete amnesia for the experience of the injury itself and the period just before the impact. According to some observers, prolonged post-traumatic amnesia increases the likelihood of post-traumatic epilepsy but at the same time suggests that the interval between trauma and the development of epilepsy is going to be longer.

Vital functions in head injury. Vital functions are judged by the heart or pulse rate, the respirations, the body temperature and the blood pressure. In general, these may be altered from the normal at the time of injury and as the results of the injury become evident.

In experimental head injury, the pulse rate may be increased at impact. Vagal effect (bradycardia) with escape is frequently recorded in a kymographic study of the pulse or the blood pressure. Experimentally, the initial result of a severe head injury is an increase in the pulse rate.

In the seriously injured patient, the pulse may be full, slow and bounding initially. As improvement takes place, the pulse may become faster, less full and bound-

ing. If the patient fails to improve, it may first become slower. A pulse rate of 40 to 55 per minute is quite common in the patient with an acute, severe head injury. Eventually in the fatally injured patient the pulse may suddenly increase in rhythm with lowering of the amplitude. It may become elevated to 120 to 180 or higher, eventually becoming thready in the patient who is failing. These changes occur in the course of ten to twenty-four hours or longer following the injury.

It is interesting to note that occasionally a low pulse rate may be noted without an associated abnormal conscious state. A pulse rate of 40 to 50, unassociated with abnormalities of the heart, is seen in some patients following head injury who are conscious and are feeling quite well. A cause for such a low rate may be a period of vagal stimulation with resultant bradycardia. Such bradycardia usually disappears in the course of two or three days. In other patients the pulse may be within the range of normal to start with but over a period of several days may show a lowering in rate. Such a decrease should be carefully evaluated in conjunction with other signs of increase in intracranial pressure due to a dynamic lesion in the cranial cavity. In patients having fatal lesions, such a pulse will eventually increase in rate and become thready. A fast, thready pulse may be seen from the beginning and may be associated with a shocklike state, particularly if injuries to other parts of the body are also present.

The respirations observed in animals with experimental head injury may be somewhat increased in rate when the blows are of subconcussive force, but with a moderate or severe head injury there is cessation of respirations for varying periods. In moderate injuries, following the return of the respiratory rhythm, the animal's respirations continue at a somewhat slower rate without much subsequent change. In more severe injuries, respirations may never return or, if they do, they may be gasping in type, eventually becoming arrested. The animal may have apneic periods ranging from seconds to a minute.

In the human being, depending upon the degree of the injury, respirations may be normal or variously altered. In a lethal injury, the patient may take gasping breaths. In the less seriously injured individual, there may be deep, stertorous breathing which may become accelerated. The hyperpnea may be associated with atony of the bronchiolar

and bronchial epithelium with collections of excretions in the upper respiratory passages resulting in typical hyperpnea (pulmonary edema). In other patients, the respirations may be slow and labored with evidence of difficulty in obtaining a satisfactory exchange. In some, following a normal respiratory rhythm there may be a lowering of the rate. Under these circumstances, the presence of a dynamic lesion may be considered likely. Rapid respirations associated

other than intracranial abnormalities, a chest lesion may be present.

Hyperpnea in patients with severe head injury is common. Its association with obstructive collections of tracheobronchial secretions is also common. The reason for this collection may be a poor exchange of air in the establishment of the vicious cycle with pulmonary edema, improper activity of the ciliated epithelium of the bronchial tree due to the severity of the injury, or improper activity of the muscular layers of the smaller bronchioles resulting in poorer excretion. These abnormalities of the muscular activity and the ciliated epithelium may result from a central mechanism with paralysis of parasympathetic and sympathetic impulses. Cheyne-Stokes respirations are also seen occasionally in the head injury patient, although the slow gasping respirations are much more common. Cheyne-Stokes respirations also indicate a poor prognosis. In the experimental animal such hyperpneic states with pulmonary edema do not occur following severe head trauma.

Respiratory embarrassment with poor exchange may be improved by careful toilet of the upper respiratory passages and employment of a tracheotomy. The latter may be lifesaving in many patients by preventing obstruction. Less effort is required to ventilate the unobstructed lungs.

The temperature of the patient with an acute head injury may be subnormal or normal soon after trauma. It may be higher several hours or days after the accident. Particularly if there is associated injury elsewhere, early subnormal temperature, as a part of a shock state, may be noted. Associated with such a low temperature there may be a peculiar yellowish gray discoloration of the skin, the extremities being quite cold. In many patients with severe head injury the blood pressure may be at a normal level.

In this respect the shock state in the craniocerebral trauma patient is different from shock in the patient having skeletal and bodily injury.

In the patient with severe contusions of the brain and with bloody spinal fluid, a slightly elevated temperature with a warm dry skin may continue for several hours and then hyperthermia may develop with a temperature of 104 to 107° F., associated with hyperpnea, pulmonary edema and a rapid pulse rate. If such a state is not attended with unconsciousness, other causes for the hyperpnea and the elevated temperature should be found. In patients with moderately severe head injury, the temperature is elevated to 101 to 103° F. and it tends to lower as the patient shows improvement. Dehydration, absorption and repair processes and infection may cause some increase in temperature. A high level of temperature sustained for many days or weeks is unusual. Even though the craniocerebral trauma may have initiated some of the upward trend of the temperature, other causative factors such as pulmonary, genitourinary or meningeal infections should be sought. In the course of convalescence, a sudden rise of temperature should be carefully evaluated, particularly in patients upon whom an operative procedure has been performed. It may signify a complicating infection requiring re-exploration of the wound.

In the experimental animal the blood pressure usually increases following a concussive blow. In subconcussive blows, there may be a drop in pressure resulting from vagoglossopharyngeal stimulation. In the severely injured animal, the blood pressure after rising 100 mm. Hg or more begins to fall within seconds. As the initial pressure is then reached, the fall is followed by a secondary rise which is not as high as the initial rise. Still later, the vasomotor tone is completely lost and the blood pressure falls to zero.

Obviously such changes in the human being are not seen in the hospital but may occur at the time of the injury. In the emergency room, the blood pressure readings of most patients with head injury are near normal. The blood pressure is well sustained even though the patient may present the appearance of a shocked state. It has been shown experimentally that in the seriously injured animal there is a central vascular dilatation with peripheral vasoconstriction. In the human being, essentially the same

peripheral limbs and a pale, yellowish gray, sweating face.

Occasionally the blood pressure may rise in association with increasing intracranial pressure as produced by a massive intracerebral hematoma. A slowing of the pulse and respirations may accompany such an increase in the blood pressure. In some patients there may be an increase in blood pressure and a high level of systolic and diastolic pressures may be sustained for several days but become normal as the patient improves. Most often the blood pressure readings are not of much help in assessing the level of the increase in intracranial pressure. Except for the fact that the pressure level records the general functional competency of the vascular system, blood pressure readings are of minor help.

Headache. Headache is a common symptom in patients with head trauma. As the seriously injured patient improves from the initial disturbed conscious state he may complain of headaches. In other instances headache may be the result of an increase in intracranial pressure in patients without traumatic unconsciousness. In still others it is seen following minor head injuries unassociated with unconsciousness at the time of impact. These patients, nevertheless, complain bitterly of headaches which in the main are caused neither by intracranial bleeding nor increased intracranial pressure.

The headaches are usually generalized, but they may be localized to one or the other side of the head and are frequently located in the vicinity of scalp lacerations and bruises. Some patients may have headaches only when in the upright position, noted upon getting up and about from bed. These headaches disappear when the patient is in the recumbent or semi-Fowler's position. It has been postulated that such headaches may be due to generalized hypotension with traction upon the intracranial blood vessels.

The mechanism of headache in the patient with a head injury may be related to several factors. Recent information suggests that headache is usually due to changes in the blood vessel tone and caliber of intracranial and extracranial vessels. The vessels at the base of the brain and those of extracerebral structures may become dilated or constricted. Pain resulting from dural vessel involvement also is possible. Abnormalities of tone in the blood vessel walls may result from both meningeal and hypothalamic disturbances.

Such a central involvement may influence blood vessels not only of the head and scalp, but also of other parts of the body such as the gastric or intestinal mucosa. The latter may be associated with ulceration, erosion of vessels and gastrointestinal hemorrhage. In the gastric mucosa, such an influence is probably through vasospasm and ischemia followed by erosion of the lining.

Traction upon the larger vessels at the base of the brain may develop from abnormal cerebrospinal fluid hydrodynamics related to the presence of blood in the subarachnoid space. In patients who obviously have no cerebrospinal fluid hypertension and yet complain of headaches, traction on the larger blood vessels of the circle of Willis may be a factor, particularly with change of the position of the patient's head. An important cause for headaches in the post-traumatic patient involves an associated injury to neck structures, including muscles, ligaments and the cervical nerves. Since many deceleration and acceleration injuries result in traction of the head away from the neck and compression of the head toward it and the trunk, damage to the second and third cervical vertebrae with associated involvement of muscles and nerves may result in head and neck pain. Particularly in injuries of the second cervical area, painful conditions in the back of the head and neck on one or both sides may result and eventually generalized headaches may develop. Hunter and Mayfield have shown that there is extensive distribution of pain in the scalp from the cervical plexuses with involvement of nerves in the upper cervical region. Neural and muscular involvement at the cranio-cervical junction may cause abnormalities of head positioning with initiation of a vicious cycle which eventuates in diffuse headache.

When in the less seriously injured individual there is history of migraine or periodic headaches prior to the head injury, the patient may complain that the headaches following the injury are aggravated. As to whether or not these complaints can be ascribed to a neurosis or a justifiable syndrome is a question. In a few instances patients have complained that migraine states which have been quiescent for three or four years have been reactivated following a head injury. It is difficult to evaluate such a relationship. The head injury in such patients probably is a precipitating factor. Other stresses involving psychic injury, such as a divorce or financial loss, may have the same effect.

Headaches observed in the post-traumatic syndrome patients are noted usually to improve in a period of three weeks to three or four months. Occasionally a patient continues to complain, but often this is found to involve compensation factors. These patients continue to benefit financially as long as their complaints are validated. Dizziness usually disappears before the attacks of headache subside. Occasionally headaches are absent from the beginning while dizzy attacks predominate. In some, the attacks of dizziness are completely absent. In general, complaints of intermittent headache and dizziness favor an organic cause, while persistent headache or dizziness which never disappears completely suggests the presence of a neurosis or malingering.

It is interesting to note that often seriously injured individuals have no post-traumatic headaches. Others with a very mild head injury have severe complaints. About 80 per cent of patients with all types of head injury complain of headaches. In others, persistent post-traumatic headaches and vertigo following knockdowns and knockouts are quite infrequent.

Dizziness. Dizziness is a common complaint during the convalescent period. When the extremely ill individual recovers, attacks of dizziness are not quite as common as in patients with less severe craniocerebral trauma. Many patients with a minor head injury with or without an initial period of unconsciousness at the time of impact may have residual dizziness. Two types are noted: first, the vertiginous type, or an actual feeling of rotation or whirling of the body or surrounding objects, is experienced and, second, giddiness with a feeling of unsteadiness and lightheadedness which is unassociated with feelings of whirling or vertigo. A change in position frequently initiates the dizziness. In the vertiginous type, certain positions of the head and the direction of gaze may result in symptoms. The patient becomes giddy, may feel nauseated and may vomit. Patients learn to refrain from the undesirable posturing of their body and their eyes.

Changing the body position, such as from a supine to a standing position, or vice versa, or bending forward, may result in a feeling of losing balance and meeting the floor. Many patients learn to move more deliberately in order to prevent the feeling of giddiness. If the patient is not careful, he may be felled by the attack. Patients frequently identify their spells by the term "blackout,"

but on questioning admit that unconsciousness does not accompany their spells. The giddiness or vertiginous attacks tend to disappear over a period of several weeks or a few months. The attacks first become less frequent and the patients feel quite well between attacks.

The cause for dizziness is not completely understood. Vertiginous attacks are due to an involvement of the vestibular nerves, the labyrinths peripherally or their central connections in the brain stem. Occasionally, true vertigo will occur as a temporal lobe irritative phenomenon. Although giddy attacks may be due to an involvement of the cerebrum, no definite area has been related to their production. The disturbance in the peripheral balancing mechanism seems a more likely cause.

The combination of headaches and dizziness as post-traumatic sequelae, particularly in minor head injuries, is known to both the physician and the layman. The protraction of such complaints may be due in part to functional factors, but that they have an organic basis in the early cases is unquestioned. In part, these complaints are on an organic level, but psychoneurotic influences alter, lengthen or reinforce these sequelae.

The study of the labyrinthian mechanism in patients with head injury has not been fruitful. Those who complain of giddiness have shown no unusual degree of abnormality of the labyrinthian structures, excepting possibly for some decrease in the reaction to stimuli. In patients who have severe vertigo, caloric tests have shown some impairment of the labyrinth function in association with nerve deafness. Many of the latter group also complain of tinnitus, usually on the one side. A ringing in the ear may be associated with a history of bleeding from one or both ears.

Vomiting. Vomiting is frequently associated with craniocerebral trauma. In a large series of patients having head injuries, it occurred in about 20 to 30 per cent of the patients. In the patient with a minor head injury, nausea and vomiting may be the result of a reflex stimulation of the vagoglossopharyngeal system. In some individuals it may be due to the activation of this reflex through the presence of swallowed blood in the stomach. In the more seriously injured patient, nausea and vomiting may develop with recovery from an unconscious state. Sometimes vomiting and nausea are associated with changing of the position of the patient. When this occurs, vestibular dam-

age with nuclear and peripheral involvement of the vestibular system may be the cause. Usually vomiting is a frequent manifestation in the less seriously injured individual. In the profoundly injured patient, it does not occur as frequently. The vomitus is usually bloody or coffee-ground color, either from the presence of swallowed blood from trauma to the oral cavity or from gastric bleeding from an abdominal injury. In some instances vomiting may be the result of hypothalamic abnormalities producing ulceration and hemorrhage of the gastric mucosa. Because of the possibility of aspiration of the vomitus, the management of patients with head injury may require the washing out of the stomach soon after admission to the hospital. Vomiting, along with dehydration and fluid imbalance, may result in chemical changes including hypochloremia and hypokalemia which delay or prevent recovery.

Neurologic manifestations in craniocerebral injuries. In acute craniocerebral injuries, neurologic manifestations may be disguised by abnormalities in the state of consciousness. Thus, an accurate evaluation of the patient's ability to cerebrate normally, his visual acuity, difficulties of hearing, abnormalities of the sense of smell, speech disturbances and sensory abnormalities may be impossible. However, important conclusions may be drawn from the neurologic examination. Repeated examinations are valuable and often mandatory. Minor changes in the neurologic status of the patient may signify abnormalities not suspected previously. In the presence of extensive intracranial damage, certain abnormalities in the sensory sphere also become evident as the patient recovers consciousness. Thus, visual defects, abnormalities in the power of thinking, sensory phenomena, and auditory, olfactory and speech disturbances may become evident.

In the early stages following an acute severe head injury, the examiner is often limited in his evaluation by the lack of cooperation of the patient. Under these circumstances, an examination of the pupils and fundi, search for bleeding from body orifices and an evaluation of gross abnormalities of motor function may be of value. Any inequality of the pupils is noted. In over 90 per cent of the patients having inequality of the pupils, the dilated pupil is on the side of the intracranial lesion. A dilated pupil may indicate partial or complete involvement of the oculomotor nerve. There may be divergent-strabismus, or conjugate deviation

of the eyes to one or the other side. Usually, in patients with cortical lesions, the eyes are turned toward the lesion. In those with nuclear lesions, the eyes are turned away from the lesion. Examination of the fundi may show the presence of hemorrhages in the aqueous or vitreous humor or in the retinas. Such hemorrhages, when present soon after injury, may indicate local forces acting directly on or about the globe. In other instances, there may be evidence of venous engorgement, diffuse retinal edema, blurring of the disks or cloaked disks.

Nuchal rigidity may be present, particularly in those patients who are resistant and uncooperative. Its absence does not preclude the presence of subarachnoid hemorrhage with bloody spinal fluid. There may be varying degrees of associated decerebrate rigidity. In some patients who are profoundly ill, there may be limpness or flaccidity with a generalized areflexia, which is an ominous sign.

Weakness or paralysis of an extremity, facial weakness and the presence of certain abnormal reflexes may be identified in the unconscious or semiconscious patient. It may be evident that the patient moves one upper extremity more frequently than the other. On stimulation, one may notice that one entire half of the body is paralyzed as compared with the other half. There may be facial distortion suggesting a weakness on one side of the face. In this connection the presence of a unilateral corneal reflex loss may be significant. Unilateral corneal reflex loss is probably due to the presence of central or peripheral facial weakness and consequently may be significant as a localizing finding. The presence of unilateral or bilateral pyramidal tract signs with confirmatory reflexes should be looked for and recorded.

Speech disturbances may occur in some patients with severe brain damage but with little or no evidence of brain stem involvement. Open, depressed skull fractures in the left frontoparietal area may be associated with motor aphasia and, in some instances, with jargon speech. An inability to understand spoken language may be present. Although large amounts of brain may have to be sacrificed during débridement, a relatively good return of function eventually occurs and usually traumatic aphasia clears up. As a patient becomes more cooperative, evidences of sensory aphasia, alexia, agaphia and apraxia may be noted.

Visual disturbances, particularly involvement of the visual fields, may be noted in

the convalescent patient, although suspected by the extent and location of damage sustained at the time of the accident. Homonymous hemianopsia with occipital lobe involvement is occasionally noted. In temporal lobe lesions due to open depressed skull fractures, there may be quadrant defects or homonymous defects. Some patients who are conscious on admission to the hospital may have a bilateral blindness which disappears after several minutes to hours. A history of a blow on the occiput may suggest the possibility of a confusional state with edema of the calcarine area bilaterally with resultant blindness. We have seen at least four or five such patients during the past fifteen years. In one of these, a residual homonymous defect was present for several days and eventually disappeared. Persisting unilateral blindness may occur in patients who are only briefly unconscious. The optic nerve of normal appearance at the first examination becomes atrophic in two to three weeks.

Sensory abnormalities of cortical origin are not common in patients with head injury. However, astereognosia may be noted. Some loss of tactile and vibratory sense on one side of the body as compared with the other may be found in some patients with extensive parietal damage. In the majority of patients, light touch and tactile sense are well preserved even though there may be known parietal lobe damage.

Certain neurologic syndromes have been described in patients with head injury involving specific areas of brain and intracranial contents. Among these are the syndrome of the superior longitudinal sinus, catatonic states, the syndrome of contusions and lacerations of the frontotemporal junction, plegic states with pseudobulbar paralytic phenomena, and the brain stem syndrome associated with temporal lobe and uncus herniations.

The syndrome of the superior longitudinal sinus was first described by Holmes and Sargent in patients with tangential fractures of the vault near the midline. Paresis of the lower limbs and one or both upper limbs was described. The pathologic anatomy was either that of contusions of the lower extremity area or a compression or thrombosis of the sagittal sinus. We have described four cases of this syndrome, which included one of a perforating wound of the sagittal sinus with an interhemispheric hematoma, two cases of depressed fracture of the interparietal region with rigidity of the lower extremities and one of an epidural hematoma

at the midline with bilateral pyramidal tract signs and triplegia. Such abnormalities may also occur as a result of brain stem herniation through the incisura.

Catatonic states in persons with head injuries almost always have left frontoparietal injuries with aphasia. The association of aphasia and catatonia was pointed out by Kleist, who thought that catatonia may be a pyramidal tract dysfunction. It is felt that a catatonic attitude suggests a left frontoparietal lesion in a right-handed individual. These patients may be conscious or semiconscious. Frequently they are aphasic and when a limb is placed in a certain position this position is sustained until fatigue causes the limb to be lowered.

Contusions and lacerations of the frontotemporal junction may be associated with central facial weakness on the opposite side and jacksonian seizures of the face and the mouth on the one or both sides. These may become generalized seizures. Frontotemporal junction contusions are common in serious head injuries. When there are circumoral twitchings associated with jacksonian or generalized seizures, the possibility of frontotemporal junction contusions should be considered.

Plegic states with pseudobulbar paralytic phenomena are common in the more seriously injured individuals with extensive brain damage. Bilateral spasticity eventually disappearing, but associated with some unsteadiness and ataxia, is seen. This may result from bilateral pyramidal tract involvement in the posterior thalamus or bilateral contusions and lacerations of the motor cortex. Associated with this condition is a change in the patient's voice to a nasal tone as well as an early inability to swallow normally. Later, swallowing may become normal, but the abnormal pseudobulbar speech may continue for many years.

An intracranial mass lesion, such as an extradural or subdural hematoma, as well as severe swelling of the brain may result in a brain stem herniation through the incisura or a temporal lobe herniation with the uncus extending into the posterior fossa through the incisura. Thus, the brain stem and certain cranial nerves, particularly the third cranial nerve, may be compressed. In some patients, involvement of the third cranial nerve, resulting in a dilated pupil, is due to hemorrhage from the middle meningeal artery in the middle cranial fossa. Pupillary inequality as a result of brain stem compression, bilateral pyramidal tract signs and

decerebrate attitudes and rigidities are manifestations of temporal lobe or brain stem herniations. With compression of the brain stem the vessels about the structure may become compressed with resultant congestion and ischemia. Hemorrhages in the upper brain stem may occur by diapedesis. Such hemorrhages occur in patients with fatal subdural and epidural hematomas, but it should be pointed out that similar lesions also may occur as a result of the initial impact. An initial impact resulting in brain stem hemorrhage may cause death within a matter of a few minutes to several hours.

Diagnosis of this condition is made by the observation of abnormalities of the pupils, body tone, the reflexes and deterioration of the conscious state. Its management in most instances consists in removal of the initial cause of the herniation. An epidural, subdural or intracerebral hematoma should therefore be removed with dispatch. Prompt surgical treatment may be lifesaving. On the other hand, if the temporal lobe or brain stem herniation has been present for too long a time, an irreversible state may be present. Some of these patients may possibly be helped by temporal lobe excision with section of the incisural border.

Herniation of the medulla and cerebellar tonsils in acute head injury is uncommon but may occur in conjunction with a posterior fossa massive hemorrhage. Sudden stoppage of respirations with heart action continuing is the typical clinical result in the untreated patient.

The cranial nerves may be injured in craniocerebral trauma. The first cranial nerves are injured in association with anterior fossa fractures with injury in the neighborhood of the cribriform plates. Anosmia may result, with improvement in olfactory function in eight to twelve months. If of longer duration, anosmia usually becomes permanent. In anomic patients the sense of taste is fairly well preserved at least for basic flavors.

Injury to the optic nerves locally may occur by impact of the fracture and by hemorrhage into the vaginal sheath of the nerve. Usually the blindness is permanent and the nerve head atrophies. We have seen only one instance of bilateral blindness due to optic nerve injury associated with a fracture extending to the optic foramen on one side.

The third, fourth and sixth cranial nerves are frequently injured in patients with extradural and subdural hematomas. The sixth nerve may be injured at the base because of

distortion of the brain at impact. Occasionally, the third and fourth nerves are also injured in this manner. Diplopia due to paralysis of one or more ocular muscles is frequently the result of intraorbital damage. Third nerve paralysis on one side with contralateral paralysis of the body may suggest a midbrain injury, but it is also seen in association with subdural and epidural hematomas in a basilar location.

Paralysis of ocular movements may occur in patients with head injuries complicated by an arteriovenous fistula between the carotid artery and the cavernous sinus. Proptosis of the eyeball develops, often within forty-eight hours; chemosis occurs and a bruit may be heard over the globe. The ipsilateral common carotid artery should be promptly ligated in treating this condition.

The fifth cranial nerve may be injured in its supraorbital and infraorbital portions by fractures involving the foramina bearing the same names. Occasionally the ganglion and the entire fifth nerve are involved with fractures of the middle fossa.

The seventh and eighth cranial nerves are injured in transverse fractures of the petrous bone. Bleeding from the ear may accompany seventh nerve paralysis with longitudinal fractures invading the facial canal and the middle ear. Complete deafness with a dead labyrinth usually indicates a transverse fracture through the internal auditory meatus. Seventh nerve paralysis of the peripheral type involves paralysis of the forehead, orbicularis oculi and orbicularis oris as well as the platysma muscles. Seventh nerve paralysis may be due to injury of the nerve at the time of impact or it may result from edema and hemorrhage in the facial canal neighborhood. In the latter instance, it makes a delayed appearance four to twelve days after the injury. In most of these patients, peripheral facial paralysis improves. An occasional patient may need a spinal-accessory-facial or hypoglossal-facial anastomosis to improve the tone of the facial musculature.

The ninth, tenth, eleventh and twelfth cranial nerves are injured in penetrating wounds of the head. They are almost never involved in the usual civilian type of head injuries. In one of our patients, the third, fourth, fifth, sixth, seventh, eighth, ninth, tenth, eleventh and twelfth cranial nerves were sheared on one side in a penetrating wound of the skull base. In a civilian patient with an occipital fracture, the twelfth cranial nerve was found to be paralyzed on one side

the convalescent patient, although suspected by the extent and location of damage sustained at the time of the accident. Homonymous hemianopsia with occipital lobe involvement is occasionally noted. In temporal lobe lesions due to open depressed skull fractures, there may be quadrantal defects or homonymous defects. Some patients who are conscious on admission to the hospital may have a bilateral blindness which disappears after several minutes to hours. A history of a blow on the occiput may suggest the possibility of a contusional state with edema of the calcarine area bilaterally with resultant blindness. We have seen at least four or five such patients during the past fifteen years. In one of these, a residual homonymous defect was present for several days and eventually disappeared. Persisting unilateral blindness may occur in patients who are only briefly unconscious. The optic nerve of normal appearance at the first examination becomes atrophic in two to three weeks.

Sensory abnormalities of cortical origin are not common in patients with head injury. However, astereognosia may be noted. Some loss of tactile and vibratory sense on one side of the body as compared with the other may be found in some patients with extensive parietal damage. In the majority of patients, light touch and tactile sense are well preserved even though there may be known parietal lobe damage.

Certain neurologic syndromes have been described in patients with head injury involving specific areas of brain and intracranial contents. Among these are the syndrome of the superior longitudinal sinus, catatonic states; the syndrome of contusions and lacerations of the frontotemporal junction, plegic states with pseudobulbar paralytic phenomena, and the brain stem syndrome associated with temporal lobe and uncus herniations.

The syndrome of the superior longitudinal sinus was first described by Holmes and Sargent in patients with tangential fractures of the vault near the midline. Paresis of the lower limbs and one or both upper limbs was described. The pathologic anatomy was either that of contusions of the lower extremity area or a compression or thrombosis of the sagittal sinus. We have described four cases of this syndrome, which included one of a perforating wound of the sagittal sinus with an interhemispheric hematoma, two cases of depressed fracture of the interparietal region with rigidity of the lower extremities and one of an epidural hematoma

at the midline with bilateral pyramidal tract signs and triplegia. Such abnormalities may also occur as a result of brain stem herniation through the incisura.

Catatonic states in persons with head injuries almost always have left frontoparietal injuries with aphasia. The association of aphasia and catatonia was pointed out by Kleist, who thought that catatonia may be a pyramidal tract dysfunction. It is felt that a catatonic attitude suggests a left frontoparietal lesion in a right-handed individual. These patients may be conscious or semiconscious. Frequently they are aphasic and when a limb is placed in a certain position this position is sustained until fatigue causes the limb to be lowered.

Contusions and lacerations of the frontotemporal junction may be associated with central facial weakness on the opposite side and jacksonian seizures of the face and the mouth on the one or both sides. These may become generalized seizures. Frontotemporal junction contusions are common in serious head injuries. When there are circumoral twitchings associated with jacksonian or generalized seizures, the possibility of frontotemporal junction contusions should be considered.

Plegic states with pseudobulbar paralytic phenomena are common in the more seriously injured individuals with extensive brain damage. Bilateral spasticity eventually disappearing, but associated with some unsteadiness and ataxia, is seen. This may result from bilateral pyramidal tract involvement in the posterior thalamus or bilateral contusions and lacerations of the motor cortex. Associated with this condition is a change in the patient's voice to a nasal tone as well as an early inability to swallow normally. Later, swallowing may become normal, but the abnormal pseudobulbar speech may continue for many years.

An intracranial mass lesion, such as an extradural or subdural hematoma, as well as severe swelling of the brain may result in a brain stem herniation through the incisura or a temporal lobe herniation with the uncus extending into the posterior fossa through the incisura. Thus, the brain stem and certain cranial nerves, particularly the third cranial nerve, may be compressed. In some patients, involvement of the third cranial nerve, resulting in a dilated pupil, is due to hemorrhage from the middle meningeal artery in the middle cranial fossa. Pupillary inequality as a result of brain stem compression, bilateral pyramidal tract signs and

for operative intervention. Epidural, subdural and intracerebral hematomas may be associated with focal seizures followed by focal neurologic signs.

Decerebrate states, resulting as they frequently do from uncus or brain stem herniation, may be treated by temporal lobectomy or, better still, by section of the tentorium cerebelli, including the incisural border. In view of the serious condition of the patients and also because the procedures are undertaken in almost moribund subjects, the results have not been too successful. The use of hypertonic solutions and lowering of the intracranial pressure by lumbar puncture have not been particularly helpful.

Cerebrospinal fluid findings. A lumbar puncture, or a cisternal puncture if the former is not practical because of the presence of skeletal and spinal fractures, is worth while and should be carried out whenever needed. Routine use of a lumbar puncture is not suggested by most neurosurgeons at the present time. Early, a lumbar puncture may upset the hydrodynamics in the cranial cavity sufficiently to influence also the signs and symptoms of a dynamic lesion. A forming epidural hematoma may be associated with lowering of the spinal fluid pressure even though the patient's mass lesion is expanding. He may expire because the mass lesion was not recognized and evacuated. Lumbar punctures may be for diagnostic or therapeutic purposes. Diagnostic lumbar punctures should be done to classify the degree of damage. The spinal fluid pressure should always be recorded. The blood content should be noted and this can be done by making a complete blood count of the cerebrospinal fluid. From previous studies and experiences with repeated lumbar punctures, it may be said that cerebrospinal fluid which is very bloody to start with may clear in about eight to ten days. Within two days, a very bloody spinal fluid may be faintly xanthochromic in some patients. The red blood cells hemolyze and disappear much more rapidly than do the white blood cells. At the end of about four or five days, a lumbar puncture may reveal xanthochromic fluid with a white cell count out of proportion to the red count in the same specimen. Usually the white cells in such a count are divided between polymorphonuclears and lymphocytes. In general, low spinal fluid pressure does not rule out the possibility of a massive lesion in the cranial cavity. However, most dynamic lesions in the cra-

nial cavity are associated with fairly high cerebrospinal fluid pressures, over 250 to 300 mm. of water. Also bloody cerebrospinal fluid is often associated with elevated pressure.

Hypotension of the cerebrospinal fluid occurs and is often a grave sign. A seriously ill patient having a cerebrospinal fluid pressure of 75 mm. or less may be in an extremely poor condition. Low cerebrospinal fluid pressure or hypotension may indicate a poor prognosis. Levels of intracranial pressure during anesthesia have been studied by Ryder, Evans and others and high levels of cerebrospinal fluid pressure were noted during such recordings. It has been suggested that increased intracranial pressure per se is not a dangerous condition. However, it should be pointed out that brain swelling may be present with or without high cerebrospinal fluid pressure. In some instances the cerebrospinal fluid pressure gives an index of the degree of brain swelling. In other instances, because of the presence of hydrodynamic abnormalities, the level of cerebrospinal fluid pressure may not be high even though the edema of the brain is present either locally or generally.

The use of lumbar puncture for therapeutic purposes should be individualized. An occasional case of weakness of one side of the body or aphasia may clear up after a lumbar puncture. Its use as a means of removing blood in the spinal fluid to lower the incidence of pia arachnoiditis is held to be unnecessary. In autopsy subjects, bloody collections in the sulci of the hemispheres have been noted in the cranial cavity even though repeated lumbar punctures have been performed.

Concomitant injuries elsewhere in the body. In the usual high velocity deceleration injuries, the possibility of damage not only to the head but to other parts of the body is great. Associated injury elsewhere in the body is often responsible for the morbidity as well as the fatal outcome. In a series of 154 consecutive head injuries studied at autopsy, in sixteen instances there was major associated damage which undoubtedly influenced the outcome. Chest injuries were present in five patients; in two, vertebral column injuries were noted; in three, chest and abdominal injuries; and in four, extremity and chest damage. Extremity injuries alone were present in six patients. Particularly in the unconscious patient, consideration must be given to the possibility of

in association with a fracture through the hypoglossal foramen.

It may be said that abnormal neurologic findings may be of value in localizing the lesion and, depending upon their pattern of appearance, may indicate the presence of a dynamic lesion. Weakness or paralysis of one-half the body seen soon after an injury may signify a laceration of the motor region, whereas weakness or paralysis of one-half the body developing over a period of twenty-four to thirty-six hours may indicate the presence of a dynamic lesion such as a subdural, epidural or intracerebral hematoma. The importance of repeated neurologic examinations cannot be overemphasized. Thereby, with sound clinical judgment, one may be able to detect the surgical type of lesion. The proper evaluation in the changes of the signs and symptoms may indicate the need for emergency intervention which may be lifesaving.

Convulsions. In patients with acute head injury, convulsive disorders are seen in less than 10 per cent. These include focal or jacksonian, generalized or grand mal, petit mal and psychomotor convulsions. Commonly noted are decerebrate rigidity patterns, particularly in patients with serious head injuries. Less common are generalized convulsive seizures of the grand mal variety. Least common are jacksonian manifestations which may become generalized.

Decerebrate spells are seen in the seriously injured. Almost always these patients have bloody spinal fluids with elevated spinal fluid pressures. The patient may become rigid. At times the rigidity may involve one-half of the body and change from one side to the other. Usually both sides become rigid when the patient is moved or stimulated. The patient has bilateral pyramidal tract signs with Babinski reflexes present bilaterally. At times, particularly among the younger, the Babinski signs may be continuous. Nuchal rigidity and opisthotonos may be seen. Usually there are no associated convulsive movements of the body, but occasionally decerebrate rigidity may be followed by a generalized convulsive seizure. The patient has a set, rigid jaw and at times there may be some foaming at the mouth. The attacks usually last from a few minutes to several hours. Frequently, short-lasting attacks may continue to occur. As the patient fails, he may be less rigid and more flaccid. Usually decerebrate rigidity attacks in the adult mean a fatal outcome. In a child, such attacks may not be as serious and

recovery often occurs. Particularly is this true when the decerebrate state is caused by a mass lesion which can be evacuated.

Decerebrate rigidity may be due to brain stem involvement from the initial impact or it may result from brain stem and/or temporal lobe herniation resulting from brain swelling or a large epidural or subdural collection. If such subdural or epidural collections are not promptly treated, an irreversible state due to brain stem herniation may occur.

Grand mal seizures occur less frequently. Occasionally they are seen soon after injury as the patient recovers consciousness. They may be seen later in the course of a serious head injury. The spinal fluid is frequently bloody. The pressure may be high. There may or may not be a history of idiopathic epilepsy and this should be noted carefully in all patients with generalized convulsive seizures following head trauma. No definite localizing signs may be present. However, in many instances there may be bilateral Babinski signs soon after a generalized convulsive seizure. At times, generalized convulsive seizures occur as a sequel to jacksonian seizures or, in some instances, following decerebrate seizures. The attacks may become continuous, resulting in status epilepticus. This is not commonly seen in head injury patients since such individuals are energetically treated early. Patients of the younger age group, particularly infants and children, are more apt to develop convulsive seizures of a grand mal variety than are adults. At times, meningitis, traumatic cerebritis or a brain abscess may be initiated with a jacksonian or grand mal seizure.

Jacksonian seizures or focal seizures are important because they imply a discrete type of lesion of the brain, commonly a mass lesion. Jacksonian seizures of the mouth and upper extremity area may be followed by generalized seizures and may signify confusions of the frontotemporal junction. More frequently, localized compression of the motor areas by a subdural or epidural hematoma and contusions of the motor region may result in jacksonian seizures. These may eventuate in generalized convulsions in the untreated patient or the patient upon whom operation has not been performed.

The management of a patient with convulsive seizures requires a proper airway. In some instances, hypoxia may be the initiating factor and a good airway provided by an intratracheal tube or tracheotomy may be valuable. Focal signs may indicate the need

removal through a small incision will restore the scalp to its normal dimensions.

Open wounds of the head include linear fractures of the skull with an overlying laceration; depression of the skull with or without dural tear (Fig. 5) and with or without brain laceration; cerebrospinal fluid rhinorrhea and cerebrospinal fluid otorrhea resulting from cranionasal and cranioaural communications. Penetrating wounds of the head by high velocity missiles, such as a bullet or shell fragment, or by low velocity wounding, such as by sharp instruments, knife, stiletto or ax, are classified as open wounds of the head.

Open fractures of the skull with no depression may be treated by closing the laceration overlying the fracture after careful cleansing and débridement of the wound. Open depressed fractures may be associated with dural lacerations in about 15 per cent of such patients admitted to large head injury services. Many patients with open depressions may have had no initial unconsciousness or may have been unconscious for a short time. The majority of depressions occur in the anterior half of the vault. Few occur in the posterior third, in the occipital and the posterior parietal areas. Such depressions occur in the forward portions of the head, since these portions are the most frequently injured. About 75 per cent of skull depressions have an overlying laceration making them open wounds. At times the laceration may be a small puncture wound not communicating with the underlying depression or comminution. At times the depression may be over functional centers of the brain so that the patient enters the hospital with weakness or paralysis of the opposite half of the body, aphasia or other clinical abnormalities. Depressions in the more forward portions of the head are attended with a low mortality. Depressions involving the frontal sinus may be associated with a high morbidity in view of the possibility of cranionasal communications with complicating intracranial infection.

The site of the depression may determine the underlying damage. Depressions may overlie the larger venous sinuses, such as the sagittal and lateral sinuses, producing a tear of the sinus which bleeds as the fragments of bone are removed at operation. The patient's preoperative roentgen ray studies should be carefully evaluated so that the surgeon may be prepared to meet such complications. In some depressions the middle meningeal vessels may be involved. De-

pressed fractures involving the temporal bone with a dynamic syndrome suggest the possibility of venous or arterial tears and a mass lesion in an epidural position.

A detailed roentgen ray delineation of depressed fractures is extremely important. When there is fragmentation of bone, the number of fragments should be noted so that at operation one can account for their removal. This is particularly true in war wounds where fragments of bone and other organic matter left in the cranial cavity are of serious consequence in the causation of post-traumatic infection.

Open wounds over the frontal sinuses and neighborhood may be associated with cranionasal communications. In many instances, such communications are established in closed injuries without evidence of a skull fracture demonstrable in roentgenograms. Such injuries in this neighborhood have to be considered as open wounds unless proved otherwise. Linear fractures extending into the base of the anterior fossa may be associated with tears of the dural lining in the region of the cribriform plate with resultant infection many months or even years later. Only at the post-mortem examination may a short fracture be seen to extend into the anterior fossa and the cribriform plate. Sometimes there may be a discrete and separate skull fracture with an unsuspected dural tear because the fracture is far removed from the region of the visible damage, such as in a bullet wound of the parietal or occipital region with cribriform plate fracture. Complicating meningeal infection may point to an injury in this region related to a patent cranionasal communication. However, the most important causes of cranionasal fistulae are compound depressions of the frontal sinus region.

With cranionasal and cranioaural communications pneumocephalus may occur with the cerebrospinal fluid leakage. When pneumocephalus is seen in the patient with acute craniocerebral trauma and is associated with an open depressed fracture and dural tear, repair of the latter usually suffices in curing the pneumocephalic condition. On the other hand, sometimes pneumocephalus may appear several months or years after the acute injury, because of the presence of a patent cranionasal communication. In some instances the patent cranionasal communication may exist even though cerebrospinal fluid rhinorrhea is not recognized or the patient shows no air in the cranial cavity upon roentgen ray examination. Under these cir-

Figure 5 A, Experimental depressed fracture in cadaver head. Note the difference between the amount of involvement on the external (A) and the internal (B) surfaces of the skull. Note that on the internal surface (B) there is extensive fragmentation of the inner table

injuries to various portions of the body, the chest and abdomen especially.

Clinical-Pathologic Correlations in Cranio-cerebral Trauma. When the patient with a head injury is first seen in the emergency room of a hospital, he may appear profoundly, moderately or slightly injured, as evidenced by the immediate clinical findings. He may present, upon examination, a closed head injury or an open wound of the head. A patient with a closed head injury may be conscious or deeply comatose. Patients with open wounds of the head may have varying degrees of involvement from a minor-appearing laceration of the scalp to an extensive wound with extrusion of brain tissue. Patients with open wounds and with extensive damage of nervous tissue may have little or no evidence of brain stem involvement, no initial unconsciousness or an unconscious state of a very short duration. In both types of closed and open head injuries, the condition of the patient may be influenced by later developments of the cranio-cerebral trauma, including swelling and edema of the brain, hemorrhages into the intracranial spaces and intracranial infection.

Contusions and lacerations of the scalp are the commonest types of head injury. Ecchymosis of the eyelids may rapidly develop with marked swelling or there may be small hemorrhagic discolorations, manifest several days after an injury, surrounding the upper and lower eyelids as well as the conjunctiva. Ecchymosis of the mastoid area has long been recognized as indicating a fracture of the base of the skull; it is known

as Battle's sign. This discoloration may be more apparent two or three days after injury than immediately after the initial trauma. Lacerations of the scalp may be single or multiple. In present-day civilian injuries caused by repeated blows upon the head by a sharp instrument, multiple lacerations are common. Lacerations extending to the subgaleal region may be associated with varying degrees of avulsion of the scalp. Careful cleansing of the wound, which then should be meticulously sutured, will frequently result in good healing.

In the depth of a scalp laceration, particles of bone and brain tissue may be seen on careful inspection, but in the final analysis a careful roentgen ray survey is much more accurate and dependable. Patients with extensive lacerations of the scalp may be conscious and may have had no period of unconsciousness following their trauma.

Hematomas of the scalp are frequent. At times, palpation of these may give the wrong impression of a depressed fracture. Hematomas occurring in the subgaleal region may extend to the limits bordering this space. This is particularly seen in young adults and children and may result in severe blood loss. In the infant, hemorrhage under the periosteal lining of the bones of the cranial vault may result in cephalhematoma. The characteristic feature of cephalhematoma is that it is within the confines of the periosteal attachment of the bone involved. Aspiration of the hematoma under aseptic conditions will enhance the healing and the absorption of blood. In cephalhematoma, aspiration or

in the middle fossa. At times there may not be an initial period of unconsciousness. The patient may reach the hospital conscious and eventually become unconscious or he may be brought into the hospital in an unconscious state with a history that initially there was no unconsciousness. A weakness of one-half of the body may not develop with a clot more posteriorly or more anteriorly located. In most of the patients there is a linear fracture crossing the middle meningeal groove of the parietal and temporal bones. Particularly in those patients who have an initial period of unconsciousness, there may be associated evidences of other involvement of intracranial structures such as pia arachnoid tears with bloody cerebrospinal fluid and bruises and lacerations of the temporal and frontal poles of the hemispheres. Massive intratemporal hematomas may occur. Oc-

casionally, depressed fractures may be associated with an epidural hematoma.

The epidural hematoma is usually seen among adolescents and adults, although it has also been described in children and infants under the age of two years. In some patients, there may be third nerve paralysis on the side of the lesion and weakness or paralysis of the opposite half of the body. If the patient's condition is not recognized and immediate operation is not carried out, he may rapidly deteriorate with irreversible changes ensuing. The vital functions at first are characterized by a slow pulse, slow respirations, a temperature of about 100 to 101° F. and a blood pressure which is usually within normal levels. In many instances, the spinal fluid may be bloody and its pressure is moderately elevated. In the untreated patient, the pulse becomes faster and even-

Figure 6 An epidural (A), acute subdural (B) and an intracerebral hematoma (C) seen in the autopsy room. Note the petechiae about the intracerebral hematoma in the right frontal lobe.

cumstances, the only basis for suspecting such a patent communication may be repeated attacks of meningitis. We have had a patient who has had twenty-six attacks of meningitis due to a patent traumatic cranio-nasal communication.

Penetrating wounds of the head of the low velocity type, such as knife-blade and other sharp instrument wounds, are commonly seen in civilian practice. Frequently there is no history of unconsciousness at the time of impact and it is possible for the blade of the knife to break off so that on inspection only a small laceration of the scalp may be seen with the end of the blade embedded deeply, beyond vision, in the scalp, skull or cranium. The frequent error of misjudging such wounds must be emphasized. Careful inspection of all wounds and roentgen ray examination of the skull should prevent the occurrence of such a mistake. When such foreign bodies are left in the cranial cavity, there may be an inflammatory reaction surrounding the foreign body and a brain abscess may form or meningitis may develop. When the patient has extensive involvement of the craniocerebral structures in open wounds, the diagnosis is usually made and prompt care of the wound results in a cure with little likelihood of infection.

High velocity wounds of the head present a different problem, particularly with bullets traveling over 1000 feet per second. The area of scalp penetration may be extensively devitalized so that incomplete débridement will result in breakdown of the wound. The passage of the missile through the cranial cavity results in forward as well as radial forces causing pulping of brain tissue and destruction of blood supply so that an adequate débridement requires complete removal of the brain tissue so destroyed. Improper débridement will result in late infection and cerebritis and brain abscess. Not seen in civilian life, but commonly seen in war experience, are shell fragment wounds due to high velocity missiles, with more extensive pulping of the brain because of the varying sizes and irregularity of the contour of the shell fragments. With wounds by shell fragments, complete removal of the fragments and foreign particles is mandatory for a good result. Brain stem involvement may be associated with both bullet and shell fragment injuries of the brain, so that these patients may be moribund soon after the injury. On the other hand, some of the patients may show little or no evidence of brain stem involvement and consciousness may be retained until lost through factors other than

the initial trauma. Secondary involvement of the brain stem centers through brain edema or hemorrhage may occur. The possibility of intracranial hemorrhage associated with penetrating wounds of the brain is stressed by experiences in recent wars. Hematomas in the track of the bullet, particularly of small firearms, are present in fully half of the patients and removal may be lifesaving.

In open wounds, the rationale of operative management is to prevent the introduction of infection into the intracranial spaces and structures. The sooner the wound is débrided and closed, the sooner protection from infection is secured. The possibility of associated hemorrhage causing compression should be considered.

Traumatic intracranial hemorrhage. Intracranial hemorrhage due to trauma may be epidural, subdural, subarachnoid or intraparenchymatous. Combinations of hemorrhagic collections in various locations in the cranial cavity are quite common. Particularly is this true with the usual type of deceleration injuries such as in falls and automobile accidents.

Epidural hemorrhage (Fig 6) may be of middle meningeal, dural sinus or diploic origin. It is located between the dura and the skull. At times it forms a large mass and in some autopsy subjects as much as 350 to 400 cc of blood may collect in such an epidural position. Occasionally the lesion is bilateral or it may cross the midline superiorly to become bilateral. The most common epidural hemorrhage is that of middle meningeal artery origin. Less common are epidural hematomas in the posterior fossa of lateral sinus tear origin and hematomas resulting from sagittal sinus tears in vertex injuries.

Middle meningeal hemorrhage is usually caused by tears of the middle meningeal artery and veins. A history of a fall or a low velocity impact, such as a bicycle-car accident, falling on the sidewalk and falling down steps, is usually present. The patient may or may not have an initial brain stem syndrome with immediate post-traumatic unconsciousness. The injury may be followed by a lucid interval of a few hours to several days. This is followed by a primary or secondary attack of unconsciousness with weakness of one-half of the body and a dilated pupil on the same side as the lesion. The pupillary dilatation may not be marked in some instances and the more completely dilated the pupil, the greater the likelihood of the lesion being in a ¹ post

comatose with increase in the respiratory rate, hyperpnea and pulmonary edema. Such patients when investigated may have a subdural hematoma on one or both sides. Prompt surgical intervention may be life-saving. The mortality in this group is 30 to 40 per cent.

The chronic subdural hematoma (Fig. 7), as previously stated, may either accompany a severe craniocerebral injury or it may occur without initial associated involvement of the brain stem centers. Under the latter circumstance, the patient may be well for three to seven weeks and then may complain of headache which becomes progressively worse. The headaches are usually lateralized to the side of the hematoma, although in many instances subdural hematomas may be bilateral (20 per cent). In other patients there may be signs of increased intracranial pressure, choked disks and weakness of one-half of the body. Diagnostic studies may show evidence of a mass lesion. In some instances a brain tumor may be suspected when a history of trauma is not elicited from the patient or relatives, though usually such a history exists.

The chronic subdural hematoma is usually covered with a thick outer wall and a thin, almost single layer of cuboidal epithelium, inner wall. Within these walls is contained clotted and hemolyzed old blood. In other instances, the hematoma may be almost all liquid with a very thin wall surrounding the mass. Chronic subdural hematomas may be bilateral in 20 per cent of patients, under any circumstance, both sides of the skull should be explored even though initial diagnostic studies may implicate only one side.

Figure 7. Chronic subdural hematoma seen in the operating room. The brain surface is exposed as the hematoma is removed through an osteoplastic flap.

The pathophysiology of the subdural hematoma may be summarized as follows: If the initial subdural bleeding is severe and if the host cannot tolerate its pressure, signs and symptoms of acute subdural hemorrhage supervene. If the hematoma is smaller, the patient may tolerate its presence for three to ten days with gradually developing signs and symptoms of subacute subdural hemorrhage. If the clot is carried by the host without any symptoms for three or more weeks, an attempt at absorption and organization results in formation of an outer thick wall on the dural side and a very thin wall on the arachnoid side. Its size may increase by transference of tissue fluids and cerebrospinal fluid because of its high osmotic pressure, with the arachnoid acting as a semipermeable membrane. The size may also increase from hemorrhages of blood vessels in its outer wall. With increase in size, eventually the mass causes symptoms.

There are exceptions to these mechanisms. The hematoma may cause little or no symptoms for many months or years. In some patients it may calcify; in others a solid unexpanding mass of clot with a consistency of hepatic tissue may result. Some small hematomas may absorb and never cause symptoms.

The prognosis in the chronic type of subdural hematoma is gratifying. Mortality is usually 10 per cent or less and patients usually regain their faculties to return to their former occupations and live usefully.

Subdural collections of cerebrospinal fluid mimic subdural hematomas of the acute and subacute variety. They are almost never diagnosed until an operation is performed. At times such collections are found in infants and they may or may not be traumatic in origin. There may or may not be a membrane surrounding the fluid. Occasionally post-inflammatory collections (postmeningitic) in the infant and the young child are described as subdural effusions.

Traumatic subdural accumulations of cerebrospinal fluid may be due to a tear of the arachnoid membrane with escape of cerebrospinal fluid into the subdural area causing localized pressure against the brain. The presence of small amounts of bloody material in an extra-arachnoid position may attract cerebrospinal fluid and tissue fluids into the subdural area because of an increase in the osmotic pressure in this region. Contusions and tears of the brain over the convolitional peaks, with resultant increased osmotic pressure, may cause fluid accumulation in the subdural area in this neighbor-

tually thready. The respirations increase in rhythm and the patient may eventually become hyperpneic, with pulmonary edema, or there may be slow gasping respirations as a final phase before death. In the untreated patient, late effects may be the result of brain stem herniation through the incisura with generalized rigidity, bilateral pyramidal tract signs, dilation and fixation of pupils and loss of corneal reflexes.

The presence of an extradural hematoma of dural sinus origin in the posterior fossa should be suspected in association with an occipital fracture. The patient may have cerebellar hypotonia and weakness on the same side of the body as the hematoma. However, because of the associated injury to other parts of the nervous system, typical signs may not be found in the patient with a posterior fossa hematoma. Exploration along a fracture site in a patient whose condition is gradually deteriorating is justified and, under these circumstances, hematomas in the posterior fossa may be located.

Extradural hematoma from diploic and emissary veins is never of sufficient size to cause compression of the intracranial contents, although fairly large extradural hematomas in depressed fractures posterior and above the mastoid area have been seen.

Subdural hematoma is a collection of blood in the subdural area, a potential space between the dural lining and the arachnoid membrane. As previously stated, mass movements of the brain may result in tear of connecting veins between the sagittal sinus and the surface of the brain as well as between the dura and the surface of the brain. Such tears result in hemorrhage into the subdural area. Depending upon the size of the torn vessels, the hemorrhage may be of proportions to result in signs of compression soon after its occurrence. On the other hand, a small amount of bleeding may occur into the subdural area and, as the subdural pressure increases, the bleeding from the venous channel may be stopped. Such a hemorrhage may be silent for varying periods.

Such hemorrhages may occur over one or both hemispheres. Depending upon the severity of the head injury, there may be clinical symptoms suggesting diffuse brain damage and masking a surface lesion. In the absence of brain stem involvement, if the hematoma is small enough so that the patient can tolerate its presence, the condition may be asymptomatic for several days or weeks. If, on the other hand, it is of larger size, there may be either immediate symptoms and signs or the symptoms and signs

may be manifested within a period of several days to a week or ten days. Thus, on the basis of the time of the appearance of clinical effects, a classification into *acute*, *subacute* or a *chronic* type, has been made. If the bleeding is severe and symptoms are manifested almost immediately, one is dealing with an acute and dangerous process. If the bleeding is somewhat smaller in amount and/or if it is tolerated by the host for a week or ten days, one is dealing with a subacute form. Patients with the chronic variety may have associated severe craniocerebral injury and therefore may be ill following the trauma. These patients may improve for several weeks until evidence of a chronic subdural hematoma is noted. In other patients, the initial hemorrhage is silent for several weeks until signs of a chronic subdural hematoma supervene. The division of subdural hematomas into acute, subacute and chronic forms is of prognostic value. The earlier an acute subdural hematoma causes symptoms and signs necessitating intervention, the worse the prognosis, the longer the time before intervention is indicated, the better the prognosis.

The diagnostic features of acute subdural hematoma include a deteriorating conscious state with focal signs. The most common position is frontoparietal on one or both sides. However, subdural hematomas may be found between the hemispheres in an interhemispheric position, in the anterior fossa and in the parieto-occipital area. They may also occur between the brain stem and the hemispheres and extend into the posterior fossa about the brain stem and medulla. The presence of a fracture of the skull is not of localizing value in most instances of acute subdural hemorrhage. In two-thirds of the patients the fracture is on the opposite side or there may be no fracture demonstrated by roentgen ray examination or by autopsy. In only one-third is the fracture on the same side as the subdural hematoma. The clot in the subdural space may be liquid and easily drainable or it may be solid with some liquid and hemolyzed portions. The type of clot is important in the management of the patient and determines the type of operative treatment to be instituted. The mortality in the acute form is 50 to 75 per cent.

Subacute subdural hematomas are tolerated by the patient for several days before signs of compression supervene. After three to ten days of a stabilizing clinical condition, the patient may show increasing drowsiness, evidences of localization not previously noted and, if untreated, become

OSTEOMYELITIS OF THE SKULL. Osteomyelitis of the skull is a rare complication of a craniocerebral injury at the present time but does occur and almost always it is the result of improper treatment of open fractures of the head. During the past four years we have had three patients with osteomyelitis of the skull due to this cause. As has been noted in Browder's classification, osteomyelitis at the site of trauma may arise as a result of an open wound or it may occur in the area of trauma with the overlying scalp intact. The latter is the "puffy tumor" of Pott's description and at the present time it is rarely seen.

The more common form of osteomyelitis due to implantation of bacteria in an open wound is preventable by careful excision of the wound soon after injury. In instances where this has not been done, an area of inflammation may supervene with purulent matter exuding from the compound wound. If improperly treated, the patient may enter the hospital with fever, leukocytosis, some rigidity of the neck and evidences of meningeal irritation. X-ray examination of the skull may show an area of bony destruction which is characteristic (Fig. 8). At operation, involvement may be seen with foreign particles, hair and other dirt embedded between the fragments of bone with purulent matter and sequestration of bone. Complete excision of the area and the use of local and systemic antibiotic therapy and chemotherapy usually result in a cure over a period of several weeks. The possibility that osteomyelitis of the skull may be associated with a subdural abscess should always be kept in mind and, if necessary, the dura should be

opened to inspect the subdural area. The skull defect may be repaired later with an inanimate transplant. However, it is important to wait at least nine months after complete healing before such a repair of the skull defect is undertaken.

CORTICAL ULCERATION, CEREBRITIS AND BRAIN ABSCESS. Cortical ulceration, cerebritis and brain abscess result from the implantation of organisms in open wounds involving the brain. Occasionally a blow to the head with concussive effects may be associated later with a brain abscess and may be unsuspected until operative removal. This type of abscess may be due to a contusional involvement with a blood-borne infection of the area. Eventually, encapsulation and evidences of compression may develop.

Cerebritis due to an infection of the brain which follows improper débridement of a penetrating wound is a common occurrence in war but is seldom seen in civilian practice. The management of such early brain abscesses or cerebritis is by complete excision of the area of inflammation with removal of all foreign matter.

The diagnosis of cerebritis is based upon the occurrence of fever and leukocytosis and demonstration of bone particles and foreign matter in the roentgen ray film in a patient with an improperly treated open brain injury.

Diagnostic Aids in the Management of Craniocerebral Trauma. In addition to the information obtained from the history and neurologic examination, various diagnostic aids are available in evaluating patients with craniocerebral trauma. These include

Figure 8. Trauma to the forehead in a patient with sinusitis resulted in an extensive osteomyelitis of the skull associated with a subdural abscess over the left hemisphere and an intracerebral abscess in the left temporoparietal junction. Note the area of bone removal (B).

hood Coughing and sneezing have been thought to cause tears of the arachnoid membrane in some patients with nontraumatic subdural accumulations of cerebrospinal fluid. Finally, certain inflammatory diseases involving the pia arachnoid may cause collections in the subdural area. Subdural collections may also be found in the posterior fossa, under the tentorium and about the cerebellar lobes.

The symptoms of a subdural accumulation of cerebrospinal fluid include a lucid interval in some patients, weakness or paralysis of one-half of the body, generalized or jacksonian seizures and a general deterioration of the patient's status. Subdural collections of cerebrospinal fluid may be found bilaterally. They may coexist with subdural and epidural hematomas.

Intracerebral hematomas are less common than subdural hematomas. Deep contusions of the brain with necrosis and bleeding from vessels may result in a large intracerebral hematoma. Actual tears of vessels in the substance of the brain may be associated with a hematoma of this type or there may be areas of infarction with hemorrhage in the distribution of larger vessels. Frontal and temporal hematomas are most common. Parieto-occipital hematomas are occasionally seen. Parenchymatous hematomas also may occur in the posterior fossa in the cerebellar lobes.

The signs and symptoms of intracerebral hematoma depend upon the location of the lesion. In the temporal and frontal portions of the hemisphere, there may be pyramidal tract signs in the opposite half of the body and speech disturbances if the lesion is on the left side. The intracerebellar hematoma is difficult to diagnose except when there is an open wound suggesting the presence of a lesion in this vicinity. If the patient can stand the initial effects of the intracerebellar hematoma, a diagnosis may be reached at the operating table by exploration of the posterior fossa as indicated by the ventriculographic studies. It is interesting to note that in several patients with intracerebellar hematomas a marked psychotic state was noted. This may possibly have been due to increased intracranial pressure brought about acutely by the compressing hematoma against the aqueductal area.

Infections. Infections complicating head injury include meningitis, osteomyelitis and brain abscess. Before antibiotic therapy and chemotherapy, otitis media and mastoiditis were fairly common following head injuries involving the middle fossa and temporal

bone. Otitis media usually was seen six to eight weeks following the injury but could also occur soon after the accident. Mastoiditis necessitating mastoidectomy was also fairly common. Such complications have been seen rarely during the past fifteen years in our services. At the present time meningitis is seen occasionally. Osteomyelitis may occur, particularly in the improperly treated open injuries of the head. Cerebritis and brain abscess may develop in inadequately débrided open injuries of the brain.

MENINGITIS Traumatic meningitis may be noted six to eight days after an injury. In the seriously ill patient, its presence may be detected only through the study of the cerebrospinal fluid. When it occurs six to eight days after the injury, it frequently is ushered in as a fulminating disease. In a patient who has improved from the initial effects of the accident, there may be severe headaches, disorientation and coma. Occasionally the disease may be initiated with a convulsive seizure. A high fever with a delirium state is common. The patient presents nuchal rigidity and there may be a Kernig sign. The spinal fluid examination reveals a turbid fluid with large numbers of polymorphonuclear cells and, in some instances, organisms which can be seen in the smear. Occasionally meningitic infection may follow upon the presence of a patent cranionasal or a cranioaural fistula. It may occur in conjunction with a brain abscess.

The prevention of meningitis is undoubtedly aided by the use of antibiotics and chemotherapy in patients who have open injuries of the head or who have communications between the outside and the cranial cavity through the nose or through the ear. Undoubtedly, many meningitic infections are prevented with the use of these drugs. In such patients, the preventive use of 400,000 to 800,000 units of penicillin and 80 to 120 grains of sulfonamides per day may be effective.

When a diagnosis of meningitis is made, the drug dosage is increased. From 10 to 15 million units of aqueous penicillin are administered daily for four or five days until the meningitis has been controlled. Daily, 200 to 400 grains of sulfonamides are given. In the meantime, the organisms are studied by smear and culture and their drug sensitivity is identified. As the results of these tests are available, the medicinal treatment is altered as indicated. The spinal fluid obtained after the fever and the leukocytosis have subsided should contain few or no pus cells.

pected. When a subdural hematoma is suspected, both sides should be explored in spite of lateralizing signs and diagnostic studies.

cranial conditions by means of four or more openings in the head, in the frontal, temporal, parietal and occipital regions on each side. The use of multiple trephinations without the additional use of diagnostic studies may lead to serious mistakes.

From studies carried out thus far, it appears that electroencephalography in the patient with acute injury is of questionable diagnostic or prognostic value. In patients with the more chronic conditions, such as a chronic subdural hematoma, electroencephalography is valuable and localizes the lesion in about 60 per cent of the cases.

Indications for Operative Intervention. About 25 per cent of patients with cranio-cerebral injuries need operative intervention, including diagnostic operative procedures. Among those with skull fractures, the incidence of required operation is higher (35 per cent). About 15 per cent require débridement for compound or open wounds of the

Figure 14. Angiograms in a patient with a right temporal intracerebral hematoma (anteroposterior [A] and lateral [B] views). Note the elevation and bowing of the middle cerebral artery and branches

survey roentgen ray studies of the skull, lumbar or cisternal puncture, air studies including ventriculography and encephalography (Figs. 9 to 11), angiography and electroencephalography. Isotope studies have been infrequently used in craniocerebral trauma and, therefore, conclusive information pertaining to their diagnostic value is not available.

Survey roentgen ray studies are extremely valuable. The presence of a linear fracture, its position, the presence of comminution of fragments, depression, the number of fragments of bone in a depression and the presence of a foreign body in the cranial cavity may be detected by such studies. In those who have a calcified pineal gland, the presence of a pineal shaft may aid in the diagnosis of a mass lesion (Fig. 12).

Lumbar puncture is a valuable diagnostic aid. The concentration of blood in the cerebrospinal fluid may indicate the degree of subarachnoid hemorrhage and the severity of the intracranial involvement. The pressure of the cerebrospinal fluid in some instances may point to a mass lesion, although normal or low levels of cerebrospinal fluid pressure may be seen with mass lesions. The total protein content of the cerebrospinal fluid, if elevated, may indicate a poor prognosis. Glutamic oxalacetic transaminase determinations may show an increase in association with brain contusions and lacerations.

Air studies are valuable for localizing lesions or ruling out their presence. Ventriculography is preferable in the acute case. Encephalography may be used in the more chronic cases after the first two weeks. In the acute case, air studies may be dangerous. Such patients may have marked swelling of the brain and additional pressure caused by the injected air may be injurious. In order to have adequate air studies, sufficient air has to be introduced in the ventricular system of cavities. This is possible in patients who have survived the early effects of the injury for three or four days, but, in those who are injured ten to twenty hours earlier, ventriculography may be fatal (Figs. 10-12).

Angiography (Figs. 13 and 14) with the patient under local anesthesia is of value in

Figure 9. Air encephalogram in a patient with a left parietal epidural hematoma.

Figure 10. Air encephalogram in a patient with a right subacute subdural hematoma. Note the relative absence of subarachnoid pathways on the right side.

the contrast medium of choice.

Multiple exploratory trephinations are often unsatisfactory in many patients. Some surgeons feel that one may survey the intra-

help in patients with hyperosmolarity caused by hypothalamic or frontobasilar brain involvement. A kidney shutdown syndrome associated with extensive injury to other parts of the body should be carefully evaluated and the patient's fluid intake should be restricted during this period of kidney dysfunction. In patients with severe head injury, the importance of proper blood matching when a transfusion is required cannot be overemphasized.

Specific measures. The use of certain drugs may be worth while to combat the effects of injury and prevent infection as well as for analgesia and sedation. Intravenous administration of hypertonic solutions and lumbar puncture for controlling cerebrospinal fluid pressure and brain swelling may be indicated.

Among the drugs used recently to help control the effects of a head injury are caffeine sodium benzoate, atropine, urea compounds and cortisone. Caffeine sodium benzoate was first suggested by Foster Kennedy and his associates as an agent to relieve increased intracranial pressure. The efficacy of this drug has not been widely accepted and its value as an agent to relieve brain swelling has not been definitely proved. Atropine, in doses of 1/10 grain for the adult, has been used by Ward, who obtained excellent results in some severely injured patients with closed head injuries. The dosage is repeated every six hours for two or three days. Atropine—a *parasympathetic paralyzing agent*—may counteract acetylcholine liberated in the cerebrospinal fluid in the patient with a serious head injury. In our experience, its use has not been of particular value.

Cortisone, given in descending doses for a period of three to five days, has been employed by us with beneficial effects upon some of the patients. The stress of the injury may be in part responsible for the patient's serious condition and for such patients the use of cortisone has seemed valuable. In some instances, moribund patients have improved spectacularly. Patients unconscious for several days and proved not to have an intracranial mass lesion have seemed to become ambulatory sooner with the use of this drug than would otherwise be anticipated. However, cortisone, or any drug, should be discriminately employed. One must not overlook the presence of a mass lesion in the cranial cavity when utilizing drug therapy.

The drugs used to prevent infection in the cranial cavity or to control infection include the sulfonamides and antibiotics. In patients with open wounds of the head, these agents

are given freely before and after operation. In patients who have cerebrospinal fluid otorrhea or rhinorrhea and bleeding from the ear, these drugs should be employed routinely. Undoubtedly the occurrence of meningitis may be prevented by their use. When meningitis is manifest, the cerebrospinal fluid should be carefully studied for the organisms responsible and adequate doses should be administered of the drugs to which these organisms are sensitive.

The restless patient may be made comfortable with provision for good hygiene—a clean, dry bed, care of the distended bladder and attention to the bowels. By such measures restlessness may be reduced and the need for sedatives and narcotics minimized. A tracheotomy and clean respiratory passages relieve a patient's distress in breathing and promote comfort and rest. However, patients who fail to obtain satisfactory relief through these measures may need sedatives. Sedatives in head injury patients should be used with care. Morphine should not be employed except in patients with long bone fractures and excessive pain and only a mild craniocerebral injury. Codeine and phenobarbital given by mouth or intramuscularly have been found adequate to allay restlessness in most patients with head injuries. These drugs do not influence the conscious state or localizing signs in a dynamic lesion as does morphine.

The use of hypertonic solutions was in vogue for many years but at the present time is seldom practiced. Weed and McKibben were able to show a definite lowering of the cerebrospinal fluid pressure following intravenous administration of sodium chloride. Fifty per cent glucose solution was used by Peet as an agent to decrease intracranial pressure. Following the reports of these men, many others have recorded their results through the use of hypertonic solutions. Browder and his associates, and Webster and Freeman have shown that glucose administration results in a temporary decrease in the cerebrospinal fluid pressure followed by an increase which frequently surpasses the initial pressure. During our study of the effects of hypertonic solutions, it was noted that the seriously injured patient showed improvement as the pressure dropped but became restless and stuporous again as the cerebrospinal fluid pressure rose. In the majority of clinics today, hypertonic solutions are used sparingly.

Recently, experimental and clinical studies have indicated that the intravenous administration of 30 gm. of urea dissolved in 300

head. The rationale for the treatment is to prevent the introduction of infection into the cranial cavity. In the remaining 15 to 20 per cent, exploration is undertaken mainly for intracranial mass lesions.

Indications for operative intervention are clear cut in open wounds of the head. As soon as the patient's condition permits, the wound is debrided and repair is carefully made. In closed depressions, the degree and area of the depression must be considered and the advisability of surgical treatment determined. The majority of patients with simple depressions should be operated upon except for those having slight depressions in the frontal area and small, simple depressions over the midline and the large venous sinuses.

Exploration for an intracranial hemorrhage is indicated when there is a deteriorating conscious state and when there are progressive focal localizing signs indicating a mass lesion.

Treatment. The conservative management of craniocerebral injuries is determined by the degree of the injury. Patients with minimal injuries are treated by observation in the hospital for two or three days. They are seen later in follow-up from time to time, since among this group a few will develop a subdural hematoma or subdural accumulation of cerebrospinal fluid. The patients with moderately severe injuries usually show improvement over a period of several hours to several days. These patients deserve careful neurologic observation during their stay in the hospital for the development of complications requiring surgical intervention. After the repair of small scalp lacerations, the patient is made comfortable with mild sedation and is placed in semi-Fowler's position in bed. The request is made for periodic observation of the pulse, blood pressure, respirations and temperature.

The patient with a serious injury deserves continuous attention. Many of these patients on entrance to the hospital have no need for surgical treatment. A few among them are moribund and a fatal outcome is evident. On the other hand, some patients in this group appearing near death may be resuscitated. Every effort should be made to accomplish this. Such patients may remain desperately sick for several days and their management involves meticulous nursing care. This includes keeping the air passages patent and clear, preventing the aspiration of vomitus, adequate fluid and food intake, temperature control, turning, bladder care and providing rest and comfort.

If there is continued respiratory distress, tracheotomy is imperative. This is usually done at the bedside and may be carried out with dispatch. Such a patient also should have a Levin tube passed into the stomach and the stomach contents removed to avoid aspiration during vomiting. The largest size tube should be used for tracheotomy intubation.

Frequent toilet of the upper respiratory passages by suction is essential. This is more important than the use of oxygen. The latter may be administered through a small catheter extending into the tracheotomy tube. Large tubes should not be placed in the tracheotomy tube because this reduces the airway and consequently makes breathing more difficult.

A small nasal tube passed into the stomach may be used for feeding the patient. The adult may be given 2000 calories of nutrient in 2500 cc. of fluid per day and proportional amounts may be used for the younger patient.

A high temperature may quickly follow a cerebral injury, without sufficient evidence of infection to account for it. In these patients, the use of an automatically regulated blanket to reduce the temperature is valuable. The production of a hypothermic state of from 31 to 35° C. in these patients with damage to the central temperature control mechanism in the brain stem has been helpful.

In the patient who remains unconscious for several days, determination should be made of the output of sodium and nitrogenous products in the urine and of the levels of urea nitrogen, sodium, potassium and chlorides in the blood plasma. These values should be checked frequently in order to detect the development of a metabolic disorder of central origin. Such an abnormality may be more common than is suspected. If depletion states are noted, these should be adjusted over a period of several days by intravenous administration of adequate amounts of solutions. If a state of hyperosmolarity is noted, careful evaluation of the kidney function as well as the composition of the patient's feeding should be made. One may find that the patient is on a diet too high in protein which is resulting in derangement of kidney function not only for the protein, but also for sodium, thus causing hyperosmolarity of the blood. Lowering of the protein intake and administration of adequate amounts of carbohydrates and fats may suffice to correct the condition. Mercurial diuretics and forced fluids may be of

thin cortex if the clot is mostly fluid. When the clot is mostly solid, an adequate bone flap, uncapping of the clot by suction and removal are indicated.

The Central and Peripheral Nervous Systems

By BRONSON S. RAY, M.D.

BRONSON SANDS RAY is an Indianian whose father is also a doctor. He graduated from Franklin College in Indiana and from Northwestern University Medical School. He received his surgical training in Chicago and at the Peter Bent Brigham Hospital in Boston. He has spent his professional life in neurologic surgery at Cornell University Medical School.

Cerebrum and Cerebellum

The surgical treatment of diseases of the brain has become an important specialty within this century. The contributing factors have been acceleration in the acquisition of knowledge of functions of the nervous system, classification of the pathologic characteristics of neoplasms, development of diagnostic methods, and the application of the

increasing improvements in surgical technique, in anesthesia and in supportive care of the patient.

INTRACRANIAL TUMORS

Although tumors constitute only one of the numerous intracranial diseases requiring surgery, they have commanded the principal

cc. of invert sugar produces a significant and well-sustained decrease in intracranial pressure which is elevated following injury or the presence of space-occupying lesions.

The therapeutic value of lumbar puncture is questionable. Amelioration both by lowering the cerebrospinal fluid pressure and removing the bloody fluid is doubtful. Lumbar puncture will lower the cerebrospinal fluid pressure, in some patients with localized areas of swelling of the brain, this may be beneficial. We have seen patients with aphasia recover their ability to speak soon after a lumbar puncture was made and unconscious patients immediately improve, but such instances are rare. Sudden deaths have also been observed immediately following a lumbar puncture, mainly in children. In patients with dynamic lesions, such as epidural and subdural hematomas, the use of lumbar puncture is contraindicated. The hydrodynamics in the cranial cavity may be upset by lumbar puncture and hemorrhage will increase. False impressions as to conditions prevailing in the cranial cavity may be obtained. When a lumbar puncture is done, it is best not to lower the pressure too rapidly. A good rule to follow is to bring the pressure down to three-fourths of its original level, even though this may involve removal of a variable quantity of cerebrospinal fluid and three-fourths of the original level may still be a high level of pressure. Incisural herniation in the presence of a mass lesion may be precipitated by a lumbar puncture.

The cautious use of a diagnostic lumbar puncture at any time in the course of the treatment of a patient with head injury is indicated. When infection is suspected, lumbar puncture should be done with dispatch to determine whether evidences of infection exist in the cerebrospinal fluid. In some instances, intrathecal medication may be advisable.

Operative management. The operative treatment of patients with head injury includes the management of simple and open depressions, of penetrating wounds and of patent cranionasal and cranioaural communications manifested by cerebrospinal fluid discharge through these paths and/or pneumocephalus due to the introduction of air through the same pathways. Repeated meningitic infection after head injury may indicate the presence of a patent cranionasal fistula.

In patients with depressions, the possibility of involvement of large venous sinuses

should be considered. A torn sinus is repaired either by the use of mattress sutures or the application of Gelfoam, which is held in place over the tear in the sinus by bridging stitches. Occasionally repair by a vein graft may be indicated. Venous sinus injuries are more frequently seen in penetrating wounds of war than in civilian casualties. When torn, the lateral sinus may be doubly ligated. The anterior third of the sagittal sinus, if torn, may also be doubly ligated. The posterior two-thirds of the sagittal sinus and confluence of sinuses must be repaired to maintain the continuity of blood flow.

In the repair of a cranionasal fistula or a cranioaural fistula the use of a fascial transplant is desirable. A complete watertight closure of the area of fistulous communication must be accomplished. Patients having repeated meningitis following a head injury should have an adequate exposure of the area of fistulous communication for repair. Closure may be made with either mattress sutures or a fascial transplant. When extensively torn areas are exposed, a piece of fascia lata, obtained from the thigh, may be sutured as a graft inside the dural opening. The use of muscle stamps or Gelfoam should not be depended upon when closure by suture or a graft can be effected. The opening in the bone may be closed with a methylmethacrylate prosthesis.

In the management of the patient with an epidural hematoma, an adequate craniotomy opening should be made over the clot, the clot removed and the dead space between the dura and the bone should be obliterated. For a patient with a posterior fossa epidural hematoma, exploration in the vicinity of an occipital fracture may be followed by enlarging this opening to an adequate size for removal of the clot.

In a patient having a subdural hematoma (acute, subacute and chronic) the use of multiple trephine openings to drain and counterdrain a liquid clot is frequently successful. When the clotted material is solid, a small bone flap is indicated. Bilateral explorations should always be carried out. Subdural accumulation of cerebrospinal fluid is best treated by trephine openings on the affected side. Such collections are often bilateral.

Intracerebral hematomas may be identified through a trephine opening. They may be drained through a larger craniotomy opening after the area of hemorrhage is uncapped by applying suction to the overlying

tracranial tumors, is indicated in Table 2 compiled from a survey for a twenty-two year period at the New York Hospital. The figures are similar to those of compilations from numerous other clinics, the slight differences reflecting some particular circumstance which may have attracted more of one type of case to one clinic than another. For example, pituitary adenomas had a high incidence of 17.8 per cent in Cushing's series because of his interest in the pituitary gland, whereas in the series reported here there is a disproportionately high percentage of metastatic tumors because of the proximity of an affiliated neurosurgical service in a hospital for cancer. The variation in the relative frequency of types of glioma in different series, particularly between glioblastoma and astrocytoma and astroblastoma, reflects the different attitudes of pathologists in regard to these tumors.

CLINICAL SYNDROMES OF INTRACRANIAL TUMORS

There are certain general effects to be expected from the presence of a tumor in or on the brain without regard to the pathologic type, yet there are distinct clinical aspects and characteristics in behavior that individualize most types of brain tumor. In addition, there are different clinical syndromes which result from the presence of tumors in various areas of the brain. In children, the majority of tumors occur beneath the tentorium in the cerebellum and brain stem, and some types of these tumors do not occur in persons of older age. The converse is true in adults, who more commonly have supratentorial tumors, many of which are meningiomas not seen in children. Symptoms indicative of pressure on the optic nerves and chiasm are likely in children to be due to craniopharyngioma, while in adults they are usually due to a pituitary adenoma.

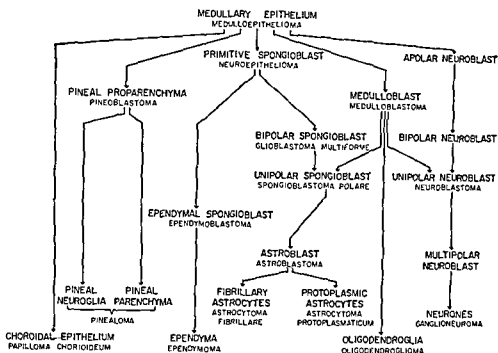

The manifestations of an intracranial tumor fall into two classes: those resulting from increased intracranial pressure and those caused by irritative or destructive effects on specific regions of the brain. While it is advantageous to recognize the presence of a tumor before papilledema and significant increase in intracranial pressure develop, tumors in so-called silent areas of the brain and those which block the cerebrospinal fluid pathways may cause only increased intracranial pressure. Supratentorial tumors, by displacing the cerebral hemispheres, may produce herniation of the temporal lobes through the tentorium, resulting in a variety

of effects including compression of the mesencephalon, narrowing of the aqueduct of Sylvius and occlusion of local blood vessels, any one of which effects may lead rapidly to serious and irreversible damage to the brain, particularly coma and the decerebrate state. Infratentorial tumors, in addition to producing direct pressure on the medulla, may cause herniation of the cerebellum into the foramen magnum and additional medullary compression with signs of vascular and particularly of respiratory failure.

As intracranial pressure increases, and before the more dire effects develop, there are frequently symptoms of *headache*, *vomiting*, *falling visual acuity* and *diplopia*, though all of these may not occur. *Headache* rarely has value in localizing an intracranial tumor, exceptions being the occasional lateralization to one side of the head over a supratentorial tumor and localized suboccipital pain with a tumor of the posterior cranial fossa. In about 15 per cent of the patients having increased pressure, there is no headache at all and, when present, headache is rarely of severe degree, if it does become an excruciating pain there is imminent danger. *Vomiting* may at times be secondary to the pain, but more often it is due to irritation of vagal centers in the medulla. Eversion, straining or sudden change in position by further altering the intracranial pressure may enhance the headache or lead to sudden and forceful vomiting. Matutinal vomiting on rising from bed is a common manifestation of posterior fossa tumors, particularly in children.

Some degree of *blurring in vision* is a very common accompaniment of papilledema which occurs with increased intracranial pressure, though significant loss of acuity is slow to develop. This characteristic is of value when a differential diagnosis must be made between papilledema and optic neuritis, since in the latter there is rapid loss of visual acuity. *Diplopia*, which sometimes accompanies increased intracranial pressure, results from compression of an abducens nerve, occasionally both abducens nerves, and before a gross squint can be recognized the patient is aware of duplication of objects on the horizontal plane.

The features which make for precise localization of a brain tumor are those that have to do with motor and sensory functions. The development in a local area of the body of a change in muscle function, such as convulsive movements, weakness, rigidity, incoordination, adventitious movements and re-

effort in the development of intracranial surgery and continue to present many unsolved problems. Intracranial tumors are relatively uncommon but are not to be regarded as rare. In one large clinic, a survey showed that 7 per cent of all neoplasms removed surgically were located intracranially. In the same survey, the incidence of carcinoma of the stomach and of the rectum was about 10 per cent, of the colon about 9.5 per cent and of the female breast nearly 10 per cent. Although intracranial tumors occur less frequently in infancy and in youth than at other times, no age group is spared. The greatest incidence occurs in individuals between the ages of thirty and fifty years. The sexes are equally affected and, as far as is known, there is no racial variation.

PATHOLOGIC CLASSIFICATION OF INTRACRANIAL TUMORS

Intracranial tumors may be secondary, occurring by metastasis from malignant lesions elsewhere in the body, or they may be primary, in which case they are derived from the brain itself or some of the other intracranial structures such as blood vessels, cranial nerves, the meninges or the hypophysis. The commonest tumors, the *gliomas*, arise from the neuroglia, or supporting tissue of the brain, and make up nearly half of all primary brain tumors. The gliomas are subclassified according to the resemblance of

the predominating cells to the various embryonal or adult cells in the brain; the more anaplastic the cells, the more malignant the tumor. The classification of gliomas proposed by Bailey and Cushing and based on the histogenesis of the brain (Fig. 15) has been almost universally employed, other classifications have usually been modifications. A more recent classification proposed by Kernohan, Mabon, Svien and Adson is based on the idea that gliomas arise from adult cells still capable of proliferation by a process of dedifferentiation, or anaplasia. These authors suggest that the commonly used names, polar spongioblastoma, astroblastoma and glioblastoma multiforme, be replaced by a gradation of malignancy using the name astrocytoma, grade 1 to 4, grade 1 being the least malignant and grade 4 the most. This has the appeal of simplicity, yet the histogenic classification has the advantage of long use and familiarity.

While the gliomas tend to infiltrate the brain, the next commonest intracranial tumors are the *meningiomas* which arise from the meninges and displace rather than invade the brain. The same obtains in most of the other tumors such as the *neurinomas* arising from nerve sheaths, the *hypophyseal adenomas*, the *congenital tumors* which arise from developmental defects and the *blood vessel tumors*.

The frequency of the different

tracranial tumors, is indicated in Table 2 compiled from a survey for a twenty-two year period at the New York Hospital. The figures are similar to those of compilations from numerous other clinics, the slight differences reflecting some particular circumstance which may have attracted more of one type of case to one clinic than another. For example, pituitary adenomas had a high incidence of 17.8 per cent in Cushing's series because of his interest in the pituitary gland, whereas in the series reported here there is a disproportionately high percentage of metastatic tumors because of the proximity of an affiliated neurosurgical service in a hospital for cancer. The variation in the relative frequency of types of glioma in different series, particularly between glioblastoma and astrocytoma and astroblastoma, reflects the different attitudes of pathologists in regard to these tumors.

CLINICAL SYNDROMES OF INTRACRANIAL TUMORS

There are certain general effects to be expected from the presence of a tumor in or on the brain without regard to the pathologic type, yet there are distinct clinical aspects and characteristics in behavior that individualize most types of brain tumor. In addition, there are different clinical syndromes which result from the presence of tumors in various areas of the brain. In children, the majority of tumors occur beneath the tentorium in the cerebellum and brain stem, and some types of these tumors do not occur in persons of older age. The converse is true in adults, who more commonly have supratentorial tumors, many of which are meningiomas not seen in children. Symptoms indicative of pressure on the optic nerves and chiasm are likely in children to be due to craniopharyngioma, while in adults they are usually due to a pituitary adenoma.

The manifestations of an intracranial tumor fall into two classes: those resulting from increased intracranial pressure and those caused by irritative or destructive effects on specific regions of the brain. While it is advantageous to recognize the presence of a tumor before papilledema and significant increase in intracranial pressure develop, tumors in so-called silent areas of the brain and those which block the cerebrospinal fluid pathways may cause only increased intracranial pressure. Supratentorial tumors, by displacing the cerebral hemispheres, may produce herniation of the temporal lobes through the tentorium, resulting in a variety

of effects including compression of the mesencephalon, narrowing of the aqueduct of Sylvius and occlusion of local blood vessels, any one of which effects may lead rapidly to serious and irreversible damage to the brain, particularly coma and the decerebrate state. Infratentorial tumors, in addition to producing direct pressure on the medulla, may cause herniation of the cerebellum into the foramen magnum and additional medullary compression with signs of vascular and particularly of respiratory failure.

As intracranial pressure increases, and before the more dire effects develop, there are frequently symptoms of *headache, vomiting, failing visual acuity and diplopia*, though all of these may not occur. *Headache* rarely has value in localizing an intracranial tumor, exceptions being the occasional lateralization to one side of the head over a supratentorial tumor and localized suboccipital pain with a tumor of the posterior cranial fossa. In about 15 per cent of the patients having increased pressure, there is no headache at all and, when present, headache is rarely of severe degree; if it does become an excruciating pain there is imminent danger. *Vomiting* may at times be secondary to the pain, but more often it is due to irritation of vagal centers in the medulla. Exertion, straining or sudden change in position by further altering the intracranial pressure may enhance the headache or lead to sudden and forceful vomiting. Matutinal vomiting on rising from bed is a common manifestation of posterior fossa tumors, particularly in children.

Some degree of *blurring in vision* is a very common accompaniment of papilledema which occurs with increased intracranial pressure, though significant loss of acuity is slow to develop. This characteristic is of value when a differential diagnosis must be made between papilledema and optic neuritis, since in the latter there is rapid loss of visual acuity. *Diplopia*, which sometimes accompanies increased intracranial pressure, results from compression of an abducens nerve, occasionally both abducens nerves, and before a gross squint can be recognized the patient is aware of duplication of objects on the horizontal plane.

The features which make for precise localization of a brain tumor are those that have to do with motor and sensory functions. The development in a local area of the body of a change in muscle function, such as convulsive movements, weakness, rigidity, incoordination, adventitious movements and re-

flex changes, indicates involvement of motor areas of the brain, the cortex, the tracts or certain cranial nerves. If there are aberrations or defects in smell, vision, hearing or of the various tactile senses, these too may point to the involvement of specific structures of the brain. Exceptions sometimes exist because of the remote effects of altered intracranial pressure, as exemplified by hemiparesis, or even a lateralized fit which may occur with a tumor that occupies a region of the cerebrum removed from the motor cortex and tracts. But the localizing value of certain sensory disturbances is highly reliable. For example, an uncinate fit in which the patient experiences fleeting episodes of unpleasant odors occurs only when the uncus in one of the temporal lobes is directly affected by tumor; loss of discriminatory and position sense in an extremity, with preservation of other forms of sensation, indicates direct involvement of the post-rolandic sensory cortex or its immediate sub-cortical connections, and a homonymous hemianopic visual field defect results only from direct involvement of the contralateral visual pathway.

Disturbances in speech are of two types: those which are related to expression and those related to reception, though rarely, if at all, does one type exist without some degree of the other. Aphasia of any degree or type indicates that the tumor lies above the tentorium in the temporal lobe or in an immediately adjacent region. The early manifestations of aphasia are easily mistaken for psychotic changes, but aphasia is a defect in language and allied functions and is not related to mood or behavior.

Convulsions, when associated with intracranial tumors, indicate that the tumor lies above the tentorium, no fits result from tumors in the posterior fossa, with the possible exception of their rare occurrence in a patient with a tendency to convulsions who develops increased intracranial pressure from a posterior fossa tumor. Patients with posterior fossa tumors may develop episodes of rigid hyperextension, sometimes spoken of as cerebellar fits, but which are really manifestations of a decerebrate state and have a serious implication. Fits, usually with focal qualities and more often diurnal than nocturnal, are a fair accompaniment on accom-

paniment of cerebral tumors. They occur in about 45 per cent of all patients with supratentorial tumors, but particularly in those with the more benign types of glioma (about 90 per cent with oligodendrogliomas) or with meningiomas with which there is an incidence of fits of about 65 per cent. Convulsions may be the only manifestation for months of a slowly growing tumor and an adult who develops them for the first time in life should be suspected of having a tumor.

Evaluation of visual symptoms and of fundusoscopic, pupillary and extraocular signs is of very great importance. Reduction in visual acuity, when accompanied by primary optic atrophy rather than by papilledema or its late effects, secondary atrophy, is usually the result of involvement of the optic nerves or chiasm by tumor. Perimetry can be particularly helpful and although careful testing on a tangent screen is desirable, often much can be learned by confrontation testing with fingers in the initial examination. A defect in the visual field of one eye indicates involvement of the nerve on that side. Bitemporal field defects indicate a chiasmal lesion, chiasmal syndrome, while homonymous field defects, as mentioned heretofore, invariably indicate a lesion in the contralateral visual pathway somewhere between the chiasm and the calcarine area of the occipital lobe.

Diplopia, with duplication of objects on a diagonal plane, results from palsy of the third or fourth cranial nerve or of a lesion in the tegmentum in the midbrain. This is in contradistinction to diplopia with horizontal duplication due to abducens palsy. Third cranial nerve palsy should be evidenced by an enlarged pupil and drooping eyelid on one side, if not also by discernible defects in movements of the involved eye except in lateral deviation. An enlarged pupil due to incomplete oculomotor nerve palsy occurs particularly on the side of rapidly developing tumors of the temporal lobe, causing shift of the brain stem and compression of the nerve.

Impairment in upward gaze results from a lesion of the quadrigeminal plate or adjacent regions of the midbrain and is nearly pathognomonic of a tumor in this region. Defects in horizontal movements of the eyes, with preservation of vertical movements, result from a lesion slightly lower in the brain stem and are seen almost exclusively accompanying gliomas of the brain stem. Nystagmus does not result from a supratento-

rial tumor but is primarily the result of a disturbance in the vestibular system and linked with tumors in the posterior cranial fossa.

TUMOR SYNDROMES

The foregoing discussions may be summarized in brief descriptions of some of the syndromes based on the pathologic characteristics of individual tumors, and the symptoms and signs which they are likely to produce because of their predilection for certain locations in the brain.

Tumors of the Cerebral Hemispheres. The commonest tumors of the cerebral hemispheres are *gliomas*, and unfortunately glioblastoma, which thus far has been incurable, outnumbers all others. Astrocytoma, which is a more benign growth and sometimes curable, occurs about half as frequently, while oligodendroglioma, the rarest of these three, is the most slowly growing and most benign. All these tumors occur with about equal frequency in the several lobes of the hemispheres with the exception of the occipital, where there is a relatively low incidence of all types of tumor.

Meningiomas, which affect the brain by compression and not by invasion, occur principally above the tentorium and with about one-third the frequency of gliomas. They are regarded as usually benign, encapsulated and surgically removable, though their location, size and vascularity sometimes may defeat attempts at radical removal. They tend to originate from regions where arachnoid villi are clustered and thus are found along the sagittal sinus, "parasagittal" and "falc" tumors, and along the course of meningeal vessels, where they compress the superior surface of the hemisphere and are sometimes referred to as convexity tumors. Other common locations are along the sphenoid ridges and the floor of the frontal fossae, particularly in the olfactory grooves, and on the tuberculum sellae. Those on the sphenoid ridge affect the temporal lobe and adjacent portions of the frontal and parietal lobes. Those in the olfactory groove encroach on the inferior surfaces of one or both frontal lobes and destroy the olfactory and optic nerves. The syndrome described by Kennedy of anosmia and visual loss on one side, with homolateral primary optic atrophy and contralateral papilledema, is pathognomonic of the olfactory groove meningioma. Tumors of the tuberculum sellae may cause compression of the optic nerves and chiasm in the early period of their

growth and can be detected by the pattern of visual changes, though sometimes they attain great size and displace the frontal lobes before vision is affected.

Frontal lobe tumors, which invade or compress the brain, cause subtle changes at first and later more pronounced alteration in personality, loss of interest, irritability, impaired judgment and memory and an attitude of facetiousness. Forced grasping can often be demonstrated and if the lesion encroaches on the prerolandic area, there may be convulsions or progressive corticospinal tract signs, lesions on the left side may also cause aphasia, particularly of the anomalous type.

Parietal lobe tumors cause striking motor and sensory changes on the contralateral side of the body. Jacksonian convulsions are a frequent manifestation, particularly in the early phase of the disease, while in later stages there is increasing hemiparesis. Involvement of the sensory cortex results in contralateral astereognosis and loss of discriminatory sense and lessens the degree of spasticity in hemiparesis. On the dominant side, parietal lobe lesions also produce aphasic defects, especially of the receptive type.

Temporal lobe tumors may be relatively "silent" and attain considerable size before detection, particularly if they occur on the nondominant side, but when they are on the dominant side aphasia is to be expected. Deep lesions involve a part of the optic radiation, sometimes causing visual hallucinations of bizarre forms and usually causing contralateral homonymous upper quadrant-anopsia of incongruous type. Uncinate fits, feelings of *déjà vu* and psychomotor seizures are inconstant effects of temporal lobe lesions, but, when present, they are diagnostically important.

Occipital lobe tumors in particular cause visual hallucinations of light and homonymous hemianopsia of congruous type, often without other localizing signs. If the lesion involves the lateral convexity of the lobe on the dominant side, there may be difficulty in reading ability (alexia) and inability to recognize objects by sight (visual agnosia).

Tumors of the Cerebellum. The common brain tumor of childhood is the benign cerebellar astrocytoma which has its peak in age distribution at twelve years and is rarely seen in persons older than twenty years. The results of surgical treatment are excellent, which makes it all the more desirable to reach a diagnosis before irreversible changes occur. The symptoms are those of gradual

increase in intracranial pressure accompanied by ataxic movements, dysmetria and hypotonia; nystagmus is an inconstant finding. Particularly in younger children, the significance of unexplained vomiting, the development of a squint from abducens palsy and the moderate enlargement of the head due to gradual growth of the tumor may go unrecognized for months.

The next most common tumor of childhood is the malignant cerebellar medulloblastoma. It produces much the same pressure effects and cerebellar disturbances as does astrocytoma, but the development of symptoms is more rapid and the peak age of occurrence is several years earlier. Even so, it is usually impossible to be sure of the differential diagnosis without operation. The medulloblastoma, as with few other primary intracranial tumors, tends to spread along the cerebrospinal fluid pathways and occasionally the tumor will give evidence of its presence in the lower spinal canal before cerebellar signs develop. The tumor is highly sensitive to x-ray treatment, sometimes for a number of years, but radiotherapy should not be employed without first identifying the tumor and performing surgical decompression.

Other tumors of the cerebellum of less frequency, though not rare, are *ependymomas*, the *papillomas of the choroid plexus* and *hemangioblastomas*. These may occur at any age, but the first two are more common in early life, while the last is the benign cerebellar tumor of adults. A differential diagnosis on the basis of neurologic signs is not usually possible, though there are a few special features which are helpful. Ependymoma and papilloma tend to become firmly attached to the floor of the fourth ventricle and at times produce facial palsy as a result of invasion of one or both facial nuclei. Because of this firm attachment, it is usually impossible to perform complete surgical excision. Ependymoma, like medulloblastoma, may seed itself along the fluid pathways and this tumor also has a tendency to bleed spontaneously, causing the symptoms of acute subarachnoid hemorrhage. Hemangioblastoma, which has a high rate of surgical cure, may produce any or all of the signs of a cerebellar tumor. But more especially, it should be recognized that this tumor may be accompanied by true polycythemia, is sometimes familial and may be associated with hemangiomatosis elsewhere in the body, most particularly in the retina, in which case the combination of

retinal and cerebellar tumor is referred to as von Hippel-Lindau's disease.

Tumors of the Brain Stem. Tumors of the brain stem are gliomas, usually relatively benign, such as *spongioblastoma polare* or *astrocytoma*, but because of their location are not amenable to surgery and can be controlled only for a while with radiotherapy. The pons is much more frequently involved than the medulla and the age of incidence is principally in childhood, occasionally in young adulthood.

The characteristic of these tumors is that they produce cranial nerve palsies usually for some time before long tract signs or increased intracranial pressure appears. It is remarkable that in many cases the aqueduct and fourth ventricle though narrowed are not occluded, and papilledema never develops. Among the various cranial nerve palsies commonly seen are extraocular palsies, vomiting, dysphagia, dysphonia and facial monoplegia or diplegia, but other cranial nerve palsies may occur. Nystagmus and ataxia in the extremities are also common.

Tumors of the Third Ventricle. Neoplasms of the third ventricle, for practical purposes, can be divided into anteriorly and posteriorly placed lesions. The *pinealoma* typifies the latter and characteristically produces increased intracranial pressure by blockade of the ventricle or aqueduct, impairment in conjugate movement of the eyes above the horizontal plane and a variety of pupillary reactions. These tumors are not suited to surgical removal, but some type of ventricular shunt is useful to overcome the ventricular block and some of the several types of tumor which occur in or about the pineal gland can be controlled by radiotherapy.

The *colloid cyst*, a benign and curable tumor, occurs in the anterior third ventricle and is so located that it blocks the foramina of Monro, thus causing dilatation of the lateral ventricles and increased intracranial pressure. Except for symptoms and signs resulting from the altered pressure, there are no other manifestations. Other tumors, such as gliomas, craniopharyngioma and ectopic pinealoma, sometimes encroach on the anterior third ventricle and are likely to cause hypothalamic disturbances characterized by diabetes insipidus, diencephalic epilepsy, somnolence, obesity and precocious sexual development.

Tumors of the Cerebellopontile Angle. T. produced by tumors in the

cerebellopontile angle deserves special mention because its recognition can be relied on to identify the presence of the *acoustic neurinoma* which is surgically curable. Other tumors which may occur in this region are *meningioma* and *cholesteatoma*, the latter being particularly favorable to treatment.

Symptoms of acoustic neurinoma develop insidiously, beginning usually with unilateral tinnitus and progressive deafness. The vestibular response on the same side disappears early in the disease and there may be vertigo and instability in walking, but paroxysms of vertigo as occur in Meniere's disease are not encountered. After many months, involvement of the adjacent trigeminal and facial nerves becomes evident, the former being particularly identified by loss of corneal sensation even before other sensory loss in the face develops. Additional growth of the tumor may cause palsy of additional cranial nerves in the posterior fossa and also ventricular block, though the presence of the tumor can usually be recognized before it has advanced to this stage.

Tumors of the Sellar Region. Tumors of the sellar region can be separated into intrasellar tumors, which are almost exclusively *pituitary adenomas*, and suprasellar tumors, which include in order of frequency, *craniopharyngioma*
lum sellae

The tumory adulthood and arise from one of three types of cells which make up the anterior lobe of the gland. The commonest is the *chromophobe adenoma* derived from the indifferent cells. It produces hypopituitarism as a result of compression of the normal gland, enlarges ("balloons") the sella turcica and compresses the optic nerves and chiasm, causing visual field defects, usually bitemporal hemianopsia, loss of visual acuity and primary optic atrophy. The growth of these tumors may be held in check by x-ray therapy, but if there is any significant impairment of vision, surgical removal of the tumor should not be delayed, for it has a high degree of success.

The *chromophil adenoma* is derived from the eosinophil cells which are known to control growth. The presence of the tumor can be easily recognized by the appearance of gigantism during puberty, or of acromegaly after puberty. A relatively small percentage of these tumors enlarge enough to compress the optic nerves and chiasm.

Since the tumors are relatively sensitive to x-ray, this has usually been the treatment of choice. But since x-ray therapy cannot be

relied on always to control the tumor and the subtle persistent bodily changes it produces, surgical excision has come to be employed more often. The risk in the past of destroying normal pituitary functions by surgical removal of the tumor is no longer a hazard since the advent of ACTH and cortisone for substitution therapy.

The *basophil adenoma*, derived from basophil cells, is sometimes believed to be the cause of Cushing's syndrome. The tumor does not attain any significant size and thus far has been regarded as not suited to surgical removal, attention centering more particularly on the target gland, the adrenal.

In the suprasellar region, the *craniopharyngioma* is the commonest of the several tumors that may be found and may be difficult to differentiate from pituitary adenomas whose effects it mimics. However, craniopharyngioma is a congenital tumor and often produces symptoms before the patient is fifteen years of age. It has a tendency to cause diabetes insipidus, sometimes for transient or intermittent periods, and to show calcification on roentgenograms, findings which are unusual in pituitary adenomas. Meningiomas produce local hyperostosis of the tuberculum sellae and gliomas of the optic chiasm cause subchneoid erosion, sometimes with enlargement of the optic foramina, which can be identified on roentgenograms.

Metastatic Tumors. The most common source of metastatic tumor of the brain is the lung, but malignant tumors of the breast, kidney, gastrointestinal tract, nasopharynx and of many other tissues of the body may give rise to secondary growths in the brain. Metastases are more commonly found in the cerebral hemispheres and, in a surprising number of cases, there appears to be only one lesion in the brain. The progression of neurologic symptoms and signs is likely to be fairly rapid and may constitute the only complaints or discernible manifestation of the malignancy. The best that can be expected from surgical removal, which is often a simple operation, is prolongation of life and possibly some reversal of palsies and relief of headache. But to many patients and their families, this much is very much worth while.

DIAGNOSIS

It would be a serious mistake to assume that the diagnosis of tumors and other diseases of the brain could do without diligent clinical study since the combination of an

accurate history and thorough physical examination remains our most reliable method. Yet without the aid of numerous present-day adjuncts, the factor of error in identification and localization would be considerable.

Roentgenograms of the skull yield some type of positive information in about 30 per cent of brain tumors. The changes to be looked for are: (1) erosion of the sella turcica; (2) shift in position of the calcified pineal gland; (3) erosion of the internal table of the skull; (4) erosion of the foramina; (5) separation of cranial sutures in children; (6) thinning or destruction of the skull in adults and hyperostotic changes caused by meningiomas.

A roentgenogram of the chest should be obtained in every patient suspected of having an intracranial tumor because of the possibility of metastasis from lung cancer.

Lumbar puncture and withdrawal of spinal fluid cannot be performed without risk in the presence of increased intracranial pressure, though occasionally the risk is justified. The possibility that symptoms of brain tumor may become rapidly worse following withdrawal of spinal fluid emphasizes the need for omitting lumbar puncture or restricting its use to a time when craniotomy can be performed promptly if need be. Compression of jugular veins sometimes erroneously performed in conjunction with the puncture adds materially to the risk.

In addition to determination of the resting pressure of the cerebrospinal fluid, the other important determinations are the protein content of the fluid and the cell count. The protein content in the fluid is elevated in the majority of, but not in all, patients with brain tumor. The most consistent elevations occur with acoustic neurinomas and meningiomas which exist near the floor of the skull. Occasionally, glioblastomas which encroach on the ventricle or metastatic tumors will produce pleocytosis in the fluid. In some cases it is possible to identify the presence of neoplastic cells in centrifuged cerebrospinal fluid. In cases of extensive involvement of the meninges by tumor there may be significant decrease in the sugar content of the fluid. Recent studies of the

enzymes of the brain; transaminase is usually increased in the former and less often altered by tumors.

Electroencephalography is found to be

useful in identifying the presence and location of a brain tumor in from 50 to 75 per cent of cases, depending on the experience and diligence of the examiner. In particular, infratentorial and deep supratentorial tumors evade detection and often an abnormal

pattern due to vascular disease cannot be distinguished from that of a neoplasm. Even so, the electroencephalogram has value as an adjunct method of examination.

Radioactive isotopes have come to be employed in the identification of brain tumors,

terial for use in the control of more brisk bleeding from torn blood vessels in the brain or dura, Gelfoam and absorbable cellulose provide ready means of dealing with the general ooze of blood that can be such a nuisance to control.

The advent of antimicrobial agents has been a godsend in neurosurgery, for the risk of infection and death from meningitis is now virtually a thing of the past. In this regard it can be added that a tuberculoma can now be removed without the almost inevitable sequence of meningitis and death, thanks to the advent of streptomycin and other antituberculous drugs.

Three recent developments give promise of adding significantly to the facility and safety of operations. One of these is the production and maintenance of a hypotensive state during operation by means of a sympathetic blocking agent (Arfonad) which minimizes blood loss, reduces the bulk of the brain, has a complementary effect on anesthesia and yet does not expose the brain to anoxic effects which often occur when blood pressure falls because of blood loss.

A more recent development is the lowering of body temperature to a degree that reduces the metabolic requirements of the brain, thus making it possible to occlude the main blood supply to the brain safely for minutes at a time while dealing with a vascular lesion.

Another recent development has been the use of urea, usually administered intravenously, for reducing intracranial pressure through "shrinking" of the brain. It appears that this agent has advantages which will lead to its replacing all other chemical agents used heretofore for this purpose.

Radiation Therapy. There is little place for radiation therapy as a substitute for surgery in tumors of the brain. Gliomas of the brain stem cannot be excised and sometimes are dramatically improved for limited periods by radiation therapy. Pituitary adenomas which have not grown to a size to compress the optic nerves may benefit by x-radiation. Pinealomas and tumors not well suited to direct surgical attack will often show favorable effects from treatment.

As a supplement to partial removal of certain tumors, x-ray treatment is beneficial, but the results are difficult to evaluate and there is a wide diversity of opinion regarding its use. Some would limit its use postoperatively to a few tumors, such as medulloblastoma and pituitary adenomas, but, at one time or another, claim of benefit from x-ray

treatment has been made for nearly every type of intracranial neoplasm. Some of these claims are unjustified, but others undoubtedly represent the occasional observation of benefit and thereby emphasize the vagaries in the response of tumors to irradiation. It is sufficient to say that no brain tumor has ever been cured by x-radiation and the decision to employ treatment is usually dependent on a number of factors pertinent to the individual case.

Recently there has been renewed interest in the use of radiation therapy since the development of the high voltage machine (betatron rays), radioactive cobalt and the activation of boron injected intravenously by exposing the patient in the atomic pile. None of these methods of radiation therapy have shown results thus far which justify enthusiasm.

PSUEDOTUMOR AND ALLIED CONDITIONS

Pseudotumor is a term applied to a condition in which increased intracranial pressure develops without discoverable cause. The condition has also been labeled serous meningitis, otitic hydrocephalus, toxic hydrocephalus and arachnoiditis.

Clinically, most of the subjects have in common headache, papilledema, increased intracranial pressure by spinal measurement and occasionally diplopia, transient palsies and convulsions. The patient's feeling of well-being is out of keeping with the potentialities implied by the increased pressure. But for elevation of pressure the spinal fluid is normal, the electroencephalogram at times shows an abnormal pattern of nonspecific nature and the pneumoventriculogram, most important of all tests, shows a normal or perhaps, small-sized ventricular system.

Some of the patients have been found by sagittal sinus venography to have unsuspected thrombosis of the sagittal sinus or of a dominant lateral sinus. The condition is believed to have been present in many of the disorders designated as otitic hydrocephalus associated with mastoiditis and middle ear infections.

In a study of twenty-eight consecutive cases followed for one to five years, it was found that in six of the patients the nature of the illness was not evident until some months had passed, but within ten months it was determined that three patients had neoplasms, one had multiple sclerosis, another had periarthritis and one had an aneurysm of the basilar artery.

In ten of the twenty-eight patients venous

obstruction was conclusively demonstrated as the cause of the increased intracranial pressure. In the remaining twelve, no cause could be discovered. The fortunate thing is that most patients with venous obstruction or without any demonstrable disease tend to recover in a period of several months without visual loss or other sequelae. A few begin to lose vision and then it is desirable to resort to decompressive procedures, such as unilateral or bilateral subtemporal decompression. Repeated lumbar puncture is safe and may serve a useful purpose in diminishing the risk of visual loss.

In *arachnoiditis* there is unexplained thickening of the arachnoid membrane resulting in obstruction to the cerebrospinal fluid pathways. The effect is at times localized about the chiasmatic cistern, causing visual loss, and there are reports of dramatic return of vision after resection of the arachnoid and release of trapped fluid. When *arachnoiditis* occurs in the cisterna magna and lateral recesses of the posterior fossa there is ventricular obstruction and increased intracranial pressure. The condition is distinguished from pseudotumor by the fact that the ventricles tend to become dilated in *arachnoiditis*. Exposure of the cisterna magna by craniotomy and disruption of the arachnoid, together with suboccipital decompression, will usually terminate the increased intracranial pressure.

INTRACRANIAL ABSCESES (BRAIN ABSCESES)

Localized suppurative infection of the brain, once a relatively common and fearsome disease, has nearly become a rarity, principally because of the advent of antimicrobial therapy. Brain abscesses result from extension of infection in adjacent regions of the head or by metastasis from remote foci in the body. Adjacent sources include middle ear and mastoid, the nose and accessory nasal sinuses, the cranium and scalp and also compound fractures and penetrating wounds of the skull through which there is implantation of infected material. Of this group, middle ear infection is by far the commonest source in civilian practice. Metastatic abscesses originate principally from lesions in the chest and less frequently from endocarditis, osteomyelitis, abscessed teeth, carbuncles, septic endometritis and suppuration in any part of the body. Occasionally the source of a brain abscess cannot be determined, in which case it is as-

sumed that the infection started in a period of unrecognized bacteremia.

The abscesses which result from direct extension of an adjacent infection are usually solitary, while metastatic abscesses are often multiple. The infecting organisms most frequently found are *Staphylococcus pyogenes* var. *albus* and *aureus*, the hemolytic streptococci and the pneumococci. Other organisms as well as mixtures have also been found, their nature depending on the source of the contamination.

Pathology. Extension of infection to the brain from adjacent foci in the head may occur by one of two pathways or possibly at times by a combination of the two. The commonest is the successive infection of intervening structures, in which osteomyelitis or localized osteitis first develops, followed by the formation of an epidural abscess which penetrates the dura and invades the underlying brain, passing through the highly vascular cortex to lodge and take growth in the white matter. In the course of progression of the infection, the subdural or subarachnoid spaces may become contaminated, giving rise to a subdural abscess and leptomeningitis, respectively. A part of this process of extension undoubtedly entails thrombosis of local veins and arteries in the bone, meninges and brain and this serves to extend the infection as well as to make the tissues more susceptible by devitalization. Brain abscesses arising from frontal sinusitis thus come to occupy chiefly the frontal lobes, while those arising from the middle ear and mastoid occupy the temporal lobe or the cerebellum.

The other common mode of extension is by way of the veins draining the structures about the upper portion of the face and head toward the dural venous sinuses. By this means, retrograde thrombosis or septic emboli may carry the infection through tributary veins to any part of the brain, thus accounting for what have been called "distant abscesses." Occasionally, abscesses have resulted from implantation by an exploring brain needle which has passed through an infected area. The location of a metastatic abscess from a distant source of infection is purely fortuitous and in about two-thirds of the cases more than one abscess develops. When an abscess results from a penetrating wound, the inciting factors are pulped brain and blood clots, which provide a splendid medium for the growth of bacteria, plus retained bone fragments and foreign material.

which have carried in bacteria that are largely skin inhabitants of relatively low virulence. Shell fragments are not usually infective even when they are retained in the brain.

Irrespective, however, of what routes the infection takes to the brain, the local reaction which follows in the brain is always essentially the same. As the infection grows in the devitalized tissues, the clinical symptoms are those of encephalitis. After some days, an equilibrium is reached between the infection and the reaction of the surrounding brain. Regional blood vessels throw off a heavy exudation of leukocytes, constituting the first line of defense. Behind this wall the blood vessels increase in size and number and connective tissue cells proliferate, producing a wall, or capsule, for the abscess. From this time on, it is a struggle between the wall and the leukocytes on the one hand and the invading bacteria on the other. If a breakthrough occurs, there may result a secondary daughter abscess, spreading encephalitis, or rupture into the ventricles, the last two conditions being rapidly fatal.

While the wall of an abscess begins to form in the first week, it is not firm enough to offer appreciable resistance to an exploratory needle until at least two or three weeks have passed. In some types of infection of strong virulence, particularly in metastatic abscess of pulmonic origin, a wall may not develop and the clinical course is one of fatal, spreading encephalitis from the start.

If surgical evacuation of the abscess is instituted, the wall of the abscess will contract and form a scar. Rarely, an otogenic abscess has been known to discharge spontaneously into the external ear or mastoid wound. Occasionally spontaneous cures take place and some abscesses when drained are found to contain sterile pus. But in spite of apparent quiescence, reactivation of even a drained or sterile abscess may take place long after the process has been thought to have subsided.

Symptoms and Signs. The symptoms of a brain abscess vary with the stages of the disease, the virulence of the infection, the degree of increased intracranial pressure and the location of the abscess. Early in the clinical course it may be difficult to make an accurate diagnosis, even though it may be obvious that infection has reached the brain. Usually the temperature remains high for the first few days and then takes on a low, spiking contour. The blood leukocyte count may rise to 20,000 or more, but it too may

decline, and rarely the count is normal from the start or soon afterward. Examination of the spinal fluid discloses an increase of pressure, protein content and leukocytes, chiefly of lymphocytes, unless frank suppurative leptomeningitis occurs.

Headache and vomiting develop early and persist. Irritability, or apathy and lethargy reflect the development of encephalitis and increasing intracranial pressure. The neck becomes stiff as a result of the associated meningeal reaction and in time, as the pressure increases, the pulse rate, at first fast, becomes slow, and papilledema appears. These are the general symptoms and signs of the initial stage of the disease, representing the struggle between destructive and reparative forces. If the virulence of the infecting organism is great and the patient's resistance is poor, surgical drainage of the abscess may be useless and profound coma followed by respiratory failure may ensue.

In more favorable cases the infection becomes localized and a wall develops around the abscess. Signs of sepsis subside and fever and leukocytosis recede. Edema of the brain abates and all symptoms improve, with the possible exception of localizing symptoms, which will usually have made their appearance some time during the first week of the illness. The patient still appears apathetic and complains of headache, so that the clinical picture at this stage may be much like that of an intracranial neoplasm.

The symptoms may continue for months throughout the quiescent stage until the abscess is evacuated or the patient dies from rupture of the abscess into the ventricle or, as may rarely happen, the abscess resolves spontaneously.

Localizing signs depend upon the size and position of the abscess. The commonest sites for abscesses in the brain are, in the order of frequency, the frontal lobes, the temporal lobes and the cerebellar hemispheres. Less commonly, the parietal and occipital lobes and the brain stem are involved. Abscesses in the *frontal lobe* may attain considerable size and still remain relatively silent, yet it is unusual if there are not at least a few suggestive signs, such as alteration in mood, contralateral convulsions, muscle weakness or pathologic reflexes and possibly motor aphasia if the lesion is on the left. *Temporal lobe* abscesses give more striking signs of their presence, namely, homonymous hemianopic defects, paralysis, sensory impairment and pathologic reflexes on the contralateral side and palsy of the third and sixth

cranial nerves on the homolateral side. If the left temporal lobe is involved, aphasia is the earliest and most striking sign. Occasionally the acute displacement of the brain stem caused by a temporal lobe abscess may cause homolateral corticospinal tract signs due to pressure on the *crus cerebri* by the margin of the tentorium on the side opposite the abscess. Cerebellar abscesses produce the usual signs of cerebellar dysfunction, namely, dysmetria in the homolateral extremities, nystagmus and frequently pathologic reflexes on the opposite side of the body. It has occasionally been observed that the patient prefers to lie on the side of the lesion and that turning the head to the opposite side induces vertigo, vomiting and vigorous nystagmus. Another sign of apparently reliable localizing value, which has been observed in the occasional case of cerebellar abscess, is strong conjugate deviation of the eyes toward the opposite side from the lesion. This is in contradistinction to the occasional occurrence of deviation of the head and eyes toward the side of the lesion in abscesses of the frontal or parietal areas.

Diagnosis. In the initial stage, it may be difficult to differentiate a brain abscess from purulent pachymeningitis (subdural abscess) or leptomeningitis. The former is a much more fulminating infection than a brain abscess, though obviously difficulties arise if both exist, as may sometimes be the case. Leptomeningitis produces relatively more cellular changes in the spinal fluid and less striking localizing neurologic changes. Differentiation from a brain tumor, when the signs of infection are minimal or are overlooked, may be difficult and most neurosurgeons have had the experience of accidentally coming upon an abscess when exploring for a tumor. Thrombosis of the lateral venous sinus in association with otitic infections may produce general symptoms like those of the early stages of an abscess, but not localizing neurologic signs. The Tobey-Ayer test of jugular compression to determine lateral sinus thrombosis is potentially dangerous, because jugular compression during the performance of a lumbar puncture in the presence of a brain abscess may lead to medullary compression and rapid respiratory failure.

Electroencephalography, angiography and ventriculography, each has value in diagnosis, though often there is enough evidence of the presence and location of an abscess so that these adjuncts are not required.

Treatment. The treatment of a brain ab-

cess, except possibly when the brain stem is involved, is always surgical drainage. The history of the surgical treatment of brain abscesses is replete with a variety of methods and even now there is lack of unanimity of opinion regarding the preferable method of evacuation of certain types of abscess. In the early stages of formation of a brain abscess, hasty operations are usually futile. At this time, reliance must be placed on supportive measures and antibacterial therapy. The opportune time for operation is after the abscess has become walled off, at least two weeks after the onset, and before the patient's condition becomes critical or before irreparable damage to important brain centers has occurred.

Although complete extirpation of the intact abscess wall or evacuation of the abscess plus removal of its wall is the ideal treatment, it is not well suited to abscesses of the cerebellum, those deeply situated in the cerebrum or those occupying the Rolandic and speech areas. For abscesses located in these latter areas, simple drainage or repeated tapping, accompanied by local and systemic antimicrobial therapy, often proves to be effective treatment.

EXTRADURAL ABSCESS (PACHYMEINGITIS EXTERNA)

Localized suppurative infections between the dura and the cranium are usually the result of otitis media and mastoiditis, frontal sinusitis or osteomyelitis of the skull. The infection may travel by contiguity or by continuity via blood vessels, chiefly veins which drain toward the dural venous sinuses.

The degree of development of the inflammatory process varies between the formation of circumscribed granulation tissue and a thin deposit of fibrin, and the formation of a local collection of thick pus. Extensive lateral spread of the abscess is prevented by adhesion of the dura to the skull, and it is rare for an uncomplicated extradural abscess to assume proportions sufficient to cause intracranial pressure. Its importance lies wholly in the necessity for early recognition and drainage before the infection spreads to deeper structures. Occasionally infection in the petrous tip may result in an extradural abscess and Gradenigo's syndrome, which is characterized by symptoms of irritation of the trigeminal and abducens nerves, namely, diplopia and pain in the eye on the side of the lesion.

Early surgical drainage and sequestrectomy are usually followed by prompt re-

covery. Complications arise only when there is inadequate débridement and drainage.

SUBDURAL ABSCESS OR EMPYEMA (PACHYMENINGITIS INTERNA)

Etiology. A subdural abscess, or empyema, is the result of extension of infection from an adjacent focus, principally the middle ear, mastoid or the frontal sinus. It may rarely follow maxillary sinusitis, septic thrombosis of the cavernous sinus, compound wounds of the skull and evacuation of a brain abscess.

Two possible pathways of infection exist. In one type, the infection advances from osteitis to an extradural abscess and thence, through the necrotizing dura, directly to the subdural space. In the other, there is retrograde extension along venous channels leading from the infected mucosa. By this means, infection arising in the frontal sinus may invade the superior longitudinal venous sinus, while in cases of otitis media and mastoiditis the infection spreads to the lateral venous sinus. From the venous sinuses, the retrograde septic thrombosis involves the cerebral veins and the infection thus comes to lodge in the subdural space which these veins traverse.

The purulent exudate which collects in the subdural space has little tendency to localize and often the entire space over one or both cerebral hemispheres will contain 100 cc. or more of pus. Unfortunately, after surgical drainage there is a tendency for isolated collections to become walled off and surrounded by a neomembrane. The remarkable property of the arachnoid to impede the spread of infection to the subarachnoid space accounts for the existence of little more than a mild leptomeningeal reaction and low-grade pleocytosis of the spinal fluid until the last stage of the disease. Thrombosis of the cerebral veins leads to edema of the brain and not infrequently to the development of large and small abscesses in the brain.

Symptoms. The symptoms of a subdural abscess at first are not readily distinguishable from the symptoms of acute infection of the frontal sinus or ear. But increasing fever, malaise and headache, usually frontal and on the side of the lesion, should give early warning of the possible existence of a subdural abscess. After a variable time, not exceeding a few days, drowsiness increasing to stupor and coma supervenes. At about the same time, focal neurologic signs develop, the most significant being jacksonian con-

vulsions, hemiplegia and, if the lesion is left-sided, aphasia. The profound illness of the patient and neurologic signs distinguish the condition from an extradural abscess. A cerebral abscess can usually be distinguished by its milder initial stages, the more insidious onset of neurologic signs and less febrile reaction.

Treatment. In the treatment of subdural abscess, it must be kept in mind that usually this is a fulminating disease which rapidly terminates in death if the patient is not treated. With the earliest sign or suspicion of the disease, exploratory trephines should be performed and if pus is encountered, it is drained through this and additional small openings. The space should be treated with an initial instillation of penicillin. Drains are usually useless since the space tends to close rapidly and reliance must be placed thereafter on obliteration of the source of infection and systemic treatment with antimicrobial therapy.

VASCULAR LESIONS OF THE BRAIN

The vascular lesions of the brain include aneurysms of the major cerebral arteries, congenital arteriovenous anomalies and carotid artery-cavernous sinus fistulae.

Aneurysms. Aneurysms of the circle of Willis and its main branches are believed to be principally congenital, the exceptions being occasional mycotic and arteriosclerotic dilatations. The congenital aneurysms represent remnants of embryonal vessels or weakness in the angle of juncture of two arteries, resulting in a saccular outpouching. They rarely produce symptoms before adulthood, at which time, however, they may rupture or attain sufficient size to cause pressure on adjacent structures. Although these lesions are common, interest in them has been greatly increased since the development of angiography and improved methods of surgical treatment. Experience has shown that the majority of cases of subarachnoid hemorrhage result from rupture of aneurysms and their importance is reflected in the 50 per cent mortality rate which occurs in untreated patients.

Rupture of an aneurysm is spontaneous and characterized as a rule by sudden severe headache, most intense in the frontal or occipital regions, and by vomiting, collapse and coma in many instances. Stiff neck nearly always ensues. There may be no localizing signs, but the commonest local effects resulting from pressure and irritation of adjacent structures are pain in the eye,

Figure 18. Angiograms by carotid injection showing a saccular aneurysm of the internal carotid artery at its juncture with the posterior communicating artery.

diplopia, unilateral dilatation of the pupil, ptosis of the lid and sometimes sensory impairment of the cornea and face. These are the result of involvement of the third and fifth cranial nerves. There may be other signs resulting from compression of the brain by collections of blood in the sylvian fissure or from subcortical hematomas which occur particularly in the temporal and frontal lobes. From the effects of blood in the cerebrospinal fluid spaces, patients may remain restless and confused for many days. There is often fever, which sometimes confuses the diagnosis with meningitis, and usually there is increased intracranial pressure. Patients surviving the initial hemorrhage are subject to one or more recurrent hemorrhages in the first month and any one of these may be fatal.

The diagnosis is confirmed by lumbar puncture which reveals grossly bloody fluid. Xanthochromia develops in the spinal fluid within several hours after hemorrhage and persists for ten days or longer.

The precise location of the aneurysm cannot always be determined from the clinical features alone, but angiography (Fig. 18) can be expected to identify the presence and location of an aneurysm in 60 per cent of patients having spontaneous subarachnoid hemorrhage. There are other possible sources of hemorrhage, such as from neoplasms and arterial rupture in vascular hypertension. But it is believed that often when an aneurysm is not visualized by angiography, it is

too small to be recognized or has become thrombosed. Fortunately there seems to be less tendency to recurrent hemorrhages when aneurysms are not demonstrated by angiography.

The main problem pertaining to intracranial aneurysms is not so much their recognition, but the preferred manner of treatment. The most appropriate plan of procedure is to verify the subarachnoid hemorrhage immediately by lumbar puncture and follow this as the patient's general condition permits by angiography, any theoretical risks attending these procedures are minimal compared to the advantages.

The demonstration of an aneurysm of the vertebral or basilar arteries, or of multiple aneurysms, usually precludes surgical treatment, but all aneurysms deserve consideration. If the angiogram discloses the presence of a hematoma, it should be evacuated promptly, but it is preferable to delay direct surgical attack on an aneurysm for ten days or so, until cerebral edema has subsided. In the waiting period, there may be advantage to ligation of the carotids in the neck, particularly for aneurysms of the internal carotid artery, and many times this comparatively safe procedure is all that is employed. Undoubtedly, the most logical surgical approach is, as in aneurysms of vessels elsewhere, to occlude the vessel on each side of the sac. This is not as easily accomplished, however, in intracranial aneurysms.

The commonest place for intracranial

aneurysms to be found is on the internal carotid, more often in its supraclinoid than in its infraclinoid portion. The next commonest place is on the anterior cerebral arteries at their anterior communication.

The serious risks* entailed are related to unmanageable hemorrhage which may occur at the time of operation and the cerebral damage that may follow occlusion, or damage to one of the main arteries.

The employment of controlled hypotension and hypothermia has added significantly to the facility and safety of the direct intracranial attack on aneurysms, but the final evaluation of the surgical treatment remains to be made.

Arteriovenous Anomalies. These lesions, variously referred to as angiomas (Fig. 19), cirrroids, varices, a-v aneurysms and malformations, are believed to be congenital and result from failure of development of the capillaries. In a small number of patients there are manifestations of the lesions in childhood, but more often they come to attention in adulthood, particularly in the third and fourth decades of life.

The lesions are found most often to involve the middle cerebral artery, but they have been observed in all parts of the brain and in sizes ranging from a small marble-sized nest of racemose vessels to the extensive involvement of half the cerebral hemisphere.

Convulsions are a common manifestation of the presence of the lesions in the cere-

brum and doubtless some patients believed to have idiopathic epilepsy have arteriovenous anomalies. In others, the lesion has been overlooked as a cause of retarded development on one side of the body which, instead, is presumed to be due to birth palsy. Headache is sometimes a symptom, but usually the lesion is brought to attention when a subarachnoid hemorrhage takes place and an angiogram demonstrates the unsuspected anomaly. A cephalic bruit can be detected in over half the patients but is not diagnostic since there are other causes for bruit. Recurrent hemorrhage into the subarachnoid space of the brain is common, but fatal hemorrhage is infrequent.

Treatment of the arteriovenous anomalies is a recent surgical accomplishment aided by exact delineation of the abnormal vessels by angiography, the use of controlled hypotension during operation and more recently by hypothermia, which permits temporary occlusion of the carotids while the vessels are being isolated and ligated.

The principal indication for surgical removal of the lesions is spontaneous hemorrhage, but occasionally progressive palsies or uncontrolled convulsions will be also benefited.

Carotid Cavernous Fistula. The development of a fistula between the intracranial portion of the internal carotid artery and the cavernous sinus is usually the result of a basilar skull fracture, though occasionally it is seen following penetrating wounds or following spontaneous rupture of the carotid.

The classical symptoms and signs include unilateral pulsating exophthalmos, chemosis, edema of the lids and fullness of orbital and retinal vessels. The patient is aware of a bruit, may suffer from considerable pain about the eye and may lose motion and sight of the eye, occasionally the other eye will become involved too.

Treatment initially is conservative since the fistula may close spontaneously. Thereafter, if closure does not take place, the carotid artery in the neck should be ligated, usually in a two-stage procedure, or it should be occluded gradually over a period of days by the use of a specially devised clamp on the artery.* If this does not serve to result in closure of the fistula, the intracranial portion of the carotid just above the cavernous sinus should be ligated. It is important to know that double ligation of the carotid in

* Editor's note: It has been shown that ligation of the common carotid artery is less hazardous when performed under local anesthesia.

Figure 19 Angiogram showing small arteriovenous anomaly ("angioma") Note the veins (arrows) connecting the lesion to the sagittal and straight sinuses.

Undoubtedly, the most logical surgical approach is, as in aneurysms of vessels elsewhere, to occlude the vessel on each side of the sac. This is not as easily accomplished, however, in intracranial aneurysms.

The commonest place for intracranial

greater number of patients with chronic mental disease who would otherwise have remained in institutions. In addition, many who remain in institutions are more tractable. While most patients show evidence of frontal lobe deficit, this is acceptable in exchange for their previous emotional illness. Convulsions and urinary incontinence which develop in some patients immediately after operation do not usually persist. The use of tranquilizing drugs in the last few years has greatly diminished but not wholly replaced the need for surgery in selected patients.

Psychosurgery in patients with persistent pain has been found not to interfere with the perception of pain, but it does reduce the emotional factors which may be more distressing than the pain, particularly in patients who recognize that they have incurable disease. It has not been of much use in patients who have severely painful lesions who would benefit more by some other pain-relieving neurosurgical procedure. Also psychosurgery in a patient of this type produces much more inertia and more profound intellectual and emotional deficits than it does in a mental patient.

CONVULSIVE DISORDERS

Convulsive disorder, more commonly referred to as epilepsy, is a symptom of disease and, strictly speaking, should not be used as a name for the disease. It is evidence of dysfunction in the brain resulting from the effects of a noxious stimulus which causes a sudden and intense discharge of cells within gray matter of the cerebrum. It is believed that the discharge then spreads into adjacent regions of the cortex or into projection tracts which reach the brain stem, from whence there is a discharge in turn to other parts of the brain. If the discharge remains localized, the nature of the convulsive effects give a clue to the area of the brain from which the impulses arise. If the discharge spreads to adjacent regions, there will be a march of symptoms reflecting in some degree the successive areas that are excited, though often events happen so rapidly that there is a limit to how accurately the spread of excitation can be correlated. If the discharge spreads to subcortical centers, a generalized convulsive seizure usually follows.

In patients with focal epilepsy, the cortical discharge and the attack is charac-

terized by an immediate generalized response which varies from minor forms in which there is only momentary suspension of consciousness, petit mal, to immediate loss of consciousness and violent generalized convulsion (grand mal). No anatomic substratum or etiologic factor has been discovered for this type of epilepsy, though some congenital abnormality in the brain has been invoked and treatment is dependent on medical management, which fortunately is adequate to control the attacks in many patients.

Surgical interest in convulsive disorders obtains only in patients who are known or believed to have some localized disease of the cerebral cortex from which attacks are easily incited (focal epilepsy). Such diseases include intracranial tumors; granulomas; arteriovenous anomalies; abscess, cortical scars with meningeal adhesions which follow inflammation or trauma; localized atrophic lesions of the cortex having numerous causes, and a variety of other lesions including porencephalic cysts, calcific lesions, gliosis, birth trauma, embolic and thrombotic lesions and tuberous sclerosis. Since every patient with a brain tumor or cortical scar does not have convulsions, it must be assumed that some predilection exists in those who do have convulsions.

In the patients with tumors, arteriovenous anomalies, granulomas and abscesses, the surgical problem is to eradicate the disease and once this is accomplished the convulsions may subside. But often the seizures do not subside and it can only be assumed that damaged cortex or disease left behind is the source.

Focal epilepsy, a term employed when a demonstrable localized cortical lesion exists, is recognized by the occurrence of initial events in the attack which reflect the site of the lesion. These phenomena include: initial unconsciousness, motor phenomena, sensory phenomena, autonomic motor and sensory phenomena, psychic phenomena and miscellaneous phenomena.

Initial unconsciousness has been the most difficult to ascribe to a specific localization, but localization appears in many to reside in the frontal lobes anterior to the motor area. Initial motor phenomena, exemplified particularly by jacksonian seizures, are characterized by turning of the head and eyes usually, though not always, away from the side of the lesion, vocalization and jerking of the muscles of some part or all of the opposite side of the body. Initial sensory phenomena

this manner will not cause blindness because of the rich arterial anastomosis with the external carotid artery in the orbit.

PSYCHOSURGERY

Psychosurgery, which was in the beginning a term synonymous with prefrontal lobotomy, now includes a variety of operations for interruption of frontal, temporal and thalamic connections by numerous technical methods designed to relieve mental disease. In 1935, Moniz and Lima performed frontal lobotomy as a therapeutic procedure in psychotic patients and, soon thereafter, Freeman and Watts introduced a variation on the procedure in the United States. A huge literature has grown up concerning the implications, methods and results in psychosurgery and to date many thousands of persons have undergone operation for mental disease.

Although the operations at first were based in large part on empiricism and rather less functional anatomy has been determined than might be expected after the large experience with the operation, it can be said that the area of the frontal lobes designated as prefrontal represents the highest association area for thought processes. The prefrontal area has connections with the dorsal medial nuclei of the thalamus, the temporal lobe, particularly the hippocampus, and the hypothalamus, so that some operations have been directed to locations other than those of the fibers in the white matter of the frontal lobe.

Originally the operations were performed with some form of leukotome and the placement was determined by directional measurements. Lyerly devised a technique, however, which permitted direct visibility, and a modification of this operation was employed by Poppen in about 500 patients.

Since some patients having complete interruption of the frontothalamic fibers show considerable mental blunting and personality changes, search has been made for an operation that by partial division of the fibers would accomplish the desired benefit but avoid the undesirable effects.

Topectomy was introduced by Pool and the Columbia Greystone Associates as a possible means of selecting certain areas of the frontal cortex as a means of benefiting abnormal mental states. There is reason to doubt that ablation of any one circumscribed region of the cortex is of special importance in psychosurgery and Pool concluded that in topectomy there was no essential differ-

ence in end results obtained whether cortex was removed from the top or bottom of the frontal lobe. But the quantitative factor proved to be important and it was determined that to obtain a therapeutic result, it was necessary to remove 30 to 40 gm. from each side. Scoville has devised a simpler operation in keeping with these findings, whereby the cortex is undercut on the orbital surface of the frontal lobes.

A still simpler technique of interrupting fibers in the inferior portion of the frontal lobes has been devised by Freeman in the use of the transorbital leukotome. There is a risk of uncontrolled hemorrhage in this procedure, though Freeman reports a mortality of but 1.7 per cent. Also, some patients with more severe psychosis subsequently have required a more extensive lobotomy to obtain benefit.

Thalamotomy by a stereotaxic method has been introduced as another method of treatment by Spiegel and Wycis. They report benefits, but from the standpoint of results compared to other methods, it is difficult to draw conclusions.

Grantham has devised a technique whereby an electrode is introduced into the inferior medial aspect of each frontal lobe and by application of endothermy a core of white matter is destroyed. Still another method of recent date has employed ultrasonic waves to destroy the white matter.

It seems obvious that the numerous techniques have a single purpose, namely, to interrupt frontothalamic connection by some safe means and in such a way that the ultimate benefit will be accomplished with the minimal alteration of the patient's intellectual and psychologic equipment. I found that interruption under direct vision of the mesial and inferior connections of the frontal lobe at the level of the tip of the ventricle has produced benefits comparable to those claimed by other methods and with a minimum of complications and risks.

Results of Psychosurgery. What can now be said about the indications for and the results of psychosurgery after years of collective experience is in large part what has been learned by trial and error. Psychosurgery has proved effective in relieving destructive drives, chronic depressions and obsessions, hypochondriasis, impulsiveness and overactivity. In general, results have been good in one-third, fair in one-third and of no benefit or disadvantageous in another third of the subjects. The operation has resulted in return to the community of a

dence in support of their belief that many epileptics suffer from temporal lobe seizures resulting from birth trauma. The pathologic findings suggest that compression of the lobe by temporary herniation through the ten-

torial incisura at birth is the mechanism whereby injury takes place. They believe this process was evident in 63 per cent of patients with temporal lobe seizures treated by surgical resection of the temporal lobe.

Spinal Cord

INJURIES

The majority of injuries to the spinal cord are the result of fractures or dislocation of vertebrae which follow violent flexion, extension or torsion. Less often, the injuries are from direct blows or penetrating wounds. Fractures and dislocations are most common in the cervical (C5 and 6) and lumbar (L1 and 5) vertebrae and least in the thoracic vertebrae, where the rib cage lends stability and protection. The damage to the cord varies from small discrete hemorrhages to complete division and, in addition, there are the factors of edema and compression which may contribute to the deleterious effects on the cord.

Cervical cord injuries usually result from falls that may also produce a head injury and if there is unconsciousness attention may be directed to the head while an important accompanying cervical injury is overlooked. The midcervical cord injury results in a classical group of neurologic changes the forearms are held in flexion and the biceps reflex is present, while the triceps action and reflex are absent; the sensory level is at the fifth cervical segment, there is a bilateral Horner's syndrome, and respiration exists only by diaphragmatic movements. A special and infrequent type of fracture or dislocation occurs at the atlantoaxial joint where the odontoid process may fracture at its base or the ligament supporting the odontoid posteriorly is disrupted. This type of injury is the one which takes place in hanging and, if the cord is seriously damaged, death occurs shortly. With less pronounced dislocation at this joint, the cord may be partly spared, enough to support respiration and some degree of neurologic function in the trunk and limbs.

Injury to the *thoracic cord* is unusual except by direct blow or penetrating wounds common in warfare, the resulting neurologic

changes correspond to the level of the injury. It must be remembered that in the upper and middle portions of the thoracic cord the segmental levels lie one to two segments above the corresponding vertebrae. All of the lumbar and sacral segments of the cord are between the levels of the eleventh thoracic and first lumbar vertebrae.

Injury to the upper *lumbar cord* produces motor and sensory paralysis of both lower limbs, though sparing of the first lumbar may preserve some sensation and flexion of the thighs. Injury to the cord of significant degree at any level produces loss of sphincter control as well as spasticity of muscles, exaggerated tendon reflexes, pathologic reflexes and loss of sensation below the lesion. If the injury is in the cervical or thoracic cord there is loss of sweating and the skin becomes dry and warm below the lesion.

Damage to the *cauda equina* from spinal injury usually is patchy and incomplete since the nerve roots are less vulnerable than the cord. The resulting *paraparesis* or *paraplegia* is of the flaccid rather than spastic type and reflexes are absent. Loss of sphincter control occurs readily and at times with incomplete injury to the cauda equina there may be little other deficit.

Care of patients with cord injuries is of extreme importance from the initial handling through the prolonged period of rehabilitation. Improper transportation from the place of injury has too often added to the damage of the cord and deprived the patient of the recovery that might otherwise have taken place. Attention must be given particularly to avoiding flexion positions; extension position of the neck and back is preferred, but this can be overdone. A flat supporting appliance to which the patient is firmly fixed is safest while he is being transported to a hospital and while being moved after reach-

and their corresponding cortical areas of representation are as follows: somatic—contralateral, central or postcentral, visual—contralateral occipital lobe; auditory—either temporal lobe, vestibular—either temporal lobe, olfactory—either temporal lobe. Autonomic motor and sensory phenomena include a variety of visceral sensations and have been found to be related to areas in the region of the fissure of Sylvius and isle of Reil. Psychic phenomena have much evidence to support their localization in either temporal lobe.

The clinical study of a patient with focal epilepsy and, in particular, a scrutiny of the pattern of the seizure is all-important in arriving at a localization of the lesion, but additional evidence is sought from roentgenograms, pneumograms, angiograms and electrograms. Great emphasis has been put on the use of the electrogram in determining the exact epileptogenic focus or firing point, since present-day surgical treatment is dependent on the assumption that seizures can only be alleviated if the irritable focus is removed. Because of the limitations of the extracranial electroencephalogram, the corticogram taken from the exposed brain has sometimes been employed in the hope of attaining more precise localization.

Those engaged in the surgical treatment of convulsions have usually insisted on the need for the assistance of electrograms, but unfortunately the number of patients who have been relieved of epileptic seizures following excision of suspected cortical foci has not met expectations. The disparity has been accounted for on the basis of practical difficulties in identifying the firing point, incomplete excision of the focus, the probable existence of other unrecognized firing points and the need for limiting the excision to avoid unwanted neurologic deficits. It is only fair to say that some have raised a doubt of the justification of this manner of rationalizing the failures of operation and they have raised, in particular, the question of whether, even with the acceptance of the epileptogenic focus as a primary factor, the site of the focus is revealed by the spike potentials that happen to be recorded by the electrogram.

To add to the difficulties of interpreting results of cortical excision in the treatment of convulsions is the older literature which records many cures and beneficial effects in epileptics following an amazing variety of surgical procedures, many of which seem without the slightest scientific justification.

But even with the recognized uncertainties of surgical treatment of convulsive disorders, it seems important to continue efforts in this direction on selected patients. The indications for surgery are generally agreed to include a clinical pattern of seizures that have focal aspects, a relatively long duration of the ailment; relatively frequent, severe seizures, and failure of control of attacks by adequate anticonvulsant measures. Under the present possibilities for benefit from operation, it appears that about 10 per cent of the populace afflicted with convulsions would conform to the indications set forth.

Penfield and his associates, who have been leaders in the effort to treat convulsive disorders in recent years, have reported their results from time to time. The operative mortality has been between 1 and 2 per cent. The evaluation of cortical excision for all types of focal convulsion has been judged to demonstrate that about 25 per cent of the patients have been cured and another 30 per cent significantly benefited in terms of lessening of the frequency and severity of seizures. The results reported by Meyers and associates are less salutary, they estimated about 11 per cent were cured and 25 per cent were improved with an operative mortality of 6 per cent.

Walker summarized the results of cortical excision in thirty-six patients who had developed convulsions following head injuries sustained in World War II. One year after operation, approximately one-third had had no attacks and another fifth had had only one attack or the isolated aura of their former attacks. The criticism of drawing final conclusions from any report is that the beneficial effects bear an inverse relation to the time of follow-up and at least ten years should elapse before the evaluation is reliable.

There have been impressive reports in the last several years of beneficial effects resulting from cerebral hemispherectomy or extensive resection of the abnormal cortex in children who have had birth palsies resulting in hemiplegia, convulsive seizures and mental retardation. Some of the reports have given convincing evidence not only of cessation of convulsions, but also improvement in mental status which can be assumed to have been secondary to termination of the seizures. Also a surprising observation has been that limbs previously spastic on the hemiplegic side have lost much of their rigidity and some useful motion has remained.

Penfield and associates have presented evi-

cial adjustment to his suddenly altered way of living and this may be the more difficult task. Passive and active exercises together with massage preserve motion at joints and prevent contractures. Braces and various supportive devices will help the patient to stand and walk, though efforts in this direction often require great effort by the patient as well as perseverance and the sympathetic direction of one skilled in management. The development of paraplegic training centers since World War II has done much to improve and advance rehabilitation methods.

TUMORS

Tumors of the spinal cord, as a category, are usually meant to include intraspinal tumors of great variety which implicate the cord, its roots and the cauda equina. Such tumors may arise from the cord itself or from nerve roots, the meninges, the vasculature of or about the cord, the vertebrae or occasionally from tissues adjacent to the spinal column. In addition, there may be metastases from tumors elsewhere in the body which spread to the vertebrae, the epidural tissues or rarely to the cord.

The tumors of the spinal canal are classified anatomically as *intramedullary* or *extramedullary* and the latter as *intradural* or *extradural* (Fig. 20). Also, some tumors are both intraspinal and extraspinal connected by a narrow tube of tumor tissue lying in the root foramen or the interlaminar space; such tumors are referred to as hour glass or dumb-bell tumors.

Incidence. The incidence of intraspinal tumors is about the same in the two sexes, with a few exceptions. For example, meningiomas, which are one of the two common primary tumors, have a higher incidence in women, while the commonest metastatic tumors occur nearly exclusively in one sex, namely, bronchogenic metastases in males and mammary carcinoma in females. Though tumors are occasionally encountered in children or in the aged, the third to the sixth decades, and most of all the fifth decade of life, are the periods when tumors most often make their appearance. If all types of tumors are included, a survey shows that they are found with about equal frequency in the cervical, thoracic and lumbosacral levels, although their occurrence at the extremes

Figure 20 Extradural tumor of the spinal canal extending from the lung and mediastinum (after Ray, B. S.: Surg. Gynec & Obst., vol. 67).

ing the hospital. Since so much depends on subsequent care, it is worth while to select a hospital equipped to care for cord injuries.

In the hospital all examinations should be performed with the least manipulation of the patient. Early evaluation of neurologic changes provides a basis for comparing any subsequent changes. Early lateral and anteroposterior roentgenography is imperative, but should be acquired cautiously, reserving special views until a more appropriate time.

In cases of fracture or dislocation of the cervical spine, traction applied to the head is the treatment of choice. There is no justification for attempting blind manipulative procedures for reduction of malalignment. While halter traction may be used as a temporary measure, skeletal traction applied to the skull is far better. Traction is begun with 5- to 10-pound weights and, if necessary for reduction of the deformity, increased to 15 or 20 pounds within twenty-four hours. But greater weights of 35 or 50 pounds, sometimes recommended, are unsafe and usually not necessary since with rare exceptions even severe dislocations are realigned with lesser weights.

Compression fractures of the thoracolumbar vertebrae occur principally as a result of hyperflexion of the spine. The anterior surface of the body of the fractured vertebra becomes compressed ("wedged"), causing an acute angulation of the spinal canal. Such injuries are best treated in hyperextension by either bed rest or a body cast.

Surgical treatment of spinal injuries with accompanying trauma to cord or cauda equina in many instances is controversial. In treatment of unreduced dislocations, crush injuries of the laminae and most penetrating wounds, there is unanimity of opinion in favor of exploratory operation, decompressive laminectomy and fusion if necessary. There is less agreement about "closed cord injuries" in which there has been no displacement of vertebrae or realignment has soon been accomplished by head traction or immobilization of the trunk in hyperextension. The decision becomes important if the degree of paralysis is severe.

The following are the criteria usually accepted in deciding on the need for decompression laminectomy: a progression of neurologic signs, a complete spinal block as demonstrated by lumbar puncture and manometric studies of the spinal fluid pressures upon jugular compression (Queckenstedt test), and occasionally when there is doubt

as to the effectiveness of reduction of the vertebral deformity by traction or positioning of the trunk.

While early operation in selected cases may be desirable, a high mortality accompanies hasty surgery performed while the patient is in shock or having respiratory difficulty from high cervical trauma or when facilities are inadequate for maintaining traction, proper anesthesia, adequate suction and blood replacement if needed.

Nursing and medical care of the patient with cord injury can be one of the most exacting yet repaying efforts in medicine. The prevention of skin abrasions and decubitus ulcers requires almost fastidious attention. Such lesions develop quickly but may require weeks and months for healing and if infected seem actually to retard recovery of neurologic function. The use of a Stryker frame makes it relatively easy to change the patient's position frequently and a great boon to the prevention of decubitus ulcers has come with the development of the air mattress with chambers of alternating pressure.

For care of the paralyzed bladder an indwelling urethral catheter is introduced immediately and a closed system of intermittent bladder irrigation maintained. It is imperative that all means be taken to prevent or minimize infection of the urinary tract. In some patients, urinary control returns at least in part while some develop a degree of automaticity in evacuation of the bladder. In others, the permanent loss of bladder control becomes a major problem in management and a threat to life. These cases constitute special urologic problems about which there is no general agreement.

Bowel habits, including use of periodic enemas, low residue diets, digital evacuation and self-care, can be taught to the intelligent patient so that loss of anal sphincter control need not be an important problem.

Spasms of muscles of the lower limbs, particularly flexion spasms, at times constitute a serious problem and are aggravated by infections of the bladder and by decubitus ulcers. Sometimes correction of these inciting lesions will control or minimize the spasms, but if not, it is appropriate to resort to extensive rhizotomy or intrathecal injection of alcohol to abolish reflex action.

A rehabilitation program should be organized as soon as the patient's condition permits. As a part of the program goes a recognition of the need for the patient's so-

compression of the cord or invasion of its fibers, is evidenced by symptoms related to changes in the long tracts. The symptoms may make their appearance simultaneously with radicular pain, although occasionally tumors cause progressive myelitis without accompanying pain; this is more likely to be true of intramedullary growths.

Unilateral compression of the cord results in the Brown-Séquard syndrome in which there are homolateral alteration of reflexes; muscle weakness, impaired touch, position and vibratory senses, and contralateral loss of pain and temperature senses below the level of the lesion. Compression of the anterior part of the cord may result in loss of pain and temperature senses with preservation of other functions, while compression of the posterior cord may produce only decreased positional and vibratory senses. Intramedullary tumors, in addition to their relative painlessness, can sometimes be discerned by a handlike area of loss of pain and temperature senses corresponding to the level of the tumor and by preservation of sensation in the saddle region in the presence of sensory loss in the trunk and lower limbs. In cases of incomplete myelitis, the upper level of sensory loss does not correspond to the segmental level of the lesion, but can be from several to many segments lower, thus making it impractical to localize the level of the lesion accurately, while in complete myelitis the sensory level corresponds more exactly.

In the *third phase*, with the advent of complete myelitis, there is complete loss of all but reflex functions below the segmental level of the lesion. If the myelitis has developed rapidly, even the segmental reflexes may be absent for a while and the muscles become flaccid. But in slowly progressing myelitis and in some days or weeks after more acute myelitis, the tendon reflexes become exaggerated, pathologic reflexes develop and muscles become spastic. There is also loss of sweating and of sphincter control. The sensory loss and the presence of muscle inaction predispose to the development of bed sores, ulcerations from pressure, edema and wasting of soft tissues and demineralization of bones, erroneously referred to as trophic changes.

Diagnosis. A comprehensive history of the nature and chronology of the symptoms is of particular importance in detecting intraspinal tumors. The neurologic examination must be complete from head to foot and not just limited to the region under suspicion

since other common diseases of the central nervous system and even brain tumors may simulate, for a while, a cord tumor. A practical knowledge of the segmental innervation of reflexes, muscle groups and sensory areas is invaluable in determining the location of a tumor. A useful accessory test is application of heavy pressure or percussion over the spinous process in the region of a tumor, thereby eliciting local pain and, occasionally, peripheral shocklike sensations (Lhermitte's sign).

Some of the common diseases that require differentiation from intraspinal tumors are abnormalities of the intervertebral disks; multiple sclerosis; syringomyelia; amyotrophic lateral sclerosis; subacute combined cord degeneration; myeloradiculitis (Guillain-Barré syndrome); diabetic myeloneuropathy, idiopathic lateral sclerosis; arachnoiditis, and syphilis. All of these diseases produce some symptoms similar to those of tumor, but each has also some distinguishing features that set it apart.

Useful adjuncts in diagnosis include roentgenography of the spine, spinal fluid studies and myelography. Roentgenograms may reveal the presence of a metastatic or other invasive tumor or disease of the vertebrae. Primary intraspinal tumors present for long periods often produce erosion of bone by pressure which may be evident particularly in the pedicles of the vertebrae or by enlargement of interlaminar or foraminal spaces.

Lumbar puncture as a diagnostic aid is particularly valuable. The Queckenstedt test will provide positive identification of a complete or nearly complete block of the spinal canal. In the majority of cases the presence of a tumor causes elevation of the protein content in the fluid while a total block of the canal will produce not only an increased protein, at times sufficient to clot the fluid, but also a degree of xanthochromia in the fluid. But it must be remembered that, while the information to be gained by lumbar puncture is important, there is distinct risk of thereby increasing the neurologic deficit through altering the intraspinal dynamics. It is preferable, therefore, that lumbar puncture be performed as one of the last tests and only when surgical facilities are made ready or available.

Myelography performed with Pantopaque or a comparable iodized radiopaque agent is the last test to be used since it is attended, similarly to lumbar puncture, by the possibility of rapidly worsening the condition.

namely, the uppermost cervical and the sacral regions, is exceptional.

Some conception of the great variety of intraspinal tumors is evident in the following classified list encountered on the neurosurgical service at the New York Hospital over a twenty-year period. The list includes certain non-neoplastic lesions which have qualities of true neoplasms in their effects on the cord and its roots.

Intramedullary

- Gliomas (varia)
- Ependymoma
- Hemangioma (blastoma)
- Angioma (vascular anomaly)
- Metastatic tumors (rare)
- Dermoid, epidermoid and teratoma (congenital)
- Benign cysts (syrinx)
- Abscess
- Tuberculoma

Extramedullary—Intradural

- Meningioma
- Nerve sheath tumor
- Hemangioma (blastoma)
- Angioma ("varicosities")
- Metastatic tumors
- Gumma

Extramedullary—Extradural

- Meningioma
- Nerve sheath tumor
- Lymphomas
- Hemangioma (blastoma)
- Lipoma
- Chordoma
- Chondroma
- Cholesteatoma
- Osteogenic tumors (benign and malignant)
- Metastatic tumors
- Dural cyst

Of the primary intradural neoplasms, nearly 75 per cent were either meningiomas or nerve sheath tumors, both are benign and usually cured by surgical removal. Of all intraspinal tumors encountered at operation, nearly 50 per cent were benign and removable. *Meningiomas* are variously known as *meningiothelioma*, *dural endothelioma*, *me-*

ngioma, *angioma* and others. *Nerve sheath tumors* are also referred to as *neurilemmoma*, *neurinoma*, *schwannoma*, *neurofibroma* and *perineural fibroblastoma*.

Gliomas of the cord arise from the interstitial elements of the parenchyma and comprise 15 per cent of the primary intradural tumors. The commonest type is the *ependymoma* arising, as the name implies, from

the *ependyma* of the central canal or from the *vestigial filum terminale*. The tumors of the *filum terminale* may reach large size, virtually filling the *lumbosacral canal*, but can be removed safely providing they have not invaded the *conus medullaris*. The *ependymomas* arising in the cord sometimes extend for many segments and are visible through the widened posterior sulcus of the cord, a few have been successfully removed. Any of the types of *glioma* occurring in the brain may also be encountered in the cord, but whereas the commonest *glioma* of the brain is the highly malignant *glioblastoma*, the commonest in the cord next to the *ependymoma* is the less malignant *astrocytoma*. These tumors are incurable, but occasionally they can be removed in large part. They often grow very slowly over a period of years and may be slowed still more by *roentgenotherapy*.

The term malignancy, when applied to the primary intradural tumors, refers only to the tendency for the tumors to enlarge locally and spread to adjacent parts of the cord; distant metastases do not occur.

Symptoms. The symptoms of intraspinal tumors can be conveniently divided into three phases: nerve root symptoms, beginning compression of the cord and advanced myelitis.

In the first phase initial involvement of nerve roots causes pain, which may be severe and lancinating, distributed in the corresponding dermatome and often aggravated by various forms of straining which suddenly increase the intraspinal pressure. A feature of the pain is that in many it is worst when the patient reclines, compelling him to seek relief in sitting upright or walking about. In addition to pain, irritation of a sensory root may cause a sense of numbness and paresthesias in the same area while at times the involved area of the skin may become hypersensitive, particularly to the light touch of clothing. Though the patient may experience abnormal sensation corresponding to the nerve root involved by the tumor, there is usually little or no demonstrable sensory loss in the area because there is considerable sensory overlap from adjacent dermatomes. With involvement of the motor fibers of the root, the corresponding muscles develop atrophy, weakness and fibrillations. In the trunk, localized palsies may go unnoticed, but in the extremities, particularly in the hand, the muscle wasting and weakness can be more easily recognized.

The second phase, caused by beginning

Repeated recurrences of sciatic pain, which in the beginning is relieved by conservative measures, commonly result in a chronic persistence of symptoms which demand surgical treatment. If pain and disability persist beyond a reasonable time or if paresis of muscles controlling the foot or bladder develops at any time, surgical removal of the nucleus pulposus is desirable. Some employ myelography for the corroboration of diagnosis and localization, but this is not routinely necessary. Diagnosis on clinical findings is usually reliable, the only difficulty arising if the symptoms and motor and sensory signs are atypical and differential diagnosis uncertain. If operation is to be performed it is perhaps as simple to explore the disks without previous myelography. The decision to operate on a disk should largely be made on the clinical findings and not alone on the myelogram.

The surgical treatment consists of unilateral exposure, excision of the ligamentum flavum, widening of the interlaminar space, retraction of the nerve root and excision of all of the nucleus pulposus. The operation thus performed does not alter the structure of the back and can be regarded as a means of accomplishing what nature has not in removing the offending nucleus pulposus. Some favor fusion of the joint by bone grafting as a part of the operation and at times there may be a need for it, but fusion is not necessary, particularly in patients whose complaints and physical findings point to root compression as the source of their complaints.

Following surgery, a regimen of rehabilitation is desirable before full activity is resumed and this in turn depends on a number of factors, not the least of which is the patient's emotional make-up and the factor of legal compensation. Some patients who minimize or accept minor discomforts and have a need for return to work do so without delay.

In the cervical region a ruptured disk, by compression of a corresponding nerve root, causes changes comparable to those of a ruptured lumbar disk. The neck is stiff and painful, particularly so on hyperextension. Pain extends from the neck across the shoulder into the arm and forearm, usually not farther than the wrist, while paresthesias and numbness are often present in the fingers. There are accompanying alterations of reflexes and at times weakness of muscle groups. As in the case with ruptured lumbar disks, it is usually possible with clinical

findings to localize the source of trouble. Rupture of the fifth cervical disk (C5 to 6) compresses the sixth cervical roots, characteristically causing numbness and paresthesias in the first two or three fingers, impairment of the biceps reflex and weakness in flexion of the forearm. Rupture of the sixth cervical disk (C6 to 7) compresses the seventh cervical nerve roots, causing numbness and paresthesias of the middle fingers, impairment of the triceps reflex and weakness in extension of the forearm.

Lateral protrusions of the nucleus pulposus which compress the nerve roots may also be large enough to compress the spinal cord, particularly in its anterolateral quadrant. The first signs of such compression may be miosis and lid ptosis of the homolateral eye, which constitute a warning of the potential seriousness of the condition. Further compression of the cord may produce a Brown-Séquard type of hemimyelitis, though there is usually preservation of the posterior columns of the cord which subserve positional and vibratory senses. Less laterally placed or centrally placed protrusion of a cervical disk is not so likely to cause nerve root compression and much more prone to affect the cord.

When the symptoms and signs point to irritation of the nerve roots only, it is appropriate to employ expectant treatment just as in the case of sciatica. Often, light traction on the head will give relief by lending support to the neck and overcoming painful spasm in neck muscles. An immobilizing neck collar is also helpful. Added comfort may follow the use of heat applications, light massage of muscles and analgesic drugs. Spontaneous recovery occurs in the majority as the reaction in the involved nerve root subsides.

Surgical removal of the herniated nucleus pulposus and decompression of the involved nerve roots are indicated in the severe and persistent cases of radiculitis. The operation is performed by means of a unilateral approach between the widened interlaminar space, much the same as in the operation for lumbar disk herniation. Through a similar approach the larger herniations affecting the cord may also be removed from the extradural space, but, in some, wider exposure through bilateral laminectomy is required.

Cervical disk "ridging" is a condition which simulates herniation of the nucleus pulposus and often the two cannot be distinguished except at operation. The ridging consists of unyielding calcified fibrous tissue

But the test may be invaluable in detecting the presence and exact location of a tumor.

Treatment. Tumors of the spinal canal, with few exceptions, should be treated surgically without needless delay. Postponement of surgery for a few hours in rapidly advancing myelitis may make the difference between permanent paralysis and recovery of function. Meningiomas and nerve sheath tumors can usually be removed completely with negligible risk and the same applies to a number of other less common extramedullary tumors. Intramedullary tumors are less favorable, but occasionally an ependymoma can be totally removed and in many of the other gliomas benefit results from partial excision, evacuation of cystic formations and by decompression through laminectomy and the opened dura. In metastatic tumors, partial excision of the compressing extradural mass and decompression laminectomy followed by roentgenotherapy will often restore function and avoid disabling paralysis during the patient's remaining life. An exception to the need for urgent operation for intraspinal tumors obtains in the lymphomas which fairly commonly invade the spinal canal, particularly in the thoracic region, by extension from mediastinal nodes. These tumors respond readily to roentgenotherapy, especially if it is administered in conjunction with nitrogen mustard. But such patients must be closely observed and, if myelitis progresses under treatment, surgical decompression is necessary.

INTERVERTEBRAL DISK

Rupture of an intervertebral disk and protrusion of the nucleus pulposus can occur at any spinal level, but the commonest sites are at the last two lumbar and the fifth and sixth cervical interspaces. Protrusions in the thoracic region are seldom encountered.

The intervertebral disk is made up of several structures: a tough fibrous membrane which corresponds to a joint capsule and is known as the annulus fibrosus, cartilaginous plates which face the surfaces of the opposing vertebral bodies, and the nucleus pulposus, the remnant of the embryonic notochord, which occupies the closed space. Repeated stress may lead to thinning or rupture of the annulus fibrosus with bulging or actual extrusion of the nucleus pulposus into the spinal canal. The nature of the resulting symptoms depends on the degree and location of the protrusion.

In the lumbar region the initial symptoms, which often begin simultaneously or soon

after some stress on the lower back, are most often pain and limited movement in the lower back. It is believed that this initial pain arises from the torn annulus fibrosus, but the pain is indistinguishable from that which may come from any number of other structures and pathologic processes in the region. Later the pain extends into a lower limb along the course of the sciatic nerve as the nucleus pulposus compresses adjacent

the other, accounting for the laterality of the symptoms.

The pain characteristically extends from the lower back on one side to the buttock, posterior thigh and calf as far as the ankle. It is aggravated by movements of the back and various forms of straining. In some patients, numbness and paresthesias also occur, particularly in the leg and toes. Tilting of the spine and limping with the painful limb are common. In more severe cases there is weakness of muscles which control the foot and toes and, rarely, there may be loss of bladder control.

Since it is rare for rupture to occur in lumbar disks other than the last two, the symptoms and signs are attributable for the most part to compression of fifth lumbar roots by the fourth disk or the first sciatic roots by the fifth. Painful limitation of low-back movements and of straight-leg raising are common to both and may be the only demonstrable abnormalities. But differences in location of the symptoms and of elicited neurologic abnormalities usually permit localization of the level of the rupture. For example, rupture of the fourth disk (L4 to 5) and compression of the fifth lumbar root are more likely to cause paresthesias in the great toe, weakness in dorsiflexion of the foot and toes and diminution of the knee reflex with preservation of the ankle reflex. Conversely, rupture of the fifth disk (L5 to S1) and compression of the first sacral roots more often cause sensory changes in the last toes, weakness in plantar flexion of the foot and toes and absence of the ankle reflex.

The degree of disruption of the disk and of the symptoms varies widely. The majority of patients recover spontaneously or improve greatly in a period of six to eight weeks aided by relative inactivity and comforted by various forms of symptomatic treatment. Natural recovery is dependent on shrinkage of the nucleus pulposus and subsidence of reaction in the nerve root.

ing on the location of the pain, are at the points of emergence of the nerves from the skull, as the maxillary and mandibular divisions, or the several peripheral branches, as the supraorbital, infraorbital and mental nerves. It must be remembered that it is one thing to infiltrate procaine in the general region of a nerve for anesthesia and another to instill a small amount of absolute alcohol directly into the nerve. The procedure of alcohol injections is sometimes an unpleasant experience for the patient and not without occasional complications. Even so, many physicians feel that relief of the neuralgia, though temporary, is worth while and that the facial numbness experienced by the patient is valuable in acquainting him with what he may expect if eventually surgical division of the nerve root is required.

Injection of alcohol or other destructive agents, such as boiling water, directly into the gasserian ganglion via a needle introduced through the foramen ovale has been recommended by a few. The procedure has the advantage of avoiding an operation and, if successful, in preventing regeneration of the nerve, but it has the disadvantage of being a blind procedure not without possibility of complications and it does not permit the selectivity which can be accom-

plished by partial surgical division of the nerve root.

Aculsion of the supraorbital or infraorbital nerves at their foramina is a more certain and often more effective procedure than attempts at alcohol injection of the nerves but is useful only when pain is limited strictly to areas supplied by these nerves. The surgical scars are unnoticed since one is within the eyebrow and the other within the mouth.

Rhizotomy, surgical interruption of the sensory root of the trigeminal nerve, is the means by which the pain of trigeminal neuralgia can with certainty be terminated permanently. The root is that portion of the nerve lying between the gasserian ganglion and the brain stem and is exposed by an opening either in the temporal bone or the occipital bone. In the former operation, the root is exposed extradurally, while in the latter the root is intradural. The choice of surgical exposure is more or less arbitrary, each possessing advantages and disadvantages. But important complications of either operation are relatively few and mortality from operation does not exceed 1 per cent. In about 5 per cent of surgical cases there is paresis or paralysis of facial muscles on the side of the operation. The most likely cause of this complication in the temporal opera-

Figure 21 Drawing to show the relative positions of the cranial nerves and the two operative approaches (from Ray, B. S. *Operative Technic in Specialty Surgery*, 2nd Ed., edited by W. H. Cole. Appleton-Century-Crofts, Inc.).

which constitutes the changes visible on roentgenograms and is referred to as hypertrophic osteoarthritis. The condition develops as a part of the aging process and of degeneration of the intervertebral disk. An exuberance of this tissue in the region of a cervical nerve root foramen may narrow the opening to the degree that the nerve is easily irritated. In other cases a prominent ridge may extend across the anterior surface of the cord, causing a chronic state of dis-

tortion, increased vulnerability of the cord to frequent neck movements and possibly changes in the intrinsic blood supply. The result is the subtle and insidious development of myelitis at this level, which at times has been confused in diagnosis with cord tumor, syringomyelia, amyotrophic lateral sclerosis and other diseases of the cord. The treatment consists of appropriate surgical decompression to alleviate the pressure on cord and nerve roots.

Cranial Nerves

While any one of the cranial nerves (Fig 21) may become involved by the many diseases of the central nervous system, only certain nerves may require surgical treatment for either intrinsic disease of the nerves themselves or for relief of disease in areas supplied by them. The trigeminal nerve is by far the commonest nerve requiring some form of surgical treatment because of the frequency of neuralgia and of painful diseases within the area supplied by the nerve.

Trigeminal Nerve. Trigeminal neuralgia (synonyms trifacial neuralgia, tic douloureux, Fothergill's disease) is one of the few true neuralgias. It is a disease of unknown origin and is characterized by paroxysms of sudden excruciating pain in the area of the face supplied by the trigeminal nerve. Since there are no physical changes to be demonstrated in the disease except some transient flushing of the face and the patient's convincing evidence of agony during a paroxysm, the diagnosis is made on the basis of the history. Because of the need for differentiating the disease from the numerous other causes of facial pain, it is imperative that the characteristic properties of the pain be recognized. The salient properties of the pain constitute a triad (1) it is strictly limited to some part, or occasionally all, of the region supplied by the sensory root of the trigeminal nerve, (2) it is paroxysmal and of short duration, a single paroxysm rarely lasting longer than 60 seconds, and (3) it is induced by stimulation of the nerve endings (trigger zones) such as light touch of the face, talking and eating.

The disease usually makes its appearance between the ages of forty and sixty years

and rarely develops at earlier or later ages. Men and women are affected equally. Though the etiology is unknown the appearance of the affliction principally in older ages suggests a relationship to vascular deficiency or some aging process of the nerve. There is a higher incidence of trigeminal neuralgia in patients with multiple sclerosis than occurs in the general populace. Also, occasionally a tumor of the gasserian ganglion or a tumor lying adjacent to the nerve such as acoustic neurinoma, cholesteatoma or meningioma occupying the cerebello-pontile angle will produce pain difficult to distinguish from trigeminal neuralgia. These accompanying diseases, unlike trigeminal neuralgia, should be evident by the presence of abnormal neurologic signs.

The pain of trigeminal neuralgia never crosses the midline and bilateral disease is a rarity. Although spontaneous remissions of pain may last for months the natural history of the disease is one of unrelenting recurrence of pain with shorter and shorter intervals of relief. Rarely, if ever, does the untreated disease fail to recur.

Over the years, many nonsurgical treatments have been proposed, but none of them provides more than temporary or partial relief at best. The pain can be relieved with certainty only by interruption of the trigeminal nerve somewhere along its pathway.

Injection with alcohol of one or more of the branches of the nerve supplying the painful region of the face is a common means of providing relief, but the effect is always temporary until the nerve regenerates as it always does. The sites of injection depend-

is uncertain, but the facial nerve has been found to be swollen in the narrow facial canal without demonstrable inflammatory lesions or proof of infection. The paralysis develops abruptly, usually within a few hours, and may be accompanied by some premonitory pain in the ear or face, by hyperacusis and by blunting of taste if the nerve damage is proximal to the point of juncture of the chorda tympani. Spontaneous subsidence of the paralysis in about 85 per cent of cases commonly begins in two to four weeks or may be prolonged for several months. The more severe the degree of paralysis and delayed the return of function, the more likely will be some motor abreactions of the face such as mass movements, twitching and overcontraction. Because of these undesired effects in the cases of delayed recovery, surgical decompression of the nerve in the facial canal is recommended, but the merits of this procedure are uncertain.

Trauma to the facial nerve in the facial canal has most often been a complication of mastoid operations, now a rarity since the advent of antimicrobial treatment has minimized the need for mastoidectomy. However, injury to the nerve is greater today from other sources such as automobile accidents and more radical operations both inside and outside the cranium. Whenever possible, anastomosis of the divided nerve is preferable. Nerve grafting within the facial canal has sometimes yielded surprisingly good results and is one of the few instances in which nerve grafting to bridge a defect has been successful. When the ends of the divided nerve cannot be approximated, the method usually resorted to for restoration of facial mobility is anastomosis of the distal end of the facial nerve to the proximal end of a divided adjacent nerve such as the spinal accessory or hypoglossal nerve. The functions of either of these latter nerves may reasonably be sacrificed in exchange for restoration of even partial facial motility.

In *facial hemispasm* the aim of surgical treatment is to alter the facial nerve by partial selective sectioning of the motor fibers, thereby lessening the degree of facial movements and at the same time preserving some degree of voluntary and involuntary motion. An ideal technique for accomplishing these ends has not developed, but sometimes the results of the operation have been an improvement over the preoperative condition.

The acoustic nerve. The importance of the acoustic nerve is brought to attention particularly in the surgical relief of symptoms designated as Meniere's disease. The disease is characterized by a syndrome which includes paroxysms of vertigo and unilateral tinnitus and loss of hearing. Without the existence of all of these symptoms, the diagnosis cannot be made with certainty and though paroxysms of vertigo may for a time exist alone its origin cannot be lateralized until unilateral tinnitus or deafness appears. Various causes of Meniere's disease have been proposed, but all lack convincing proof and it is not established whether the inciting lesion lies in the peripheral endings of the nerve or in the nerve itself.

The vertigo occurs characteristically in explosive attacks so severe at times that the patient may be thrown off balance. There are usually associated vomiting and at times prostration by the more severe attacks which may not subside for many hours. Between the paroxysms of vertigo there exist only the tinnitus and hearing impairment. In some, the vertigo is of mild degree, insufficient to cause concern, and in some there is spontaneous subsidence of the vertigo. A variety of medical treatments have been given credit for benefit, but the occasional patient is so distressed by the severity and frequency of the paroxysms of vertigo that relief is sought in surgical measures.

Relief of the vertigo can be accomplished by either surgical destruction of the labyrinth or division of the acoustic nerve intracranially on the side of the tinnitus and hearing loss. The results of nerve section are good in terms of relief of the vertigo, but tinnitus is not always relieved and hearing is made worse unless a differential section of the nerve is performed by which the cochlear neurons are preserved. Unless some useful hearing exists at the time of nerve section, it is usually preferable to divide the entire nerve since a partial section may preserve some of the vestibular fibers and perpetuate the vertigo and, too, there is greater likelihood of terminating the tinnitus if a total nerve section is performed.

The glossopharyngeal nerve and sensory fibers of the vagus nerve. The principal interest in these nerves pertains to glossopharyngeal neuralgia which in all respects is akin to trigeminal neuralgia except in its location. While the condition is not common, neither is it rare and sometimes neuralgia of both nerves exists in the same patient. The pain characteristically occurs in sharp,

tion is traction during the operation on the superficial petrosal nerve, a branch of the geniculate ganglion of the facial nerve. Recovery of facial motion is much the same as occurs in Bell's palsy. If the operation results in corneal anesthesia, precautions must be taken to avoid trauma to the insensitive cornea and resulting ulceration. With reasonable care of the eye such ulcerations can be avoided. All patients experience some degree of paresthesias in the anesthetic area and, for most, accommodation is no problem. But for a few, particularly the over-anxious, there may be considerable unhappy preoccupation over the sensations for which, unfortunately, there is no satisfactory remedy.

Partial or selective section of the sensory root is employed particularly in patients whose pain is restricted to the lower part of the face, in which case nerve fibers supplying the cornea can be preserved, thus obviating the risk of corneal ulceration. The motor root of the trigeminal nerve is preserved if possible since its loss results in paralysis of masticator muscles on that side. It may not always be possible to preserve the root, but fortunately patients readily adjust to the paralysis.

Section of the descending tract, pain fibers only, of the trigeminal nerve in the medulla oblongata was proposed by Sjoqvist in the hope thereby of avoiding total anesthesia of the face and possibly diminishing the degree of paresthesias that follow rhizotomy. The operation is attended by greater risks, but these might be acceptable if the operation had accomplished what was hoped for. Unfortunately, in about 35 per cent of cases there was recurrence of pain and paresthesias in the same degree as following rhizotomy. For these reasons, tractotomy is now rarely performed for relief of trigeminal neuralgia.

"Decompression" of the root of the trigeminal nerve was proposed by Taarnhøj. It was his concept that the neuralgia might result from some degree of compression and irritation of the root along its course and that relief might result from dividing the meningeal coverings of the root. A certain degree of success attended the operation, but the uncertainty of the means by which the operation accomplished success has led to a variety of other technical procedures in which the nerve root or ganglion is exposed and lightly traumatized. No doubt, in such operations some of the sensory fibers are interrupted, but the principal claim of ad-

vantage made for the operations is preservation of most of the facial sensation. The rate of recurrence of neuralgia following the operations is not established, although it is probably at least 50 per cent. But if even half the patients were relieved of neuralgia by an operation which preserved most of the facial sensation this would be one of the useful methods at our disposal for treatment of this disease.

Other Cranial Nerves. The other cranial nerves which sometimes may be advantageously divided for therapeutic effects are the seventh (nervus intermedius), eighth, ninth, tenth (sensory portion), eleventh and twelfth. These nerves all lie in an area, intracranially, readily exposed by a suboccipital craniotomy of the type used to expose the trigeminal nerve in the cerebellopontile angle. The seventh, ninth, eleventh and twelfth nerves in their extracranial course lie in general proximity in the superior triangle of the neck.

The facial nerve. The sensory division of the facial nerve is the nervus intermedius of Wrisberg. A rare type of neuralgia comparable in quality to trigeminal neuralgia, but principally localized deep in the ear, is believed to implicate the nervus intermedius and relief is obtained by division of the nerve intracranially. The principal risk of the operation is damage to the motor division of the facial nerve with resulting facial paralysis. There is also chance of damage to the auditory nerve which lies in proximity to the facial nerve.

Disturbances of the extracranial portion of the facial nerve are evidenced by either paralysis or paroxysmal spasm of the face. Paralysis is most commonly of the Bell's palsy type but may result from operations on the parotid gland or mastoid bone and from lacerations of the face, skull fracture through the petrous bone, facial nerve tumors, geniculate herpes zoster, birth injury and congenital maldevelopment. Hemifacial spasm is often the sequel of incomplete recovery from Bell's palsy, but the etiologic factors are usually not evident. The condition is to be distinguished from facial tic, or habit spasm, which is a manifestation of neurosis.

Bell's palsy, a unilateral paralysis of the face, involves all branches of the nerve and is sometimes spoken of as "peripheral" in contradistinction to "central," a supranuclear type of paralysis seen for example in hemiplegias in which the distortion of the face is not so profound and motion in the forehead is unaffected. The cause of Bell's palsy

Peripheral Nerves

INJURIES

Peripheral nerve injuries in peacetime, even in busy civilian hospitals, are not common and teaching clinics find a paucity of material suitable for sustaining interest and for demonstrating to students the principles of this important subject. But the two world wars produced thousands of these injuries and it is to the credit of many physicians working under the hardships of war that important advances were made in diagnosis and treatment. Not only was this concerted effort invaluable to the wounded soldier, but it has provided us with far more understanding of civilian nerve injuries than would otherwise have been possible.

The increased number of injuries from automobile accidents has made most physicians aware of the problems of acute trauma, but the point cannot be overstressed that lacerations, fractures and deep tissue bruises of the extremities are likely also to injure important nerves. Failure to recognize the nerve injuries and institute early care can be a serious oversight. It is especially important to identify the presence of a nerve injury before attempting to reduce fractures or encase an extremity in dressings or plaster.

Besides lacerations and fractured long bones there are other common causes for peripheral nerve injuries, such as dislocations; retained hematoma; accidental injury by the surgeon's scalpel; compression by tourniquet, splint or cast, aneurysms; sudden stretching; malposition during sleep or while under anesthesia; birth palsies, adjacent callus formation; repeated local trauma, and injury from injection needles.

From United States Army records, Pollock reported the distribution of peripheral nerve injuries in 7050 cases. There is prob-

ably little variation from this in civilian cases.

Pathology. A divided or seriously traumatized nerve undergoes wallerian degeneration characterized by fragmentation and disappearance of myelin and axons of the segment distal to the injury. Regenerative changes soon begin but in the distal segment are abortive. In the proximal segment, within the first week, protoplasmic bands form providing pathways along which regenerating neurofibrillae of the segment find their way distally. If the nerve has not been divided, the downward growth of neurofibrillae continues to complete the regeneration. Regeneration occurs only from the proximal segment.

If the nerve has been divided, the ends draw apart and scar tissue fills the interval. As regenerating axons of the proximal segment meet the scar tissues in their downward growth, they are turned back to form a coiled bulbous neuroma. A bulbous enlargement also develops at the end of the distal segment but is made up of connective tissue and known as a false neuroma. A neuroma may also form on the proximal end of interrupted fibers of an incompletely divided or "notched" nerve trunk, while intraneural injury to an intact nerve may result in a fusiform neuroma within the nerve sheath, also referred to as neuroma in continuity. Scar tissue resulting from injury or infection adjacent to a normal nerve may occasionally compress the nerve and result in a degree of degeneration, but more often the scar in perineural tissue is a part of a traumatic scar in the nerve.

Symptoms. All of the peripheral nerves in the extremities are made up of afferent, efferent and sympathetic fibers. Interruption of a nerve therefore results in loss of motions subserved by muscles supplied by that nerve and the muscles become atrophied. Sensation of all forms disappears within an area, the pattern of which with slight variations is fairly constant for each nerve. Loss of sympathetic innervation is evidenced by loss of sweating and a degree of warming and reddening in the corresponding area due to loss of sudomotor and vasomotor control. Not only do muscles atrophy in the area supplied by the divided nerve, but many so-

(and small groups of others)	

short-lived paroxysms in the region at the base of the tongue and tonsillar fossa on one side. It is usually induced by swallowing or by internal or external pressure in the tonsillar region. Intracranial division of the glossopharyngeal nerve is a satisfactory form of treatment since it can be counted on to relieve the pain and does not result in any demonstrable neurologic deficit. Experience has shown that in a few instances full relief of pain is not obtained unless several rostral sensory fibers of the vagus nerve are divided as well as the glossopharyngeal nerve. For this reason both nerves are usually divided to insure the desired relief of pain. Rarely, the paroxysms of glossopharyngeal neuralgia are accompanied by syncope resulting from cardiac asystole. The phenomenon is explained by the role which the glossopharyngeal nerve serves in the transmission of afferent impulses arising in the carotid sinus. In the investigation of this striking combination of glossopharyngeal neuralgia and syncope from cardiac asystole, the latter effects can be obliterated by atropinizing the patient while the paroxysms of pain persist. Both can be temporarily abolished by cocainization of the region of the tonsillar fossa and permanently abolished by section of the glossopharyngeal nerve.

Occasionally, and particularly in older patients with arteriosclerosis, hypersensitivity of the carotid sinus and syncopal attacks exist in a degree sufficient to constitute a serious threat to the patient's safety. While the condition can be corrected by local resection of the nerves about the involved carotid sinus, intracranial section of the glossopharyngeal nerve can be performed with as much safety and with more assurance of benefit.

Because intracranial section of the glossopharyngeal nerve interrupts afferent fibers from the carotid sinus which influence the cardiovascular reflexes, there is frequently a significant but temporary rise in blood pressure following rhizotomy. The elevation of pressure, if present, rarely lasts longer than a few hours.

Another instance in which the glossopharyngeal nerve may be involved is in the condition known as the auriculotemporal syndrome and characterized by excessive sweating in the temporal region induced by gustatory stimuli. The condition results from

an abnormal union of the chorda tympani and the auriculotemporal branch of the trigeminal nerve following penetrating wounds or surgical procedures in the region of the parotid. Section of the glossopharyngeal nerve intracranially interrupts the reflex and causes no untoward effects.

The spinal accessory nerve. This nerve has origin from both cranial and spinal levels and is a motor nerve supplying the sternocleidomastoid and trapezius muscles. It has surgical significance in several circumstances. Injury to the nerve from penetrating wounds or surgical procedures in the neck is relatively common. While the loss of muscle function resulting from the division of the nerve is not seriously disabling and is accompanied by certain compensatory muscular actions, repair of the divided nerve should be performed if feasible. Damage of the nerve should be avoided in operations on the neck.

In surgical treatment of spasmodic torticollis the spinal accessory is sometimes divided along with several upper cervical motor roots to accomplish deliberate paralysis of the muscles responsible for moving the head and neck. The operation has limited use but has occasionally proved helpful.

A more common practice in which the spinal accessory nerve is divided is in repair of facial paralysis, particularly that resulting from interruption of the nerve in the removal of acoustic neurinomas in the cerebellopontile angle. In the reparative operation, the main trunk of the nerve is divided and its proximal end anastomosed to the distal end of the facial nerve at its site of emergence at the stylomastoid foramen. An additional refinement of the operation is to divide the descending hypoglossal nerve and anastomose its proximal end to the distal end of the divided spinal accessory nerve. This operation provides a degree of innervation for the muscles supplied by the spinal accessory nerve and, in particular, has value for its cosmetic effects.

The hypoglossal nerve. As an alternate procedure to the use of the spinal accessory nerve for anastomosis to the facial in the alleviation of facial paralysis, the hypoglossal nerve may be used to equal advantage. The choice in use of either nerve for the anastomosis is arbitrary—any advantages or disadvantages being about equal.

arm, the most notable deformity is wristdrop in which there is inability to extend the hand at the wrist or the fingers at the metacarpal joints (Fig. 22). In addition, there is loss of extension and abduction of the thumb and failure of the brachioradialis to contract with forceful flexion at the elbow. It is not possible for the patient to make a firm fist or hold objects in the hand with the wrist in full flexion. With support to the wrist, such as a splint holding the wrist in mid-position or slight cock-up, full strength in grasping is possible. The thumb, deprived of extensor and abduction motions, interferes with flexion of the index finger and patients may hold the thumb aside with the other hand when making a fist.

If the nerve is injured at a high level in the arm there is loss of triceps action and inability to extend the forearm in addition to the other paralyses. If the branch of the nerve in the forearm is injured the typical palsies in the hand occur but without loss of extension at the wrist. Injuries of this kind are not uncommon because of the frequency of lacerations of the forearm and of accidents in surgical operations near the elbow such as removal of the head of a fractured radius.

Sensation is lost in a small area in radial nerve lesions (Fig. 23). It is unimportant to the patient and easily overlooked by the

Figure 23 The sensory loss of radial nerve paralysis is small because of the overlap from adjacent uninjured median and ulnar nerves. The solid black represents loss to all modalities, the dots represent the loss to pinprick, and the straight lines, the loss to touch.

examiner, but if present along with motor palsies, it is a fairly reliable sign of the completeness of the nerve injury. The isolated area of anesthesia lies in the region of the dorsal aspect of the thenar web, adjacent areas of sensory overlap being supplied by the median, ulnar and musculocutaneous nerves.

Median Nerve. Although the commonest site of injury to the median nerve is at the wrist, particularly from cuts by glass, the nerve may be injured at higher levels by stab wounds and lacerations of the arm and forearm or by extensive fractures about the elbow. The most striking changes are in the small muscles in the hand, but with the higher lesions of the nerve, the characteristic loss of flexion of the distal phalanx of the index finger from loss of contraction of the flexor profundus is a highly reliable sign (Fig. 24). This defect is easily demonstrated by having the patient clasp fingers of the two hands in the attitude of prayer, a position which will emphasize the absence of flexion of the index fingers, or the patient

Figure 22 The characteristic wristdrop deformity of radial nerve paralysis

called trophic changes take place, the result principally of disuse and minor trauma to anesthetic tissues. These changes include demineralization of bones, stiffening of joints, atrophy of skin, keratosis, diminution of subcutaneous tissue, ulcerations, overgrowth and ridging of nails and overgrowth of hair. Incomplete severance of a peripheral nerve results in partial loss of the normal functions and tissue changes are less profound. If regeneration of a divided nerve takes place and in the meanwhile proper care of the denervated tissues is provided, these changes can be kept at a minimum and are in large part reversible with reinnervation.

A variety of unpleasant sensations may accompany interruption of peripheral nerve function. They include principally paresthesias, hyperalgesia, stiff and wooden feelings, coldness and pain. The pain is of two varieties, so-called spontaneous pain and causalgia. The former pain is ill defined and inconstant. Its nature is not fully understood, but it probably represents overresponse to unrecognized stimuli from marginal areas.

Causalgia is a term coined by S. Weir Mitchell at the time of the Civil War. It is characterized by intense, persistent, burning pain radiating diffusely up the injured limb and is adversely affected by extremes of temperature, light touch and psychologic stimuli to the degree that an afflicted patient will hold the limb immobile and devote his entire attention to avoiding the stimuli which he soon learns add to his misery. Causalgia occurs only with partial division of nerves and is more likely to result from injuries to the median nerve in the upper limb and the tibial nerve in the lower limb. In spite of many investigations, the cause of causalgia remains an enigma, for none of the proposed theories accounts for all the facts. Unfortunately, the diagnosis is too often used loosely to include many or all discomforts associated with nerve injury. This error becomes important since sympathectomy will usually alleviate causalgia, whereas sympathectomy is wholly ineffective in other complications associated with the injury.

Diagnosis. The recognition of common nerve injuries is not difficult if a few simple tests for motor and sensory functions are employed, particularly in the distal parts of the extremities. One need be acquainted only with the major functions of the principal nerves, though once the existence of a nerve injury is recognized more detailed studies are important.

In examining muscle function to determine the possible interruption of nerve supply, there are several factors to consider. One of these is to have in mind the levels at which branches to various muscles leave the main trunk of the nerve. For example, in testing for possible injury to the median nerve from a wrist laceration one would not conclude that the nerve was intact because the patient could flex the last joint of the index finger. This action is produced by a flexor muscle which receives its innervation from a branch of the median nerve above the wrist.

Other factors to be considered are anomalous or dual innervation of some muscles, such as the flexor and opponens muscles of the thumb, and anomalous muscle action. The latter term is used to describe unusual action of a muscle without reference to its nerve supply. Two types are recognized—supplementary and trick movements. These movements result from (1) tension on paralyzed muscles by their antagonists as occurs when formation of a fist causes extension at the wrist in the presence of radial paralysis; (2) rebound movements which occur when normal muscles are suddenly relaxed and (3) movements resulting from gravity. Failure to recognize these accessory movements leads to error in evaluating the presence and degree of a nerve injury.

In sensory tests for determining nerve injury there is also variability. For example, the autonomous sensory zone of the ulnar nerve in the hand usually includes the fifth finger and the ulnar half of the ring finger, but occasionally it is limited to the fifth finger and median nerve sensory fibers overlap the ring finger.

Numerous electrodiagnostic tests have proved to be useful in the study of peripheral nerve injuries both in determining the degree of the injury and in assessing regeneration. These electrical tests refer particularly to the results of stimulation of various strengths to a motor nerve, the determination of chronaxia as an index of excitability, and electromyography which measures action potentials of muscles. These refinements in examination of nerve and muscle functions are important and at times of great practical use but not always simple to perform or interpret.

Radial Nerve. The intimate relationship of the radial nerve to the humerus makes the nerve particularly vulnerable to injury and, as a result, it is the most frequently injured nerve in the arm. With a lesion in the mid-

tude which is due to unopposed action of the extensor digitorum communis (Fig. 27).

When the lesion is at the elbow or higher there is loss of ability to flex the proximal or distal phalanges of the last two fingers; to abduct or adduct the fingers when they are put in extension by placing the hand on a flat surface; to adduct the thumb; to abduct or oppose the little finger, and to contract the flexor carpi ulnaris. In lesions at the wrist or distal part of the forearm the flexor muscles of the last two fingers and the flexor carpi ulnaris are spared.

There are a few simple tests well suited to demonstrating the loss of function. Inability to bring the fingers together when

held in extension; loss of strength in grip in the ulnar side of the fist; inability to hold an object by adduction of the thumb without flexing it, and inability to approximate the tips of the last three fingers in forming a cone (Fig. 28).

Sensation is lost over the little finger, ulnar side of the ring finger and ulnar side of the hand on both the palmar and dorsal aspects (Fig. 29). Occasionally, sensory overlap will reduce the area of absolute sensory loss to the fifth finger. The sympathetic paralysis accompanying ulnar nerve lesions causes loss of sweating, dryness of the skin and a violaceous discoloration on the ulnar side of the hand.

Combined Median and Ulnar Nerve Lesions. It is not uncommon that both the median and ulnar nerves are divided in lacerating injuries at the wrist. Such injuries also divide the flexor tendons to the hand. Serious disability can be avoided only by the most painstaking care in surgical repair of tendons and nerves followed by diligent after-care. The deformity resulting from the combined nerve injuries represents a composite of the changes seen with each. The simian hand is even more striking than that occurring in median nerve paralysis; the

Figure 29. A drawing which illustrates the loss of all modalities and pinprick and touch sensation in an ulnar nerve lesion.

Figure 24 The deformity of median nerve paralysis is characterized by the position of the thumb in the same plane as the palm of the hand, and inability of the patient to flex the index finger as in making a fist

when asked to scratch with the nail of the index finger while holding the hand on a flat surface will be unable to do so

The striking changes in the hand from atrophy of the small hand muscles due to median nerve paralysis produce a characteristic deformity referred to as ape hand, in which the thenar eminence becomes flattened and the thumb takes a position in the plane of the palm. The single examination most often used in testing for median nerve paralysis is to have the patient oppose the tip of his thumb to the tip of the little finger to form the letter "O". Care must be taken, however, in the testing since supplementary movements develop readily in median nerve palsy, with the exception of flexion of the distal phalanx of the index fingers

The area of sensory loss is over the radial side of the palm and the palmar aspect of the thumb, index, middle and radial side of the ring finger (Fig 25). On the dorsum of the hand the loss is limited to the distal half of the index and middle fingers. Because of extensive overlap from the ulnar and radial nerves there is considerable variability in the extent and degree of sensory loss except for the distal ends of the index and middle

Figure 25 A drawing which represents a typical loss of sensation to all modalities, pinprick and touch as a result of a median nerve lesion.

finger.

skin is lost, resulting in dryness and chapping.

Ulnar Nerve. The most striking changes in ulnar nerve paralysis are in the hand.

The marked degree of wasting in the dorsal aspect of the thenar web and of the interosseous spaces gives the hand a skeleton-like appearance (Fig. 26) and the last two or three fingers assume a clawing atti-

paralysis, moisture of much of the palmar

determine at the time of injury whether a nerve has been anatomically or physiologically interrupted and in nonpenetrating injuries there is seldom need for immediate surgery. Recovery will often occur spontaneously, but it is imperative that frequent periodic examinations be made and, if within three to five months recovery is uncertain or not proceeding satisfactorily, there should then be no hesitation about exploring the nerve surgically. Even earlier exploration is sometimes justified since the attending risks of the operation are negligible, if the nerve is found intact, no harm has occurred. For example, when the radial nerve is caught between the fragments of a fractured humerus, valuable time is saved in healing of both bone and nerve if early exploration is performed. In traction and pressure paralyzes of the brachial plexus or some of its branches, such as the axillary nerve, there is so little to be expected from operation that exploration is rarely required.

In the presence of puncture or lacerated wounds the ideal time for repair of injury to a peripheral nerve is immediately. It is even reasonably safe with the use of antimicrobial therapy to repair a wound as long as forty-eight hours after its infliction and carefully repair a divided nerve. Even if infection develops in the wound the nerve may regenerate or, if a secondary operation and reanastomosis of the nerve are required later, the ends will be approximated and retraction will have been prevented.

In the repair of a divided nerve the approximation of the freshened ends without torsion and by the use of fine silk stitches in the epineurium is sought. When tension on the nerve is necessary in order to approximate the ends, usually sufficient relaxation can be had by flexion or extension of the extremity and immobilization in that position for six weeks. Occasionally, transposition of the nerve will afford the needed gain in length for anastomosis. For example, the radial nerve divided in the midarm has a shorter route in the arm if its position is transposed to the opposite side of the humerus. Larger defects in a nerve have not been successfully treated by interposing grafts but occasionally a defect can be overcome by procedures designed to stretch the proximal segment of the nerve gradually to bring it in approximation with the distal segment.

When important peripheral nerves cannot be repaired one has recourse at times to

muscle and tendon transplantation or arthrodesis of joints with good functional result. Also, occasional good results follow direct implantation of a nerve end into a muscle.

After-care. It is not possible to overemphasize the place of carefully supervised and persistent physiotherapy to the limb following peripheral nerve injury, both before and after surgical repair. The treatments are directed toward preservation of the intact skin, prevention of fibrosis and atrophy of muscles and of contraction of joint capsules. The methods should include application of wet and dry heat, massage, passive movement of joints, electrical stimulation of paralyzed muscles and re-education exercises as soon as possible. Mechanical splints help not only in early use of the limb but provide support in the normal position, thereby preventing contraction at a joint or overstretching of paralyzed muscles.

As a part of the after-care it is important to detect the early evidences of regeneration of the nerve and to follow the progress. One of the oldest and most easily applied tests is Tinel's sign. The test consists of eliciting a tingling or shocklike sensation in the area of sensory distribution of a nerve by tapping gently over the nerve distal to the site of injury. The response is presumed to result from stimulation of regenerating unmyelinated sensory axons. Its accuracy as a test is sometimes questioned but, in practice, it usually proves to be a simple and satisfactory way of following the downward progress in a regenerating nerve.

A highly reliable test which can be utilized when it is important to detect regeneration of motor fibers in a nerve is intraneural stimulation by means of fine wire electrodes introduced percutaneously directly into the nerve.

Electromyography and chronaxy tests, useful means of detecting function in the initial evaluation of the nerve injury, are of equal value in assessing regeneration. The tests can show evidence of reinnervation of a muscle some time before it can be recognized by clinical methods and thus give early assurance that a nerve suture is intact.

Tardy Nerve Palsy. Occasionally palsies of peripheral nerves in the upper extremities develop insidiously years after a fracture which has healed either with excessive callus that compresses the nerve or with a deformity that displaces the nerve and exposes it to easy trauma. Such lesions of the radial or median nerves are not often seen,

thumb is held in abduction in a plane with the palm and the last two phalanges are held in moderate flexion. Sensation is absent in the palmar side of the hand, both sides of the fingers and the ulnar side of the dorsum of the hand, the thumb is partly supplied by overlap from the radial and musculocutaneous nerves. Discoloration from loss of vasomotor control, dryness of the skin and "trophic" changes develop in the entire hand.

Brachial Plexus. Lesions of the brachial plexus are usually designated on the basis of the anatomic site or the mode of injury. The plexus arises from the fifth cervical to the first thoracic nerve roots, the roots combine to form trunks and the trunks to form cords. The modes of injury are traction, pressure and laceration.

A common type of traction injury is that which occurs to the child at birth. If by some means the head and shoulder are forced apart, the upper part of the plexus is stretched and the resulting paralysis of the deltoid, biceps and brachioradialis muscles is referred to as Erb's palsy. The same type of injury is encountered postnatally from a great variety of accidents which cause stretching of the head and neck away from the shoulder, sudden forceful depression of the shoulder or violent downward pull on the arm.

If hyperabduction and traction are put on the arm the injury occurs to the lower part of the plexus and is referred to as Klumpke's palsy. These injuries also occur during childbirth as well as in later years and result in palsies of ulnar or ulnar and median nerve types, often accompanied by Horner's syndrome.

Pressure injuries to the plexus occur in a variety of circumstances, some of the more common being, prolonged dislocation of the shoulder; pressure in the axilla from a crutch, pressure from shoulder braces in prolonged Trendelenburg position, aneurysm of the subclavian artery, and displaced fragments of a fractured clavicle.

Injury to the axillary nerve occurs almost exclusively as a complication of dislocation of the humerus at the shoulder. Usually the continuity of the nerve remains intact though it may be disrupted. The paralysis is recognized by loss of function of the deltoid muscle and by a small patch of sensory loss over the muscle. The motor deficit requires differentiation from disruption of the "cuff" of rotator muscles attached to the humerus.

Lesions of the cords of the plexus more often result from penetrating wounds. In

their effects they simulate the changes which follow nerve injuries more peripherally. Involvement of the medial cord affects areas innervated by the ulnar, lower portion of the median and the medial cutaneous nerves. Lateral cord injuries cause paralysis of the areas supplied by the musculocutaneous and upper portions of the median nerves. Depending on the location of injury in the posterior cord, the thoracodorsal, subscapular, axillary or radial nerves are affected. But it is rare that injury to the plexus involves a single component and recognition of the exact degree of injury is often further complicated by local edema, hemorrhage, traumatic aneurysm or the later development of scar tissue.

Sciatic Nerve. Severance of the main trunk of the sciatic nerve from penetrating wounds is a seriously crippling injury since it results in paralysis of all muscles below the knee and loss of sensation over the outer side of the leg and the entire foot, with the exception of the inner border of the arch. Partial injuries of the sciatic nerve, particularly in the lower part of the thigh, may involve one or the other of its two main divisions, the peroneal and tibial nerves.

Peroneal Nerve. The peroneal nerve is the most frequently injured nerve in the lower extremities as a result of common fractures of the upper end of the fibula and from pressure by casts, splints, traction devices and under-knee rolls. To this list of causes should be added pressure from the crossed-leg position that some people assume for hours while in sitting posture, and resting pressure in emaciated bedridden patients. The deformity is easily recognized by foot drop and alteration in gait characterized by lifting the leg to avoid tripping with the toe. Partial paralysis can be identified by weakness in dorsiflexion of the foot and great toe when an attempt is made to walk on the heel. The sensory loss is over the lateral aspect of the leg and dorsum of the foot to the base of the toes.

Tibial Nerve. Isolated lesions of the tibial nerve are uncommon, particularly from injuries below the knee. The principal motor supply is to the muscles that plantar flex the foot and toes and the paralysis is identified simply by inability to walk or support weight on the toes. Sensation is lost over the sole of the foot except the inner border of the arch. Traumatic ulceration of the sole is a complication which readily occurs if the patient walks on the foot.

Surgical T

Recklinghausen's disease. In this disease there are multiple tumors, sometimes hundreds, varying in size and in degrees of malignancy, though they are usually benign. Less often the same type of tumor occurs as an isolated single lesion. Whether these tumors take origin from the neurilemma, perineurium or epineurium is often difficult to determine and has led to confusion in classification as well as many synonyms (perineural fibroma, neurinoma, neurilemmoma, schwannoma, neurofibroblastoma, neurofibrosarcoma and others).

Since the longest course of peripheral nerves is in the extremities, it is understandable that these neoplasms are most numerous there. In the upper limbs they are somewhat more common on median and ulnar nerves in the forearms but may arise from small nerve branches even in the fingers. In the lower limbs they are usually found on the posterior aspect of the thighs and legs. The neck, with its multiplicity of nerves, is a favorite location and nerve tumors must always be considered in the differential diagnosis of tumors in this region.

Von Recklinghausen's disease is of congenital origin though the tumors do not usually grow to recognizable or disturbing size till young adulthood. Not only are peripheral nerves involved, but in many cases the cranial nerves, spinal nerve roots and sympathetic nerves as well. Associated conditions include scattered areas of pigmentation of the skin producing café au lait spots, abnormalities of bone, cutaneous tumors that are sometimes plexiform or pedunculated, evidence of defective development of the nervous system and other malformations. Any of the tumors may undergo sarcomatous degeneration and become actively invasive in adjacent tissues.

Neurofibromas that involve major nerves and threaten paralysis should be removed and this can usually be accomplished without sacrifice of the nerve if malignant changes have not developed. Tumors known to be or suspected of being malignant should be excised with a wide margin and residual tumor can be expected at times to respond well to radiation therapy. Rarely, such tumors develop distant metastases.

Neuromas are usually understood to be traumatic enlargements at the ends of divided nerves or along the course of injured nerves though true neuromas of benign nature are occasionally found on peripheral and sympathetic nerves. Traumatic neuromas in scars and in amputation stumps as-

sume importance sometimes because of pain associated with them. Surgical revision of painful scars and stumps may be repaying in relief of pain but more often fails due in part to psychologic factors.

Glomus tumors are made up of the end-organs of the nerve together with elements of small blood vessels and smooth muscle. They are rare, but their presence should be recognized by the intense pain caused by pressure over them. They are usually small, rarely more than a few millimeters in size, and though they have been encountered in the subcutaneous tissues in many parts of the body the majority occur in the subungual region of the fingers. The tumors are benign and curable by excision.

Invasion by malignant tumors adjacent to peripheral nerves is often met with, particularly in the brachial plexus and in the lumbosacral plexus in the pelvis. The malignant tumors of the breast and lung which invade the brachial plexus produce neurologic symptoms and signs referred to as the superior sulcus syndrome or Pancoast syndrome. Initial symptoms are pain in areas supplied by the lower part of the plexus, namely, the inner side of the arm and forearm, and also sympathetic paralysis in the limb from involvement of the region of the stellate ganglion. With advance of the disease there are progressive motor and sensory palsies in the limb. Treatment is restricted to appropriate methods of controlling pain.

but tardy ulnar palsy is a well-recognized syndrome that follows injuries about the elbow which alter the carrying angle of the extremity. There is a gradual loss of sensation, sometimes accompanied by paresthesias, in the ulnar distribution of the forearm and hand, more particularly in the fifth finger at the outset. Palsy of muscles supplied by the ulnar nerve also occurs and is usually evidenced first by wasting of the dorsum of the thenar web and the dorsal interosseous spaces. Later, the little finger assumes an abducted position and cannot be approximated to the ring finger. If the process is permitted to go on untreated complete ulnar paralysis may occur.

Surgical treatment should be employed just as early as the condition is recognized since often the best that can be hoped for from surgery in chronic palsy is cessation of the progress with relatively little reversal of the neurologic changes. Treatment consists in moving the ulnar nerve from its position in the olecranon groove to a position in the cubital fossa where it is no longer exposed to repeated stretch and easy trauma.

Median Nerve Compression in the Carpal Tunnel. The insidious development of median nerve palsy in the hand has sometimes been found to occur with osseous deformity of the wrist following fractures and has been appropriately regarded as tardy median palsy. However, the carpal tunnel syndrome of median nerve palsy has come to attention in recent years. The pathogenesis of the syndrome is not entirely understood, but it is believed the nerve somehow becomes irritated and swollen within its tunnel through the volar carpal ligament. The condition is more often seen in patients who have overindulged in some kind of unaccustomed manual work.

The clinical picture is characteristic. Sensory symptoms in the distribution of the median nerve in the hand and fingers constitute the earliest and major disability. Tingling, burning and sometimes painful dysesthesias are usual and, as numbness increases, the patient finds increasing limitation in facile use of the fingers. Motor symptoms and signs are less prominent and may be absent. Moderate wasting and weakness occur in the opponens pollicis and abductor pollicis brevis muscles. A helpful sign in diagnosis is the elicitation of Tinel's sign on tapping over the median nerve at the wrist.

Rest and immobilization of the wrist are sometimes helpful in mild early cases, but in more advanced cases surgical decompression of the nerve by division of the carpal liga-

ment over the course of the nerve has proved to be highly successful.

CERVICAL RIB AND ANTERIOR SCALENE SYNDROME

A cervical rib is a supernumerary rib arising from the seventh cervical vertebra. It is accompanied by a number of variations in anatomic arrangement of the regional structures, including muscles, nerves and blood vessels. A relatively small percentage of those born with cervical ribs develop symptoms and, then, usually not till middle life.

The symptoms and signs resulting from the presence of a cervical rib are due to stretch and compression of the subclavian artery and components of the brachial plexus in the acute angle between the rib and the scalenus anticus muscle. The muscle is a very important part of the arrangement and this is emphasized by the fact that somewhat the same, though less marked, symptoms occur at times in the absence of an extra rib, the anterior scalene syndrome.

The characteristic symptoms include pain, disturbances in sensation, wasting of muscles and peripheral vascular changes. Paresthesias and sensory loss occur along the ulnar side of the forearm and hand. Pain of variable degree is experienced along the inner aspect of the arm and forearm and occasionally in the suprascapular region. Aggravation of pain occurs on rotation of the neck, depression of the shoulder or overhead stretching movements. The same motions may obliterate the radial pulse.

Motor signs include gradual muscle wasting and weakness in the hand in a pattern comparable to that of ulnar palsy. But in more severe cases the muscle changes simulate combined ulnar and median palsy. The peripheral vascular changes due to compression of the subclavian artery are not always present but can be of such severe degree that gangrene develops in one or more fingers.

The treatment consists of dividing the anterior scalenus muscle at its lowest attachment for alleviation of the anterior scalene syndrome. The same procedure may also be adequate for relief in the presence of a cervical rib, but if the nerves of the plexus and the subclavian artery do not appear to have been fully released by division of the muscle the cervical rib is resected.

TUMORS

The commonest primary tumor of peripheral nerves is the neurofibroma. von

The Autonomic Nervous System; The Neurosurgical Relief of Pain

By JAMES C. WHITE, M.D.

JAMES CLARKE WHITE was born in Vienna, Austria, where his father was studying dermatology. His father's family originated in Maine, dating back to their departure from Ireland after the siege of Londonderry. His mother's forebears, too, were New Englanders. Educated at Harvard University and its medical school, he is Chief of the Neurosurgical Service of Massachusetts General Hospital. His interest in the surgery of the sympathetic nervous system and treatment of chronic painful conditions has been long recognized, as has the scholarly presentation of his experiences.

THE AUTONOMIC NERVOUS SYSTEM

Surgery of the autonomic nervous system did not develop with the earlier knowledge of its anatomy, but with an understanding of the function of the craniosacral and thoracolumbar systems of nerves which has been built up by physiologists since the time of Claude Bernard.

The modern neurosurgeon stands particularly in debt to W. H. Gaskell and J. N. Langley of Cambridge University, to François-Franck of Paris and to Walter B. Cannon of Harvard. He is especially indebted to the Cambridge physiologists for the knowledge of the finer arrangement of the autonomic neurons and also for the classification of these nerves into two functionally antagonistic systems: the *craniosacral* or *parasympathetic* system on the one hand and the *thoracolumbar* or *sympathetic* system on the other. The latter leaves the spinal cord only between its first thoracic and second lumbar segments, while the former is given off from the brain stem and the sacral segments (Fig. 30).

Cannon is chiefly responsible for the investigation of the activity of the adrenal medulla. He also discovered that the sympathetic hormone liberated at the nerve endings on smooth muscle, which he called *sympathin*, could not be epinephrine alone. His studies foreshadowed the recognition of the role of norepinephrine as a chemical mediator of nerve impulses in smooth mus-

cle, similar to the role of acetylcholine in striated muscle and the synaptic junctions in sympathetic ganglia.

While Gaskell and Langley were investigating the motor activity of the visceral nerves, François-Franck first conceived of their importance in pain and urged surgeons to remove the cervical sympathetic chains for the relief of angina pectoris.

Surgeons of the present generation have applied these fundamental principles most successfully to cases of peripheral vascular disease, to the reduction of hypertension and to the relief of many types of visceral pain. By regarding each sympathectomy as an experiment in human physiology, certain surgeons have contributed a practical understanding of the subject far beyond the limits of laboratory investigation.

Tests for Evaluating the Response to Sympathectomy.* In addition to determining the degree of arterial occlusion by observation of pulsations in the major vessels of the extremities, the competence of collateral circulation by noting the degree of blanching on elevation, the rate of venous filling, the amount of cutaneous congestion on dependency and the demonstration of arterial obliteration by arteriography, it is necessary to estimate the degree of superimposed vascular tone of neurogenic origin.

* Editor's note: Dr Robert S. Shaw, Director of the Peripheral Vascular Research Laboratory at Massachusetts General Hospital, assisted in revising the text concerned with vasospastic disorders.

This initial steady state may be secured by one hour's exposure in an environment of 68° F. and 50 per cent relative humidity. Peripheral autonomic activity is determined by observing the effect of body warming or nerve block on skin temperature and digital plethysmographic pulse in the exposed extremity. Sudomotor activity is determined by measuring electrical skin resistance.

Measurement of circulatory impairment produced by organic vascular occlusive disease requires the elimination as far as possible of circulatory decreases from vasoconstriction. The patient studied is warm and his peripheral vessels are maximally dilated. Study of limb circulation during the reactive hyperemia, after release of a tourniquet by a method such as venous occlusion plethysmography, allows the best determination of circulation without vasoconstriction.

Prediction of the degree of warming which can be expected after sympathetic denervation is accurate in Raynaud's disease when there is only a slight degree of endarteritis, although the initial increase in temperature of the hands will not be fully maintained. In the advanced case, complicated by sclerodactylia, any increase in circulation is limited by the constricting fibrosis of the skin and subcutaneous tissue. In occlusive vascular disease, when lumbar sympathectomy is so often helpful for relief from cold feet with burning discomfort, the predicted degree of improvement follows lumbar sympathetic ganglionectomy in seven out of ten individuals. In the others the permanent clinical response is likely to be somewhat better than that predicted. Measurement of cutaneous temperatures alone, together with clinical observation of color and sweating, will permit as useful an evaluation as more complicated methods of recording digital pulsations.

For the investigation of obscure painful syndromes, such as causalgia, or unusual types of visceral pain, paravertebral injection can give a selective block of the sympathetic pathways. From the response to these tests it becomes possible to select certain patients for treatment by sympathectomy, without recourse to the more mutilating procedures of cutting posterior roots or the spinothalamic pain pathways in the spinal cord. Procaine block constitutes the most accurate form of diagnostic test and should be used in all doubtful cases.

Vasospasm in Peripheral Vascular Disease.

There is a wide variation in vascular tone in the hands and feet of individuals who have

no evidence of occlusive vascular disease. This ranges from the warm, dry-handed individual, whose extremities maintain brisk circulation in relatively cool surroundings, to the person chronically afflicted with cool, moist hands and feet. In certain young individuals who are often emotionally unstable the palms of the hands and soles of the feet are continuously wet with perspiration, cold and are often cyanotic as well. This may persist even in a relatively warm environment. The hyperhidrosis is due to abnormal activity of the sympathetic sudomotor nerves, the coldness and cyanosis of the extremities in part to evaporation of moisture as well as to excessive vasoconstriction. Both hyperhidrosis and acrocyanosis respond in a dramatic fashion to regional sympathetic denervation.

Raynaud's disease. The condition first described by Maurice Raynaud in 1862 is characterized by phasic color changes of the fingers and, to a lesser extent, of the hands and feet as well. The extremities are sensitive on exposure to cold and even more so to general chilling of the body. This syndrome includes a number of conditions. The typical Raynaud's syndrome consists of blanching ischemia or cyanosis with numbness of the tips of the fingers. On warming, the digits develop a reddish hue with tingling, followed by return of normal color and sensation. As the condition advances there is a tapering of the fingers with the appearance of superficial ulcers at their tips, which are slow to heal. Sclerodermatous thickening of the skin and stiffness of the fingers may later complicate the picture, leading to necrosis of the finger tips and a severely crippled hand. The condition most often develops in young adults, in women more often than men. It usually affects the hands, much more rarely the feet, in a remarkably symmetrical fashion with the thumbs much less involved than the other digits. The radial and pedal pulses are unaffected.

There are a number of factors which lead to the phasic color changes known as Raynaud's phenomenon, most of which are related to organic vascular disease. It may be seen in various forms of endarteritis, as an early sign in rheumatoid arthritis, scleroderma, dermatomyositis, lupus, in cases of cervical rib with compression of the subclavian artery and in men who use vibrating tools. Sir Thomas Lewis, who contributed so much to our understanding of this condition, concluded that the primary disorder is hypersensitivity of smooth muscle in the

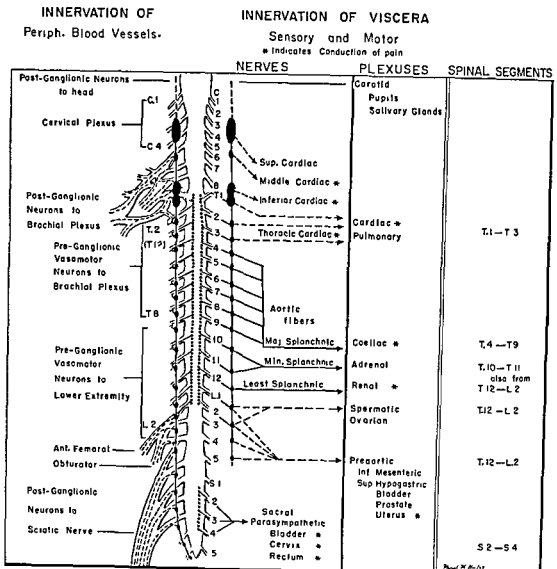

Figure 30 The outgoing vasomotor and sudomotor fibers to the extremities from the lateral horn of the spinal cord are illustrated diagrammatically on the left side. On the right side are shown the mixed visceromotor (sympathetic) and viscerosensory (posterior spinal root) fibers, together with the principal visceral plexuses which they supply and the spinal segments from which they are derived. Preganglionic sympathetic axons are indicated by continuous lines and postganglionic by interrupted lines. Direct preganglionic connections with the stellate ganglion via the first thoracic nerve are marked by dotted lines. Recent anatomic studies suggest that they are often present, possibly in C8 as well. The asterisk indicates the presence of pain fibers running to the posterior roots.

It should be pointed out that there is rarely an actual increase in sympathetic activity. This is seen only in a few younger individuals with cold, clammy cyanotic hands and feet. This condition usually occurs in emotionally unstable individuals and signifies abnormal vasomotor tone. In normal individuals, the vasomotor tone is normal. This, however, by no means precludes a valuable response to sympathectomy, especially when the individual happens to have a high degree of normal tone. It is in these patients that laboratory tests to predict the

increase in warming of the cold, uncomfortable extremity prior to a contemplated sympathetic denervation are most important.

Evaluation of the degree of sympathetic vasomotor activity and particularly of the effect of various procedures or pharmacologic agents on vascular tone is complicated by the great lability and responsiveness of the autonomic nervous system to environmental stimuli, emotional states, digestive activity and many other factors. Study of the peripheral circulatory manifestations of autonomic activity therefore requires initial equilibration of the patient in a basal state, in a quiet room with constant temperature and humidity.

This initial steady state may be secured by one hour's exposure in an environment of 68° F. and 50 per cent relative humidity. Peripheral autonomic activity is determined by observing the effect of body warming or nerve block on skin temperature and digital plethysmographic pulse in the exposed extremity. Sudomotor activity is determined by measuring electrical skin resistance.

Measurement of circulatory impairment produced by organic vascular occlusive disease requires the elimination as far as possible of circulatory decreases from vasoconstriction. The patient studied is warm and his peripheral vessels are maximally dilated. Study of limb circulation during the reactive hyperemia, after release of a tourniquet by a method such as venous occlusion plethysmography, allows the best determination of circulation without vasoconstriction.

Prediction of the degree of warming which can be expected after sympathetic denervation is accurate in Raynaud's disease when there is only a slight degree of endarteritis, although the initial increase in temperature of the hands will not be fully maintained. In the advanced case, complicated by sclerodactylia, any increase in circulation is limited by the constricting fibrosis of the skin and subcutaneous tissue. The extremities are sensitive on exposure to cold and even more so to general chilling of the body. This syndrome includes a number of conditions. The typical Raynaud's syndrome consists of blanching ischemia or cyanosis with numbness of the tips of the fingers. On warming, the digits develop a reddish hue with tingling, followed by return of normal color and sensation. As the condition advances there is a tapering of the fingers with the appearance of superficial ulcers at their tips, which are slow to heal. Sclerodermatous thickening of the skin and stiffness of the fingers may later complicate the picture, leading to necrosis of the finger tips and a severely crippled hand. The condition most often develops in young adults, in women more often than men. It usually affects the hands, much more rarely the feet, in a remarkably symmetrical fashion with the thumbs much less involved than the other digits. The radial and pedal pulses are unaffected.

There are a number of factors which lead to the phasic color changes known as Raynaud's phenomenon, most of which are related to organic vascular disease. It may be seen in various forms of endarteritis, as an early sign in rheumatoid arthritis, scleroderma, dermatomyositis, lupus, in cases of cervical rib with compression of the subclavian artery and in men who use vibrating tools. Sir Thomas Lewis, who contributed so much to our understanding of this condition, concluded that the primary disorder is hypersensitivity of smooth muscle in the

digital arteries to cold. It is still a debatable point whether pallid asphyxia of a digit can take place primarily from local susceptibility to cold or whether there must first be endarteritis with superimposed vasospasm. Biopsies have shown striking degrees of occlusion and recanalization of the digital arteries. It is certain, as Lewis pointed out, that neurogenic vasoconstriction of normal arteries can never produce blanching ischemia of a finger.

Occlusive vascular disease. Patients with thromboangitis obliterans and arteriosclerosis may benefit from release of neurogenic vasoconstriction if they have a high degree of normal vascular tone. Patients favorable for sympathectomy can be selected by appropriate clinical and laboratory examination, as described. It should be pointed out, however, that sympathectomy is less commonly used today because of the improvement in technique of reconstructive vascular surgery permitted by arteriography and arterial grafting.

Treatment of Peripheral Vascular Disease by Release of Neurogenic Vasoconstriction. There are no very effective vasodilator drugs for therapeutic use. Raudixin is helpful in 50-mg doses twice daily, especially in the group of younger, emotionally unstable individuals, as are estrogens in women at the time of menopause. Priscoline has also been recommended but is ineffective in severe cases. In using ganglionic blocking agents it must be remembered that any generalized vasodilatation may do more harm than good by depriving an extremity with occlusive vascular disease of blood by shunting the blood to other areas of lower vascular resistance.

When patients with favorable cases of peripheral vascular disease have given up smoking, have failed to respond to medication and cannot be protected by wearing warm clothing, mittens and woolen socks, they may often be helped by sympathetic denervation.

Sympathectomy has the great advantage that it can produce relatively local release of arterial tone where it is most needed. The operation must produce complete interruption of the vasoconstrictor fibers to the part

both preganglionic and postganglionic, to regenerate. Essentially complete recovery of vasoconstrictor tone in the upper extremities occurred in a patient submitted nine years previously to removal of the ganglia from the inferior cervical through the second thoracic on the right side and a preganglionic sympathectomy as described by Smithwick on the left. Time and again regeneration of vasomotor and sudomotor fibers has been observed in the upper extremity and even in the legs when inadequate lengths of lumbar ganglionic chain were removed. Proof that these recurrences are due to regeneration is given by the return of vasodilatation which occurs following procaine block or a secondary, more radical sympathectomy.

It has been stated that the phenomenon of sensitization of denervated smooth muscle in the arterial walls to circulating epinephrine prevents satisfactory lasting vasodilatation after cervicothoracic ganglionectomy, as this operation results in degeneration of the postganglionic network of vasoconstrictor neurons. While this general principle of sensitization to epinephrine after postganglionic denervation, which was described by Cannon and Rosenblueth, is undoubtedly true in experimental animals, it is relatively unimportant in man. For this reason, the so-called Telford-Smithwick form of preganglionic sympathectomy for increasing circulation in the upper extremity is no more effective than removal of the ganglia, except the patient is spared the mild disfigurement of a Horner's syndrome. Experience with this operation has shown that regeneration of vasoconstrictor fibers is likely to take place. A second objection is that recent anatomic evidence strongly points to the possibility of sympathetic rami containing vasoconstrictor fibers leaving the cord via the first thoracic and possibly in the eighth cervical nerve as well. Some fibers appear to reach the brachial plexus directly through the stellate ganglion, probably also through the middle cervical and vertebral ganglia, as well as coming up from lower levels (Fig. 30). The really essential point is to remove a considerable length of the ganglionated chain, as far down as the fourth rib and preferably upward above the stellate ganglion to include the vertebral and middle cervical ganglia, which lie in relation to the subclavian artery. This operation may be carried out extrapleurally by resecting the central ends of the first and second ribs or by using a supraclavicular approach. The latter gives the surgeon a better opportunity to remove

racic and lumbar vertebrae

Operative measures designed to interrupt vasoconstrictor tone must take into account the extraordinary proclivity of these fibers,

the upper portion of the stellate and the small ganglia around the subclavian and origin of the vertebral artery.

For the lower extremity, the second, third and fourth lumbar ganglia should be resected. This is best carried out posteriorly through a modified renal incision. The retroperitoneal space behind the cecum or sigmoid is entered and the lumbar chain is exposed in the gutter formed by the outer edge of the vena cava or aorta, the vertebrae and the psoas muscle.

In experienced hands the risk from thoracic and lumbar ganglionectomy is remarkably slight. The chief essentials to justify surgical intervention are accurate diagnosis and demonstration by procaine injection or other diagnostic procedures that an adequate degree of vasodilatation will ensue. In these circumstances, thoroughly satisfactory and lasting improvement has followed resection of the lumbar ganglia in a large series of patients with Raynaud's disease treated at the Massachusetts General Hospital. Surgical attempts to achieve a lasting effective vasoconstrictor denervation of the upper extremity have been beset with many difficulties, particularly by regeneration after preganglionic operations or limited ganglionectomy, and also because Raynaud's disease in the hands is likely to be more severe than in the feet, as a result of complicating obliterative arteriolar disease and secondary fibrosis of the skin and subcutaneous tissue. Really satisfactory results may therefore be anticipated only in patients with the early uncomplicated form of the disease. In patients with severe attacks of digital blanching and ischemia or in those with advanced scleroderma in whomendarteritic changes have already occurred, a really satisfactory permanent recovery of circulation cannot be expected.

Young men with occlusive vascular disease due to thromboangitis obliterans (Buerger's disease) may derive much benefit from the elimination of superimposed neurogenic constriction, especially those with increased sweating and an active vasomotor tone. These individuals can be selected by appropriate tests. Improvement in circulation generally turns out to be better than the predicted degree. This gives considerable relief from cold extremities and related pain in most cases. It should be pointed out, however, that follow-up studies have demonstrated no advantage in collateral circulatory development, in blood flow through the muscles or in measured ability to walk with-

out claudication. The resultant vasodilatation occurs mainly in the cutaneous vessels and the digits. In the absence of actual gangrene, but with a critically low pedal circulation, lumbar sympathetic ganglionectomy should often be performed in the younger group of patients, in whom reconstructive arterial surgical procedures are not feasible, even if all the major arteries have been obliterated.* A significant number of major amputations may thus be avoided. However, in the presence of painful digital ulceration or incipient gangrene it is better first to crush the peripheral nerves above the ankle. This operation is far more effective for relieving pain and can be counted on to cause maximal vasodilatation for a period of several weeks. If adequate collateral circulation fails to develop, lumbar ganglionectomy can be carried out at a later date with the assurance of producing a corresponding degree of vasodilatation which is likely to be permanent.

Lumbar ganglionectomy has also been used with increasing frequency in recent years in arteriosclerosis, in both its senile and diabetic forms, especially when abnormal sweating and cyanosis indicate a high degree of vasoconstrictor tone. Selection of patients must be made with extreme care, because in some with critically low peripheral circulation gangrene has been precipitated by sympathectomy. It should be emphasized that sympathectomy is of little benefit in cases of rapidly advancing arterial occlusion, whether for relief of pain, for improvement of deep ulceration or for increasing walking tolerance in cases of intermittent claudication. Individuals with atheromatous occlusion at the aortic bifurcation and others with iliac, femoral or popliteal occlusion should all be submitted to arteriography and treated by arterial grafting whenever limited obliteration makes this feasible.

Prophylactic Sympathectomy in Acute Arterial Occlusion. Sudden occlusion of a main artery to an extremity by embolism, trauma or ligature may lead to gangrene. The risk of this complication is greater in the leg than the arm as its collateral circulation is less competent. In the case of popliteal aneurysms, reconstructive surgery by means of arterial grafting is now a practicable sub-

* To secure the maximum

the upper leg, removed along is done on both sides, the power of ejaculation may be lost and the male patient rendered sterile but not usually impotent.

stitute for ligation and excision or for endoaneurysmorrhaphy. In the cases of embolism or penetrating arterial wounds with threatened circulatory insufficiency in the arm or leg, therapeutic efforts should be directed at restoring major vessel continuity whenever this is possible. Some protection, however, may be gained against critical reduction in collateral blood flow by repeated injections of the stellate or lumbar ganglia with Xylocaine or by means of a fine polythene catheter inserted through a 17-gauge needle. Continuous drip infiltration may thereby be safely maintained over a period of several days if small amounts of penicillin are added to the anesthetic solution.

Pain in Extremities. Pain in the forearm and hand or in the ankle and foot after trauma and amputation of digits is a rare but serious complication.

This usually takes the form of cutaneous hyperalgesia in the extremity or a deep aching or burning sensation which runs up the limb. There is often a patchy decalcification of the bones in the hand or foot. This condition is most commonly seen in individuals with cold, cyanotic, moist extremities and can often be relieved by interruption of the underlying vasospastic state. Even temporary interruption of sympathetic impulses by paravertebral procaine block of the regional sympathetic ganglia may clear it up, especially if repeated on a number of occasions. When pain is relieved, but recurs as the vasodilator response to procaine disappears, thoracic or lumbar sympathectomy can be counted on to give lasting relief. It is evident that the pain is not transmitted by the sympathetic nervous system but that unknown physiologic factors which produce it are activated by the efferent sympathetic discharge.

This is likewise true of another post-traumatic state which came to attention during World War II because of the intense suffering and incapacity which it produces. Typical causalgia, as described by Weir Mitchell in 1864, consists of dysesthesia and burning pain with extraordinary exacerbations aroused by emotional stimuli. It develops after partial injury of a peripheral nerve from a penetrating wound. Experience by military surgeons has shown that diagnostic procaine injection followed by regional sympathectomy has resulted in effective relief in the great number of cases reported during the last war. A critical review of sixty-two patients suffering from causalgia revealed that they were effectively relieved

of their burning pain for periods of up to seven years, with the exception of a few improperly selected individuals and those with inadequate sympathetic denervation.

The effect of sympathectomy on post-traumatic pain from the extremities is not known. In contrast to visceral innervation, the sympathetic does not appear to be an accessory afferent pathway for pain arising from injury below the shoulder or groin. Only visceral sensation can be evoked on stimulation of sympathetic ganglia in conscious patients, except in causalgic states. It seems most likely that causalgic pain is produced by efferent sympathetic impulses short-circuiting in the area of the injured nerve to the somatic sensory fibers.

The Autonomic Nervous System and the Regulation of Blood Pressure. The regulation of blood pressure for the varying demands of the body on changes in external and internal environment is mediated by the autonomic nervous system. The central control lies in groups of cells situated in the medulla and diencephalon. Trauma, encephalitis and tumors which injure these areas occasionally produce profound changes in the vasomotor tone.

Carotid sinus syndrome. An important peripheral mechanism for the reflex regulation of blood pressure and heart rate has been found to lie in the aortic nerves and in the carotid sinus. The latter, which has nervous connections with the vagus, the cervical sympathetic and the medulla through a branch of the ninth cranial nerve, may become hypersensitive and produce an interesting clinical syndrome. Depending on the efferent pathway involved, three forms of this carotid sinus syndrome are found, cardioinhibitory, vasodilator and cerebral attacks with convulsions. The first type is due to a vagal reflex and can be abolished by atropine, the fall in arterial tension can be prevented by ephedrine, but the cerebral variety can be treated only by denervation of the sinus. This can be carried out either by local periarterial stripping of the carotid bifurcation or by intracranial section of the glossopharyngeal root. Numerous patients with spontaneous epileptic seizures induced by slight pressure on an irritable sinus have been relieved by operation.

Essential hypertension. Aside from rare conditions such as pheochromocytoma, occlusive disease of the renal artery, Cushing's syndrome and coarctation of the aorta, the etiology of hypertension remains unknown. In the common essential form of hyperten-

sion significant lowering of the blood pressure, relief of symptoms and modification of degenerative vascular changes have been achieved in the last twenty years by surgery, diet and drugs. Following the lead of Adson, Peet, and Smithwick extensive resection of sympathetic ganglia and splanchnic nerves has been widely used, though the exact physiologic mechanism by which lowering of the blood pressure may result is unknown. There is no evidence that essential hypertension is related to an abnormal increase of vasoconstrictor activity.

The operations formerly advocated fell into three main groups: bilateral one-stage supradiaphragmatic ganglionectomy and splanchnicectomy, subdiaphragmatic resection of the splanchnic nerves and upper lumbar ganglia and the combined, more radical thoracolumbar denervation. The last requires a two-stage operation, performed first on the right side, then on the left. Even more radical operations, by the thoracic transpleural and transdiaphragmatic route or by removal of a portion of the eighth and twelfth ribs with extrapleural and extraperitoneal exposure of the paravertebral trunks, have permitted resection of the entire vasoconstrictor outflow from the upper thorax down through the third lumbar ganglia. Surgical experience has demonstrated that thoracolumbar denervation is in general the most satisfactory procedure and that more radical sympathectomies are likely to be followed by unpleasant complications without a significantly greater or more lasting reduction of blood pressure.

Of suitably selected patients under fifty years of age, and preferably under forty years, who are free from advanced cerebral, coronary and renal damage and who still have a labile blood pressure which falls with bed rest and sedation, it is to be expected that over 80 per cent will have satisfactory symptomatic relief and somewhat under 50 per cent a worth-while early reduction in blood pressure. Smithwick has reported a significant improvement in retinal lesions, reduction in cardiac hypertrophy with reversal of abnormal electrocardiographic patterns, and a notable decrease in headache. The operative mortality is low, less than 3 per cent. On the other hand, the operation is followed by much discomfort and requires a long period of convalescence. Long-range studies of the earlier patients operated upon at the Massachusetts General Hospital have shown that less than a fourth

maintained a blood pressure below the critical range after three to five years. Even among the group whose blood pressure has fallen to a normal range for one or more years, many have subsequently returned with recurrent hypertension and serious cerebrovascular, coronary or renal complications.

In recent years an impressive number of drugs have been developed that lower blood pressure, reverse organic vascular changes and relieve symptoms with a high degree of effectiveness. These comprise the derivatives of the *Rauwolfia serpentina* group of alkaloids, singly or in various combinations with chlorothiazide and other diuretics, and hydralazine ganglionic blocking agents. Medication with these promising new drugs has almost entirely superseded surgical and dietary treatment. Sympathectomy may now be recommended only for the rapidly advancing malignant variety of hypertension with papilledema in the period before irreversible renal damage has set in.

Other patients in whom operation may be worth while are those who will not or cannot follow the exacting details of medical treatment and a few individuals with angina pectoris or resistant tachycardia. The two latter conditions derive a specific benefit from transthoracic sympathectomy if the entire thoracic chain is removed on each side up through the first thoracic ganglion, as this high denervation interrupts the cardiac sensory and accelerator impulses. As a result of the increasing effectiveness of medical therapy, surgical intervention in hypertension is now rarely undertaken.

Sympathectomy in the Treatment of Disordered Visceromotor Activity. Correction of states of abnormal activity on the part of the autonomic nervous system is possible in certain rare but incapacitating conditions. Two of these, hyperhidrosis of nervous origin and tachycardia, are of special interest.

Hyperhidrosis of nervous origin. Excessive sweating limited to the palmar surfaces of the hands and soles of the feet is occasionally seen in young, nervous persons of either sex. It differs from perspiration in a hot environment, in which the whole surface of the body is involved except the palmar and plantar surfaces, and is distinctly a reaction on the part of the sympathetic system to psychogenic stimuli. This type of sweating may become so intense under nervous strain that beads of water drip from the fingers. As a result it becomes embarrassing to shake hands, delicate materials

Figure 31 The nerve supply of the pelvic viscera

are wet in handling and when rubber gloves are worn they become filled with sweat. The same condition may also involve the feet, with the result that the socks and even the shoes are constantly wet through. In these circumstances the skin becomes foul smelling and macerated and is therefore a prey to fungus infections. Psychotherapy, radiation or local applications fail to give relief, but the results of sympathectomy are usually satisfactory and frequently give dramatic psychic as well as local benefit. Only the second and third thoracic or the corresponding lumbar ganglia need be removed. It is inadvisable to perform sympathectomy for both upper and lower extremities. This may lead to excessive sweating over the chest and abdomen, which can be as annoying as the original condition.

Control of tachycardia by sympathectomy. Experiments on animals have suggested that many ectopic cardiac rhythms are produced by epinephrine and abnormal activity on the part of the cardiac accelerator nerves. Clinical application of this work has demonstrated that upper thoracic sympathectomy is an effective method of controlling recurrent bouts of paroxysmal atrial tachycardia and fibrillation which cannot be stopped by medication. After bilateral resection of the upper four thoracic ganglia, the frequency and severity of these attacks are greatly reduced, but the pa-

tients may continue to experience asystole and occasional episodes of tachycardia on emotional strain, excessive fatigue or other illness. The attacks, which were formerly so frequent, severe and resistant to medication that the victim was totally incapacitated, become infrequent, mild and readily controlled by quinidine. The majority of patients are able to lead normal lives.

No untoward results have followed complete sympathetic denervation of the heart, as it can still accelerate on reduction of vagal tone or through the chemical response to epinephrine.

In a number of neurogenic disorders associated with impaired emptying of the bladder and rectum, release of "sympathetic inhibition" was formerly advocated. Further investigation has shown that detrusor reflexes are in no way influenced by the pelvic sympathetic nerves in the inferior mesenteric and superior hypogastric plexuses (Fig. 31). Control of micturition and defecation is mediated entirely by the parasympathetic sacral nerves. There is no effective neurosurgical operation for the so-called cord bladder. Megacolon, for which sympathectomy was often performed with slight benefit, can now be cured by resection of the paralyzed rectosigmoidal portion of the large bowel.

It is interesting to recall that cervical and

lumbar ramisection, proposed by Royle and Hunter for the reduction of muscular tone, although not generally accepted for the treatment of this particular condition, led directly to the present operations which are so frequently utilized in peripheral vascular disease. With the possible exception of the much discussed subject of hypertension, experience with sympathetic neurosurgery in the conditions discussed has now reached a point where the effects of operation are well known and its therapeutic value in properly selected cases is thoroughly established.

NEUROSURGICAL RELIEF OF PAIN

Severe pain from any source, if persistent, soon becomes a major problem to both its victim and his physician. There is a group of patients in whom there is no possibility of eliminating the cause of the pain and no other recourse save resort to narcotic drugs or interruption of sensory pathways. Narcotic medication is justifiable only when the patient has a fatal illness advanced to the point that he has but a month or two to live. Relief by neurosurgery has now reached the point where its risks and possible complications are distinctly less than those of narcotic addiction. In patients with malignant disease it is therefore best to consider desensitization at about the time the sufferer first demands medication stronger than codeine, but yet has a life expectancy of several months or more. In nonmalignant neuralgias it is important to be sure that the patient has an underlying organic cause for his pain and is not psychoneurotic.

Spinothalamic Tractotomy. The fiber tract

which carries pain from the skin, deep tissues and viscera runs in the opposite anterior quadrant of the spinal cord. It is most accessible to the surgeon's knife at the level of the second thoracic or second cervical vertebra, where only a very limited laminectomy is required to make a small opening in the dura, snip an attachment of the dentate ligament and rotate the cord by this convenient handle. The technique of anterolateral section is illustrated in Figure 32. The pain fibers vary greatly in their distribution, sometimes being relatively compact and superficially placed between the insertion of the dentate ligament and the origin of the anterior spinal roots. This convenient arrangement, commonly illustrated in anatomic textbooks, is unfortunately by no means the general rule. In order to obtain consistently a high level of analgesia it is best to make as complete a transection of the anterior quadrant as possible, with due respect to the corticospinal tract posteriorly and the anterior spinal artery in the midline ventrally, and then to test the level of sensory loss on the operating table. This requires local anesthesia, which may be supplemented by light Pentothal sodium and nitrous oxide anesthesia, allowing time for the patient to awaken for testing.

When this operation has been properly performed, it should result in satisfactory loss of sensibility to pain in 90 per cent of patients. After high thoracic cordotomy, this level usually reaches to the xiphoid, at times as high as the nipple, but sometimes only to the umbilicus. Analgesia will not remain complete in an additional 10 to 15 per

Figure 32 Technique of anterolateral cordotomy at upper thoracic level

cent of individuals over the course of weeks or months, but relief of pain will be permanent in the remaining 75 per cent. After high cervical cordotomy, maintenance of effective analgesia above the upper thoracic level cannot be assured in a high proportion of the subjects. We have been able to maintain relief from pain of brachial plexus distribution in less than half our subjects. A slightly higher level of analgesia can be gained by tractotomy in the medulla, although at an appreciably greater risk. If the pain tract is cut in the mesencephalon, analgesia may be produced over the entire opposite side of the body, but at considerable risk of mortality and also of burning dysesthesia which resembles the thalamic syndrome.

When the pain tract is cut unilaterally at the level of the second cervical or second thoracic vertebra, mortality is slight and very few patients will suffer lasting motor or bladder impairment. On the other hand, when bilateral transection is required in malignant disease, prolonged urinary retention will be a problem in about 30 per cent of the subjects. This complication is particularly likely to occur when there is pre-existent injury of the detrusor innervation. Other disagreeable sequelae are few as almost no useful sensation is lost save perception of heat and cold.

Experience in 165 cordotomies has taught us that pain in malignant disease is relieved in over 70 per cent of the patients, with the exception of those with cancer of the breast and lung. In these the high level of pain and the tendency for the brachial plexus to be invaded make terminal relief a difficult problem. The failures in 30 per cent of our patients who have had cordotomy have been due to incomplete division of the pain fibers or spread of pain into nonanalgesic areas. In nonmalignant conditions, such as the lightning pains of the tabetic, the neuralgias of the lower extremity which follow gunshot wounds of the cauda equina, surgical incisions and amputations, pain has been controlled in 73 per cent of the patients. Contrary to the experience of those who make more limited incisions in the anterolateral quadrant, we have had impressive success even in patients with phantom pain following lower extremity amputation. Pain in the ghost foot or hand has rarely persisted when analgesia has remained complete. Enduring high analgesia, however, has been difficult to achieve in the upper extremity, especially in patients who have had shoulder amputations.

Posterior Rhizotomy. Division of posterior spinal roots interrupts all forms of sensation. As a result, the denervated area feels numb, if the sensory roots of the brachial or lumbosacral plexus are cut, the anesthetic limb will become a useless appendage lost in space; the desensitized bladder is atonic and incontinent. Furthermore, even if appropriate anesthesia is produced, pain sometimes continues. This is the case with postherpetic pain, yet this condition, when the painful scars are favorably situated in the trunk or a lower extremity, can be relieved by cordotomy if an adequate level of analgesia is obtained. For these reasons, section of posterior spinal roots has limited usefulness. It can be counted on to relieve angina pectoris and pain of carcinomatous invasion of cervical nodes and also the postoperative intercostal neuralgia which occasionally follows thoracotomy. In the latter condition, at least two sensory roots must be cut above and below the scarred nerve, in order to avoid sensory overlap.

Section of Cranial Sensory Nerves. Section of cranial sensory nerves is much more effective and useful than spinal rhizotomy. Pain is carried from the face, nasal passages, internal ear and oropharynx by the trigeminal, nervus intermedius (sensory component of the seventh nerve), glossopharyngeal and vagus nerves. These structures may be cut on one side without too great handicap, except for the lowest vagal rootlets which innervate the muscles concerned with swallowing, closure of the glottis and vocal cords.

Pain in malignant disease of the pharynx. When the posterior tongue, tonsillar region or upper pharynx is invaded by cancer, pain may be persistent and severe. It can often be relieved by section of the sensory roots of the fifth, ninth and tenth cranial nerves in the posterior fossa, but when pain is felt deep in the ear it is best to cut the nervus intermedius as well and the upper three cervical posterior roots if the lymph nodes in the neck are involved. *Intramedullary* section of the descending trigeminal root is an alternate procedure and is often successful when the lower cranial nerves are invaded by malignant disease. In order to interrupt the pain fibers of the seventh, ninth and tenth cranial nerves, which accompany the fifth in this descending bulbar tract, it is necessary to make the incision into the medulla at or slightly above the level of the obex (the lower end of the fourth ventricle) and cut to a depth of 3.5 mm between the nucleus gracilis dorsally and the spinotha-

lamic tract ventrally. Section of the descending bulbar tract should deliberately include a few of the contiguous fibers of each of these structures. A cut of this extent should be followed by some evidence of spinothalamic tract injury, viz., slight contralateral hypalgesia of the torso and extremities, in addition to analgesia of the ipsilateral face and oropharynx, but no signs of posterior column involvement. At this level of the medulla some of the fibers entering the restiform body may be injured and the patient may develop a mild degree of lateropulsion. This is usually of brief duration, while the ensuing interruption of pain fibers from the fifth and lower cranial nerves is satisfactory and enduring. It is advisable to carry out this procedure with the patient under local anesthesia with supplementary Pentothal sodium and nitrous oxide anesthesia so that he can be awakened and tested after cutting the tract.

Frontal Lobotomy. In patients with certain types of pain, specific sensory denervation is extremely difficult, if not impossible. The conditions in which this is most often the case include atypical facial neuralgia, the Pancoast syndrome of carcinoma of the thoracic apex, and malignant conditions involving both sides of the pharynx or neck. Other unfortunate individuals in the late stage of malignant disease, in addition to their pain, may suffer extreme mental anguish from the fear of imminent exsanguination or strangulation and from the disfigurement and the foul odor of sloughing tissue. In terminal malignant disease, unilateral complete transection of the frontal white matter, as proposed by Scarff, may give gratifying relief without serious psychologic impairment. As this improvement rarely lasts for more than six months, it is not suitable for atypical facial neuralgias or other benign conditions.

Bilateral frontal lobotomy, which stops mental suffering as well as pain, can only be justified if done in a strictly limited way. As originally advocated by Freeman and Watts, it results in such grave psychologic deterioration that the nonpsychotic individual will become a hopeless vegetable no longer interested in his friends or able to associate with others. This operation, therefore, cannot be recommended for any person who may survive for a prolonged period or hopes to lead a useful life. For these individuals, Grantham and Spurling have proposed limited destruction of the medial inferior white matter in front of the anterior

tips of the ventricles on both sides by electrocoagulation, increasing the area of destruction in stages to the point where the patient is freed from fear of his disease and concern about his suffering.

This procedure has been modified recently by implanting fine wire electrodes under roentgenographic control in the inferior medial quadrants of white matter in each frontal lobe. These are left in place for several weeks while the frontal association fibers are coagulated by radiofrequency current. This is applied in stages as the electrodes are withdrawn with the patient under careful observation. By this means it is often possible to carry out a graded leukotomy just sufficient to eliminate pain and all need for narcotics, as well as the fear of imminent death, without serious psychologic deterioration.

Sympathectomy. Pain from the heart, aorta and abdominal viscera can be relieved with a high rate of success by regional sympathetic denervation. In order to obtain satisfactory results, the pathologic process must be confined within the capsule of the organ involved. Malignant disease of the lung, gastrointestinal or genitourinary tracts generally is not painful until it has invaded the parietal pleura, peritoneum, bone or the major spinal nerve plexuses. In these circumstances, the appropriate posterior spinal roots or the spinothalamic tract must be sectioned.

The classic conception of the autonomic nervous system was that its preganglionic and postganglionic neurons were purely regulators of visceral activity. It is now generally conceded that many afferent fibers capable of transmitting pain and of activating visceral reflexes reach the posterior sensory root system from the cardiac, splanchnic and mesenteric plexuses.* The fibers transmitting visceral pain pass through the paravertebral ganglia, the white rami communicantes and the mixed spinal nerves to reach their cells of origin in the posterior root ganglia. Their dendrites end in the posterior horn of spinal gray matter, where they establish synapses with the secondary sensory neurons that decussate in the cord and ascend to the brain in the opposite spinothalamic tract.

Studies of the conduction of pain from the internal organs have demonstrated two main types of afferent conduction:

1. Referred pain of the type described by

* On numerous occasions White and Sweet have evoked diffuse abdominal pain on stimulating lumbar ganglia or splanchnic nerves in patients at operation under regional block anesthesia.

Head and Mackenzie. This theory assumes that visceral afferent impulses run only as far as the posterior horn of the spinal cord. It is further postulated that impulses reaching this region from a diseased organ set up an irritable focus and thereby reduce the sensory threshold to stimuli from the surface of the body. As a result, the constant bombardment of afferent impulses from the skin, which normally fails to reach the level of consciousness, becomes magnified into painful sensation. This type of pain is sharp, it is not necessarily localized over the organ in question but is often referred to such a distant area as the medial side of the arm in angina pectoris. This occurs because some of the cardiac rami enter the spinal cord at the same level as the ulnar and medial brachio-cutaneous nerves.

2 Direct transmission of visceral pain. Over sixty years ago Ross wrote that in addition to sharp, well-localized referred pain, a diseased organ might also cause a deep, ill-defined sense of discomfort. He called the latter splanchnic or direct visceral pain. This important contribution was lost sight of in later years, but there is good evidence that visceral pain may reach the thalamus without any referred cutaneous mechanism, because it can be evoked in animals and in human beings after all cutaneous afferent impulses have been interrupted. This direct type of sensory conduction presumably carries the dull aching form of visceral pain which is vaguely localized in the region of the diseased organ. Lewis has shown that pain from all deep structures, whether skeletal muscle, fascia, periosteum or an internal organ, is fundamentally alike. It is of the slow-conduction type and poorly localized.

The reason for this is the paucity of sensory nerve endings in the viscera as well as in all other deep structures except periosteum. Accurate localization of painful stimuli is present in the skin, and to a lesser extent in the periosteum, because of the large number of overlapping sensory terminals. There is also evidence that there are not sufficient numbers of secondary pain fibers in the spinothalamic tract to supply all the primary neurons in the posterior root system. Hence it seems probable that many primary visceral and cutaneous afferent fibers must share secondary spinothalamic neurons in common, thus accounting for the frequent reference of visceral pain to surface areas which receive their innervation over similar posterior spinal roots.

In the last analysis, there is no fundamen-

tal difference between sensation of pain of visceral origin and from deep somatic structures.

Whenever an inflammatory process spreads from a viscus to the neighboring parietal pleura or peritoneum, the intercostal nerves become the chief pathway for conduction of pain, e.g., in pleurisy and appendicitis or cholecystitis with local peritoneal involvement. This is also the case in carcinoma of the abdominal viscera. As long as the disease remains confined within the visceral capsule, interruption of sympathetic innervation will stop pain, but once the retroperitoneal nerves and lumbosacral plexuses become involved the posterior spinal roots or spinothalamic tract will have to be severed.

Pain from the bladder, prostate, cervix uteri and rectum differs from that arising from the abdominal viscera. It is transmitted over the inferior hypogastric plexuses and posterior roots of the second to fourth sacral nerves (Fig. 31). While no form of pain from the heart, pulmonary parenchyma or abdominal organs is conducted over the cranial portion of the parasympathetic outflow, the vagus carries sensation from the esophagus, trachea and main bronchi.

From a knowledge of these mechanisms it is obvious that pain from the heart and abdominal organs can be interrupted by destroying either the regional sympathetic ganglia or their rami. Section of the posterior spinal roots or section of the contralateral spinothalamic tract will also produce a loss of visceral sensation, but at the risk of more serious complications and loss of cutaneous sensibility, whereas sympathectomy is accompanied only by regional vasomotor and sudomotor paralysis.

Table 4 summarizes the segmental afferent innervation of the thoracic and abdominal organs. The affected segments are easily identified by paravertebral procaine injection in patients with intractable visceral pain. When the ganglia through which the pain is transmitted have been accurately located, they can be resected surgically or destroyed by alcohol injection.

The method of treating cardiac pain by paravertebral alcohol injection is the safest method of treating pain in patients with angina pectoris or aortic aneurysm, but accurate injection is technically difficult to achieve in about 10 per cent of the subjects. Furthermore, in a small number of patients the alcohol sets up irritating neuritis, which may last for a number of weeks. The advantages of injection therapy for the patient

Table 4. Sensory Innervation of the Viscera

ORGAN	SUPERFICIAL AREAS TO WHICH PAIN IS REFERRED	VISCERAL RAMI WHICH CARRY PAIN
Heart	Precordium and inner arm	T_1-T_4 or T_4
Lung	No evidence of pain until parietal pleura and intercostal nerves are involved	
Liver and gallbladder	Right upper quadrant distress with pain referred to right scapular region	T_7-T_9
Pancreas	Epigastrium and midback	T_7-T_9
Stomach	Epigastric region	T_7-T_9
Small intestine	Umbilical region	T_9-T_{10}
Colon and rectum	Suprapubic region	$T_{11}-T_{12}$, also S_2-S_4
Kidney	Loin and groin	$T_{11}-L_2$
Ureter	Loin and groin	L_1-L_2
Bladder	Suprapubic region, penis and perineum	S_2-S_4
Uterus	Suprapubic region and lower back	$T_{11}-L_4$

who is a poor risk so far outweigh the disadvantages that this method should be used for patients with advanced cardioaortic disease. If it fails to give sufficient relief, posterior root section may be undertaken later. For the patient with angina pectoris who is a fair surgical risk, resection of the upper four thoracic sympathetic ganglia is the ideal surgical procedure. In the case of cardiac pain it has been shown that the direct thoracic cardiac nerves, which connect the upper thoracic sympathetic ganglia with the heart, account for the frequent failures of the older operation of cervical sympathectomy. When these ganglia or the upper four posterior thoracic spinal roots are destroyed, pain from the heart is consistently interrupted.* White and Bland have reviewed results in eighty-five patients with medically intractable angina pectoris who have been treated by paravertebral block or upper thoracic ganglionectomy. These statistics and the results recorded by Lindgren and Olivecrona from their series of seventy-three upper thoracic ganglionectomies demonstrate the effectiveness of sensory denervation of the heart.

In addition to its effectiveness in the relief of otherwise intractable cases of angina pectoris, regional sympathetic denervation has proved to be equally valuable in the treatment of numerous other forms of visceral pain, such as may be encountered with

aneurysm of the aorta, as a complication of surgery of the gallbladder and in pancreatic fibrolithiasis, nephralgia and idiopathic dysmenorrhea. In patients with upper abdominal visceral disease it is best to remove the splanchnic nerves and lower thoracic sympathetic ganglia by a paravertebral approach, resecting the central portion of the eleventh rib on one or both sides. For relief of chronic renal pain, which can be reproduced by ureteropelvic distention and relieved by subdiaphragmatic splanchnic block, it is best to perform modified thoracolumbar sympathectomy. This is carried out by removing the eleventh and twelfth the posterior . . .

The splanchnic . . . through its medial arcade and can be resected from the celiac ganglion well up into the chest, together with the lower thoracic and first lumbar ganglia on the painful side. For relief of idiopathic dysmenorrhea, the presacral or superior hypogastric plexus is resected from the bifurcation of the aorta and down between the common iliac arteries (Fig. 31). Mortality and annoying complications after these procedures have been exceedingly rare and the incidence of relief from pain most gratifying. Success depends on careful selection of patients who are free from psychoneurosis or severe narcotic addiction and whose pain arises from within a diseased viscus, relief during a preliminary trial period of procaine block must be clear cut and the denervation anatomically complete.

Pain in disease of the bladder, which may be persistent and severe in tuberculosis and chronic interstitial cystitis despite all known methods of treatment, cannot be relieved by sympathectomy. The reason for this is that the afferent pathway is over the second to

* Although pain in the precordium and arm is consistently relieved after these operations for medically

intractable angina pectoris, palpitation or

fourth sacral nerves, as illustrated in Figure 31. These posterior roots cannot be divided with impunity, as this takes away all sense of bladder and rectal filling, thereby resulting in overdistention and incontinence. Bilateral anterolateral cordotomy can be utilized as a last resort, but may also be followed by lasting retention of urine in a small proportion of cases. This procedure must also be used for the relief of unbearable pain in malignant disease of the viscera. In these circumstances pain does not become a problem until the disease process has invaded the retroperitoneal and lumbosacral plexuses or metastasized to bone, so that interruption of viscerosensory nerves can no longer be effective.

Congenital Anomalies

By DONALD D. MATSON, M.D.

DONALD DAHROW MATSON is a New Yorker by birth and was educated at Cornell University and at Harvard Medical School. From the beginning, he directed his training to the field of neurologic surgery in children based upon a wide training in general surgery. The Children's Hospital of Boston offers him a wide experience from which to make his contribution upon the congenital anomalies of the nervous system.

Congenital anomalies of the central nervous system and its coverings include spina bifida and cranium bifidum in their various forms, congenital dermal sinus tracts, craniosynostosis and congenital types of hydrocephalus.

Spina Bifida. Spina bifida designates a developmental abnormality of the spinal axis. It is one of the commonest of all embryologic anomalies. Probably more than 20 per cent of all individuals will show some minor defect of a vertebral spine or laminae if survey roentgen ray examinations are made. Most of these defects occur in the lumbosacral area and have no clinical significance.

Whereas the cause of spina bifida is not known, the embryologic circumstances under which it occurs have been widely investigated and documented. In brief, this anomaly represents a segmental abnormality of the invagination and separation of the neural ectoderm from the epithelial ectoderm, as well as a simultaneous abnormality in the development of the primitive mesoderm which gives rise to the bone and other supporting structures surrounding the neural tissue of the same segments.

If the fundamental embryologic error is limited to mesodermal derivatives there is no protrusion to the surface of intraspinal contents and the condition is known as spina bifida occulta. If the spine defect is accompanied by protrusion of meninges to the surface to form a sacklike structure containing spinal fluid, the condition is known as *spina bifida with meningocele*. If the embryologic defect includes involvement of the neural tube as well, so that neural tissue protrudes to the surface adherent to the meninges, or if neural tissue fails to develop and function

normally, the condition is known as *spina bifida with myelomeningocele*. If there is complete absence of all of the covering structures so that neural tissue itself presents on the surface of the body, the condition is known as *spina bifida with rachischisis*. These varieties of embryologic fusion defects or spinal dysraphism are diagrammed in Figure 33.

From a surgical point of view the lesions which are of importance include certain types of spina bifida occulta, spina bifida with meningocele, and some of the cases of spina bifida with myelomeningocele. Most patients with spina bifida occulta do not need any treatment and most infants born with rachischisis are stillborn or survive only a very short period.

The presence of *spina bifida occulta* may be indicated by one of several types of cutaneous defects: an abnormal growth of hair located over the midline of the back and tapering off laterally on either side; irregular, cutaneous angiomatous malformations over, or just away from, the midline; soft, poorly circumscribed, nontender, subcutaneous masses of fatty tissue, dimpling of the skin in the midline, or just off the midline, with fixation of the epithelium to the underlying tissues. Children with any of these cutaneous defects should have roentgenograms of the spine made to establish the extent and type of the underlying spina bifida and should be watched carefully throughout growth for evidence of neurologic disturbance.

Spina bifida occulta may first be detected because of a neurologic deficit involving the lower extremities or control of the vesical and rectal sphincters. Often at about the

Figure 33 A, *Spina bifida occulta* The intraspinal contents do not protrude to the surface, although often the site of the underlying bony defect is marked by a cutaneous abnormality B, *Spina bifida with meningocele* A meningeal sac containing cerebrospinal fluid protrudes on the surface, but there is no abnormality of spinal cord or nerve roots C, *Spina bifida with myelomeningocele* Nerve roots of the cauda equina are atrophic, displaced and adherent to the exposed membranous sac D, *Spina bifida with rachischisis* Disorganized and distorted central neural tissue is exposed directly to the surface

beginning of the second year of life when these youngsters begin to stand and walk, minor degrees of muscle weakness and gait disturbance are noted for the first time. Valgus, varus and cavus deformities of the feet, atrophy of the lower leg musculature, deformities of the toes, real or apparent shortening of one leg, pelvic tilt and limp have all been noted as primary complaints in

patients with spina bifida occulta. Every infant or child who shows a congenital type of scoliosis, dislocation of the hips, pelvic asymmetry, positional deformity of the feet, absence of deep tendon reflexes or evidence of sensory impairment in the lower extremities should have careful roentgenograms made of the entire spine in search of congenital abnormalities. Occasionally the pri-

mary complaint may be incontinence of urine, intractable bed wetting or difficulty in bladder and bowel training.

The diagnosis of spina bifida occulta is confirmed by roentgen ray examination. Anteroposterior films show widening of the spinal canal, absence of the spinous processes, defects of the laminae, pedicles or vertebral bodies or possibly the occurrence of anomalous bony masses. Myelography in patients with spina bifida occulta may disclose the presence of fatty tumors, dermoid cysts, intraspinal meningoceles or fibrous cords which distort the subarachnoid space. Spina bifida occulta may occasionally be found at more than one level.

One type of spina bifida occulta of particular interest is that in which a spicule of bone arising from the posterior aspect of a vertebral body protrudes through the spinal canal, dividing its contents into two separate compartments. This is known as *diastematomyelia*; it can be recognized on plain x-ray films by the presence of a midline shadow of increased density in an area of fusiform widening of the spinal canal and can be confirmed by contrast myelography, in which the subarachnoid space is shown by the opaque medium to be completely split by the midline spicule of bone. Treatment consists of complete removal of the midline spicule of bone, lysis of adhesions from dura to the divided cord and conversion of the double dural compartment into one space.

Surgical treatment in spina bifida occulta is limited to those patients who show evidence of a progressive neurologic disturbance as growth proceeds and who by myelography demonstrate an intraspinal deformity which might lend itself to operative correction or improvement. This includes removal of bony spicules, dermoid cysts and fibrous bands which actually compress neural structures. Overenthusiastic attempts to remove poorly circumscribed masses of fat may result in increased neurologic damage. This should be regarded usually as prophylactic rather than corrective surgery, its purpose being to allow further growth of the nervous system to proceed in as nearly a normal fashion as possible.

There is tremendous variation in the anatomic location, morphologic type and clinical importance of *meningoceles* and *myelomeningoceles* associated with spina bifida.

By far the commonest location is in the lumbosacral area, as might be expected, since this region is the last to be closed when

the neural ectoderm is folded inward from the surface (posterior neuropore). The next most common location is in the suboccipital, high cervical area (anterior neuropore). Meningocele occurs with much less frequency in the low cervical, thoracic and upper lumbar segments. They may occasionally be multiple. Anterior meningoceles protruding into the thorax, abdomen or pelvis rarely occur.

The visible lesion may be simply a flat, partially epithelized membrane overlying a bony defect limited to one vertebral segment or there may be a huge sac, several inches in diameter, even at the time of birth, with a thin, almost transparent, partially ulcerated membrane through which can be seen directly or by transillumination with strong light many nerve elements. A meningocele sac may have a narrow stalklike base so that it is a pedunculated lesion or it may be broadest at its base, extending over several vertebral segments. Associated with many meningoceles and myelomeningoceles there is often an overgrowth of fibrous, poorly circumscribed fatty tissue, so that in actuality a large proportion of the mass is not spinal fluid but fat. Except in very small lesions, the margins of the bony defect can usually be palpated. It may be impossible to tell on physical examination, particularly when the sac is well covered with skin or thickened, contracted, translucent fibrous membrane, whether nerve elements are present or absent.

In addition to the size, location and covering of the meningocele itself, the most important clinical features pertain to the neurologic status of segments caudal to the lesion and to the adequacy of cerebrospinal fluid circulation, that is, the presence of hydrocephalus. In early infancy, the limitations of neurologic examination are many. However, gross neurologic deficit is readily apparent and the most careful motor, sensory and reflex evaluation possible of the lower extremities, as well as estimation of sphincter tone, should always be carried out. Structural deformities of the feet and legs are common in the presence of paraplegia.

Abnormalities of spinal fluid circulation resulting in hydrocephalus constitute complications to the management of infants with spina bifida. This hydrocephalus is due to malformation in the development of the hindbrain (Arnold-Chiari malformation). This anomaly consists of caudal displacement of the cerebellum through the foramen

magnum, elongation, distortion and caudal displacement of the medulla oblongata and fourth ventricle, and partial to total obliteration of the cisterna magna and surface subarachnoid pathways of the upper cervical spinal cord by dense adhesions. In general, the most severe degrees of obstruction of spinal fluid circulation at the level of the foramen magnum due to the Arnold-Chiari malformation are seen with the more severe degrees of paralysis associated with lumbosacral myelomeningocele. Hydrocephalus is rarely seen with spina bifida occulta or simple meningocele.

There are few general rules which can be laid down for the surgical treatment of meningoceles and myelomeningoceles. Each patient's problem must be individualized. Ordinarily, simple meningoceles, without evidence of loss of neurologic function, should be repaired as soon as it is technically feasible. There is general consensus among neurosurgeons that operation is contraindicated in early life in the presence of total paralysis of both lower extremities and complete loss of bladder and rectal sphincter control; this is true whether or not hydrocephalus is present at the time. It is neither justifiable nor desirable to perform surgical procedures when it is clear that the infant is hopelessly and permanently crippled and that the chances of surviving to adult life in a useful fashion without encountering disastrous infection and gross retardation from progressive hydrocephalus are so limited. It must be explained carefully to all parents that removal of a myelomeningocele can do nothing to bring about recovery of paralyzed limbs or sphincters and, indeed, operation may increase the neurologic deficit if adequate repair is to be achieved. If children with paraplegia survive on nonoperative treatment and appear to be developing normally, excision of a myelomeningocele may be indicated later in life as a means of facilitating nursing care and paraplegic ambulation.

In the presence of less than total paralysis associated with myelomeningocele, the lesion should be repaired at a time when the judgment and experience of the neurosurgeon indicate that the most favorable result can be achieved. In general, delay in surgical repair increases the possibility of an optimum technical result. It is essential before such repair is performed that hydrocephalus be absent or controlled by surgery or spontaneous arrest. The leaking meningocele of the newborn should probably be repaired at

once if any attempt at all is to be made to preserve life.

Home management, in lieu of or awaiting surgical treatment, consists of regular careful cleansing of the meningocele and the surrounding skin, protection of the sac against friction by a padded circular dressing, physiotherapy to the lower extremities and regular observations for evidence of hydrocephalus.

The purposes of surgical treatment are removal of the protruding, disfiguring mass and prevention of infection. Operation should be performed in such a way as to protect all neural elements and not produce or increase any neurologic deficit. Electrical stimulation of the various roots in and adherent to the sac may be useful to this end. An attempt is made to obtain a tight closure of the meningocele membrane supplemented by firm approximation of the overlying skin and subcutaneous tissues. No attempt is made to repair the bony defect. Cerebrospinal fluid circulation must either be normal or surgically corrected before meningocele repair is performed.

The treatment of spina bifida is not finished with completion of a successful operation. It should be the surgeon's responsibility to see that head measurements are obtained for many months following operation to detect the possibility of delayed onset of hydrocephalus. It should also be his duty to see that orthopedic help is obtained to direct physiotherapy and rehabilitation of musculoskeletal abnormalities and to see that bladder and bowel training are pursued when these are indicated.

Cranium Bifidum. Fusion defects of the cranial vault occur much less frequently than do their spinal counterparts. At the Children's Medical Center in Boston more than six times as many spinal meningoceles have been treated as have *encephaloceles*. An *encephalocele* may occur at any point over the cranial vault or base, usually in the midline or extending to the midline. By far the commonest region is in the occipital area where, in a high proportion of subjects, there is associated intracranial malformation of nervous tissue or spinal fluid pathways. Rarely, *encephaloceles* may project into the nose, nasopharynx or orbit. Whenever a nasal polyp is discovered in an infant, the possibility that it may represent an anterior *encephalocele* must be entertained to avoid the tragedy of creating a spinal fluid fistula and perhaps meningitis from excision of the lesion transnasally.

It is important that x-ray films of the skull be made whenever there is a midline protrusion of any kind on the scalp. If there is an underlying bony defect, the lesion should be considered as an encephalocele and operation carried out with preparations for dealing with intracranial structures should this be necessary.

Morphologic types of encephalocele are comparable to those lesions seen along the spine. The external sac may be tiny or may, indeed, be as large as the baby's head itself. It may be pedunculated on a very narrow stalk, passing through a small cranial defect, or the base of the lesion may be its broadest point. The sac may be covered with normal skin or with membrane of varying thickness. The encephalocele may communicate only with the surface subarachnoid pathway and contain simply clear spinal fluid with no neural tissue. It is often obvious on clinical inspection or transillumination that large amounts of brain tissue extend into the sac. Hydrocephalus is commonly associated with encephaloceles in the suboccipital area because of impairment of spinal fluid circulation through the posterior fossa.

Except in instances of obvious irreversible brain damage where fatality appears imminent, surgical removal of encephaloceles is usually indicated in early life. The difficulties of feeding, handling and ordinary nursing care are such with an encephalocele of any size and the psychic trauma to the par-

ents is so great in the presence of this disfiguring and unconcealable mass that the earliest possible excision is highly desirable. Surgical treatment consists in amputation of the membranous sac with watertight closure of the neck supplemented by firm approximation of the skin in two layers. If progressive hydrocephalus is present, this must be controlled before or at the same time the encephalocele is excised. Large bony defects in the frontal and parietal regions should usually be closed by cranioplasty either at the same time or subsequent to excision of the meningocele. It is ordinarily unnecessary to repair the bony defect in suboccipital lesions.

Congenital Dermal Sinus. When the neural ectoderm fails to be pinched off completely from the epithelial ectoderm, a persistent tract or tube of stratified squamous epithelium may extend from the skin surface inward to the central nervous system. Such a congenital dermal sinus may occur at any point along the midline of the central neural axis. It is most commonly found in the same areas where spina bifida is seen, namely, in the lumbosacral region and in the suboccipital region.

Because of its persistent communication with the skin surface, such a sinus tract serves as a constant potential port of entry for infection into the central nervous system and its coverings. In addition to the danger of infection, such a dermal stalk may, by its

Figure 34 Longitudinal section illustrating congenital dermal sinus in the lumbar region expanding into dermoid cyst within the spinal canal (Ingraham, F. D., and Matson, D. D.: *Neurosurgery of Infancy and Childhood*. Charles C Thomas, Publisher).

magnum, elongation, distortion and caudal displacement of the medulla oblongata and fourth ventricle, and partial to total obliteration of the cisterna magna and surface subarachnoid pathways of the upper cervical spinal cord by dense adhesions. In general, the most severe degrees of obstruction of spinal fluid circulation at the level of the foramen magnum due to the Arnold-Chiari malformation are seen with the more severe degrees of paralysis associated with lumbosacral myelomeningocele. Hydrocephalus is rarely seen with spina bifida occulta or simple meningocele.

There are few general rules which can be laid down for the surgical treatment of meningoceles and myelomeningoceles. Each patient's problem must be individualized. Ordinarily, simple meningoceles, without evidence of loss of neurologic function, should be repaired as soon as it is technically feasible. There is general consensus among neurosurgeons that operation is contraindicated in early life in the presence of total paralysis of both lower extremities and complete loss of bladder and rectal sphincter control; this is true whether or not hydrocephalus is present at the time. It is neither justifiable nor desirable to perform surgical procedures when it is clear that the infant is hopelessly and permanently crippled and that the chances of surviving to adult life in a useful fashion without encountering disastrous infection and gross retardation from progressive hydrocephalus are so limited. It must be explained carefully to all parents that removal of a myelomeningocele can do nothing to bring about recovery of paralyzed limbs or sphincters and, indeed, operation may increase the neurologic deficit if adequate repair is to be achieved. If children with paraplegia survive on nonoperative treatment and appear to be developing normally, excision of a myelomeningocele may be indicated later in life as a means of facilitating nursing care and paraplegic ambulation.

In the presence of less than total paralysis associated with myelomeningocele, the lesion should be repaired at a time when the judgment and experience of the neurosurgeon indicate that the most favorable result can be achieved. In general, delay in surgical repair increases the possibility of an optimum technical result. It is essential before such repair is performed that hydrocephalus be absent or controlled by surgery or spontaneous arrest. The leaking meningocele of the newborn should probably be repaired at

once if any attempt at all is to be made to preserve life.

Home management, in lieu of or awaiting surgical treatment, consists of regular careful cleansing of the meningocele and the surrounding skin, protection of the sac against friction by a padded circular dressing, physiotherapy to the lower extremities and regular observations for evidence of hydrocephalus.

The purposes of surgical treatment are removal of the protruding, disfiguring mass and prevention of infection. Operation should be performed in such a way as to protect all neural elements and not produce or increase any neurologic deficit. Electrical stimulation of the various roots in and adherent to the sac may be useful to this end. An attempt is made to obtain a tight closure of the meningocele membrane supplemented by firm approximation of the overlying skin and subcutaneous tissues. No attempt is made to repair the bony defect. Cerebrospinal fluid circulation must either be normal or surgically corrected before meningocele repair is performed.

The treatment of spina bifida is not finished with completion of a successful operation. It should be the surgeon's responsibility to see that head measurements are obtained for many months following operation to detect the possibility of delayed onset of hydrocephalus. It should also be his duty to see that orthopedic help is obtained to direct physiotherapy and rehabilitation of musculoskeletal abnormalities and to see that bladder and bowel training are pursued when these are indicated.

Cranium Bifidum. Fusion defects of the cranial vault occur much less frequently than do their spinal counterparts. At the Children's Medical Center in Boston more than six times as many spinal meningoceles have been treated as have *encephaloceles*. An encephalocele may occur at any point over the cranial vault or base, usually in the midline or extending to the midline. By far the commonest region is in the occipital area where, in a high proportion of subjects, there is associated intracranial malformation of nervous tissue or spinal fluid pathways. Rarely, encephaloceles may project into the nose, nasopharynx or orbit. Whenever a nasal polyp is discovered in an infant, the possibility that it may represent an anterior encephalocele must be entertained to avoid the tragedy of creating a spinal fluid fistula and perhaps meningitis from excision of the lesion transnasally.

The diagnosis should be made in early infancy. It should be suspected from the shape of the infant's head and can be confirmed definitely by x-ray examination. Roentgenograms reveal readily the characteristic contour of the skull and satisfactory films even of newborn infants will demonstrate which have closed prematurely.

The contour of the cranial vault depends upon which sutures are prematurely closed, that is, if growth is restricted in any one direction an attempt at compensation results in overgrowth in whatever direction expansion is still possible. If a single suture is involved, the skull expands in a direction parallel to this closed suture. Thus, if the sagittal suture is closed at birth, the head ex-

pands abnormally in an anteroposterior axis and appears elongated and narrow (Fig. 35). If the coronal suture is fused at birth there is abnormal lateral growth so that the skull appears wide, with a broad, flattened forehead (Fig. 36). If the coronal suture is fused prematurely on only one side, this flattening is asymmetrical. When there is premature fusion of all the cranial sutures, growth is restricted in all directions and the head remains small with a tendency for it to expand upward in the direction of least resistance, that is, against the region of the anterior fontanel (Fig. 37).

In addition to cranial deformity, there may frequently be facial abnormalities due to involvement of the sphenoid and orbital

Figure 35 Anteroposterior and lateral appearance of infant with premature closure of the sagittal suture.

Figure 36 Anteroposterior and lateral appearance of infant with premature closure of the coronal suture. Often the orbital and nasal bones are also involved with much more deformity of the facial structures than is shown in this illustration.

attachment to neural tissue, distort the normal growth and function of the latter. At any point along a congenital dermal sinus, and particularly at its innermost extent, there may be expansion of the sinus into a cyst (Fig. 34). Such a cyst may continue to grow in size because of desquamation of the stratified squamous epithelium which lines it and because of collection of sebaceous material from the glands within this skin. When such a mass occurs within the cranial vault or the spinal canal, it may act as any other expanding lesion to interrupt neurologic function by local compression of the brain or spinal cord or it may cause interference with the normal circulation of cerebrospinal fluid. In addition, such a cyst may be the site of abscess formation because of the constant possibility of infection from the surface.

Every child who exhibits a sinus tract opening in the midline of the scalp or of the back should have x-ray films made of this area. If there is an underlying defect in the bone of the skull or of the spine, surgical excision of the sinus tract should be carried out forthwith. This should be done by a neurologic surgeon who is prepared to trace the tract into the central nervous system in itself if necessary.

In the presence of an unexplained meningeal infection, particularly due to *Staphylococcus pyogenes* var *aureus* or *Escherichia coli*, the entire skin of the midline over the neural axis should be examined carefully for the existence of a sinus tract opening. Whenever there is a history of meningeal infection or of redness, swelling, tenderness or of thin or purulent discharge from the midline sinus tract opening, complete excision of this sinus tract should always be carried out. The results of surgical treatment after abscess or meningitis has been established in patients with congenital dermal sinus are so poor that it is of the utmost importance to discover and remove these lesions prophylactically. Under the latter circumstances, the surgical treatment is simple and the prognosis excellent.

Neurenteric Cyst. A rarer type of embryologic spinal defect is the neurenteric cyst. In this condition there is a cystic structure within the spinal canal usually anterior to the cervical or thoracic spinal cord. The cyst wall itself or a fibrous stalk from it may be intimately attached to the anterior surface of the cord. There is usually a circular defect through one or more vertebral bodies easily visible on x-ray films of the area and there may be an overlying spina bifida oc-

culta as well. The cyst itself is lined ordinarily by mucosa of entodermal origin which may have the characteristic appearance of esophagus, stomach, intestine or respiratory tract. This entity represents a failure of the mesoderm to separate completely the entoderm from ectodermal layers as they arise from the primitive mass of totipotential cells. Treatment consists of intraspinal removal of the cyst or stalk attached to the cord, followed if necessary by transthoracic excision of the extraspinal portion of the cyst wall.

Craniosynostosis. For reasons entirely unknown, but presumably as a result of a genetic defect in the germ plasma, the membranous bones of the skull, which normally are completely separated from one another at the time of birth, occasionally become fused prematurely. This condition, preferably called craniosynostosis, may involve any of the cranial sutures alone or in combination.

The human brain normally expands rapidly during the first two to three years after birth and then at a steadily decreasing rate until the individual is twelve years of age. In order for this normal growth of the brain to be possible, the bones of the skull must remain ununited and capable of expansion. Therefore, if premature obliteration of the cranial sutures is present at birth, significant restriction of subsequent brain growth may occur.

It is important to differentiate carefully between craniosynostosis, in which there is primary union between the bones of the cranial vault that restricts growth of the brain, and microcephaly, in which there is secondary approximation but not union of the bones of the cranial vault which occurs because of failure of the brain itself to grow and push the skull ahead of it. In craniosynostosis, the primary defect is in the membranous bones of the skull and the condition is subject to surgical treatment. In microcephaly, there is primary agenesis of the brain itself which causes secondary failure of the skull to expand normally. The head is

Craniosynostosis appears twice as commonly in males as it does in females. Fusion of the sagittal suture alone is by far the most common variety. Coronal suture closure alone is the next most common and, following this, total synostosis of all the sutures is most frequent. Other single suture closure or combinations of various sutures are less frequently seen.

face subarachnoid pathways. It seems clearly established that when the exit of any of the ventricles of the brain is obstructed, that ventricle becomes dilated, and when the surface subarachnoid pathways are destroyed there is enlargement of the cisternae at the base of the brain as well as of the entire ventricular system.

Hydrocephalus refers to a pathologic condition characterized by an increase in the size of the ventricles and sometimes also part of the surface subarachnoid pathways as a result of the cerebrospinal fluid at some time being under increased pressure. The controlling factor in production of hydrocephalus appears to be the rate of reabsorption of cerebrospinal fluid into the vascular system and not its rate of formation. Hydrocephalus is caused therefore, by the inability of cerebrospinal fluid to gain access to or be transmitted across the subarachnoid-vascular barrier at a normal rate. Common sites of obstruction to spinal fluid flow include the foramen of Monro, the lumen of the third ventricle, the aqueduct of Sylvius, the outlets of the fourth ventricle (foramina of Magendie and Luschka) and the basilar cisternae.

Among the types of hydrocephalus seen as a result of congenital anomalies are those associated with stenosis of the aqueduct of Sylvius (Fig. 38); obstruction of the fora-

mina of the fourth ventricle (Fig. 39), and prenatal obliteration or failure to develop of the surface subarachnoid pathways (Fig. 40), particularly those at the base of the

Figure 39. Hydrocephalus due to prenatal obstruction of the foramina of Magendie and Luschka. The fourth ventricle is dilated into a huge cystlike structure filling the posterior fossa and herniating into the upper spinal canal.

Figure 38. Hydrocephalus due to congenital obstruction of the aqueduct of Sylvius. The lateral and third ventricles are dilated, but there is no demonstrable communication through the midbrain to the fourth ventricle.

Figure 40. Hydrocephalus due to prenatal obstruction or failure to develop of the intracranial surface subarachnoid pathways. There is dilatation of the entire ventricular system and cisterna magna as well.

Figure 37 Anteroposterior and lateral appearance of infant with premature closure of all the cranial sutures. Note prominence in the region of prematurely obliterated anterior fontanel.

bones. This occurs particularly in association with fusion of the coronal suture, whether alone or in combination with fusion of the other cranial sutures. Exophthalmos and choanal atresia are common findings. Chronic papilledema and optic atrophy with visual loss may also occur under these circumstances.

There is a high incidence of mental retardation among patients with craniostyostosis, particularly when multiple sutures are involved, if surgical treatment is not performed in early life. It is of primary importance, therefore, to make the correct diagnosis and carry out surgical treatment as early as possible not only to minimize the cranial deformity but to provide the best opportunity for optimum mental development.

Many types of operative procedures have been performed in this disease. In youngsters over three to five years of age, any type of procedure which decompresses the intracranial contents is probably satisfactory. In the first months of life, however, when surgery should be carried out if possible, the most physiologic type of treatment would appear to be creation of an artificial suture by linear craniectomy at the site of or parallel to the prematurely closed suture. In the first year of life new bone forms very rapidly from the dura mater and from periosteum and closes such an artificial craniectomy quickly. The use of an inert substance such as polyethylene plastic film placed over the margins of the craniectomy openings has proved satisfactory in delaying the bony closure of these artificial sutures long enough

to allow the brain to expand throughout the early period of rapid growth. It should be emphasized that this is prophylactic surgery in early life and one should not wait for signs and symptoms of increased intracranial pressure to appear before carrying out craniectomy to open up prematurely closed sutures. The prognosis for normal mental development after treatment during the first year of life is excellent when only one or two sutures are involved. After this period the percentage of patients with retardation increases markedly. In premature closure of all sutures, there may sometimes be irreversible brain damage by the time of birth.

Hydrocephalus. The central nervous system is normally bathed in its entirety in a clear colorless fluid which is contained in a series of connected spaces. These include the lateral ventricles within the cerebral hemispheres, the midline third ventricle, aqueduct of Sylvius and fourth ventricle, the large cisternae at the cerebellomedullary angle and base of the brain and the widespread intricate surface subarachnoid pathways covering the spinal cord and the cerebral and cerebellar hemispheres. There is still much uncertainty about the exact source and mechanism of formation of the cerebrospinal fluid. However, it seems clear that its point of principal origin is within the ventricles of the brain and its point of principal absorption is in the diffuse vascular bed of the pia arachnoid investing the cerebral cortex. Because of this, the fluid appears to flow from the ventricular system toward the sur-

surface subarachnoid pathways to a variety of distant locations, including the mastoid antrum, the pleural space, the peritoneal cavity, bone marrow, urinary tract and intrathoracic vascular channels. The shunting procedures which have given the most promise have been those into the peritoneal cavity, into the ureter and by way of the internal jugular vein directly into the right atrium of the heart. In the latter procedure a competent valve must be placed in the shunt tube which permits only unidirectional flow from the lateral ventricle to the blood stream. Although far from perfect, diversion of cerebrospinal fluid through a catheter from an obstructed part of the subarachnoid pathway to some area of excretion or more adequate reabsorption appears to offer today the best treatment of internal hydrocephalus available.

brain. In addition, hydrocephalus frequently occurs in association with spina bifida and especially with lumbosacral myelomeningoceles. In these instances the hydrocephalus is apparently always related to a congenital anomaly of hindbrain development which results in the so-called Arnold-Chiari malformation in which there is obliteration of the surface subarachnoid pathways around the brain stem and upper cervical spinal cord at the level of the foramen magnum. There may also be obstruction of the aqueduct of Sylvius and fourth ventricle in severe degrees of this anomaly. Hydrocephalus is also seen associated with the

arachnoid pathways in the posterior fossa. Hydrocephalus may rarely be due to congenital malformation of the cerebral vascular system, this is usually an arteriovenous malformation which obstructs the posterior third ventricle or aqueduct of Sylvius.

The symptoms and signs of hydrocephalus due to congenital anomalies are those of increased intracranial pressure. These are usually seen in early infancy. They include enlargement of the head, an increase in the normal rate of growth of the head, congestion of the scalp veins, enlargement and bulging of the anterior fontanel, separation of the cranial sutures, displacement of the eyeballs downward and abnormal ocular movements. . . .
intracranial
ity, increase

clonus and vomiting and there may be convulsions and alterations in respiration and pulse rate. In slowly advancing hydrocephalus there may be little in the way of symptomatology other than an accelerated rate of head growth.

The diagnosis of hydrocephalus is confirmed and its type may be determined by a series of tests. Every hydrocephalic infant should be studied to an extent that an authoritative decision regarding the indications for and type of treatment appropriate can be reached. These studies include: measurement of the occipitobregmatic circumference of the head and comparison of this figure with standard charts; x-ray films of the skull; bilateral puncture of the subdural spaces through the coronal suture to rule out the possibility of the presence of subdural hematomas, combined puncture of one lateral ventricle and the lumbar spinal subarachnoid space with simultaneous measurement of pressures, protein and cell content of the

fluid; introduction of a quantitative amount of a tracer dye into the cerebrospinal fluid to test its passage from one compartment to another and to test the rate of absorption of fluid from the subarachnoid space, and ventricular air studies, usually carried out with removal of only a small amount of fluid and replacement by air (30 to 50 cc.). It is only on the basis of clinical experience supported by this group of tests that surgical treatment can be planned intelligently.

If there is reasonable evidence that there is still a chance for normal development and it is established that progressive hydrocephalus is present, then the best available surgical procedure should be carried out as soon as possible. In the presence of gross irreversible central nervous system damage which precludes a desirable result no matter how successful operative treatment may be, custodial care only should be recommended. Temporizing operations which permit infants who are blind, decerebrate or otherwise irreversibly damaged to survive, but do not allow for normal brain growth, should be avoided.

The treatment of hydrocephalus is surgical. Dehydration, diuresis and all known forms of drug therapy are of no more than temporary avail. Until the past decade, the surgical treatment of hydrocephalus has been a record of occasional optimism and rare success but mostly of discouragement and failure. More recently, a variety of operative procedures in which spinal fluid has been shunted from one compartment of the spinal fluid pathway to another, or from the spinal fluid pathway to some other location in the body where it could be reabsorbed or excreted from the body, have been employed with increasing success. When obstruction has occurred in the third ventricle, a rubber or plastic catheter has been used to shunt spinal fluid from one of the lateral ventricles into the cisterna magna in the posterior fossa or into the surface subarachnoid pathway within the cervical spinal canal. If the surface subarachnoid pathways are well developed and normally patent, this operation should successfully control increased intracranial pressure. If the surface pathways are inadequate to handle the fluid shunted to them, as is usually true in very young infants who have marked hydrocephalus from aqueduct obstruction, then a further procedure must be done to remove the excess fluid from the surface subarachnoid pathways. Fluid has been shunted both from the ventricular system and from the

medicine for hundreds of years. Believing in the supernatural, early physicians applied themselves more energetically to the formulation of incantations designed to cast out demons than they did to the study of physical evidences of disease. Although Galen (131-201 A.D.) was the founder of experimental physiology, his few primitive discoveries so entranced him that he expanded his small array of facts into comprehensive theories to explain every phenomenon of pathology. Garrison stated: "Galen, with fatal facility and ingenuity, proceeded to explain everything in the light of pure theory, thus substituting a pragmatism of medical philosophy for the plain notation and interpretation of facts as taught by Hippocrates. The effect of this dogmatism and infallibility upon after-time was appalling; for . . . his assumption of omniscience was specially adapted to appease the mental indolence and flatter the complacency of those who were swayed entirely by reverence for authority." The effect of Galen's contributions was more negative than positive, and for two reasons. First, he made the fatal error in research of adopting postulates in advance and directing his investigations to their support rather than permitting his experiments to lead where they would. And second, his systemization of medical knowledge exerted of itself so great an appeal to those who came after him that for fifteen centuries anyone who questioned his conclusions was regarded as a heretic.

Surgery largely escaped such handicaps. As Susruta noted, it was less liable than internal medicine to the fallacy of conjecture. For the most part, early surgeons were practical men and this characteristic continues to distinguish them from speculative philosophers. It also accounts for their interest in and development of the basic sciences of anatomy and pathology and a working knowledge of these subjects became one of the first qualifications of a surgeon. It was, perhaps, this pragmatism of surgeons which was responsible for their low social status until modern times. The knowledge of Latin and Greek was not essential to the use of the knife and one of the sources of the attacks made upon Ambroise Paré by the physicians of his day was that he wrote in his native tongue rather than in a classical language.

The progress of surgery has been marked with successive barriers to further advancement, each of which was pushed back by a significant discovery. For the most part, these obstacles have been real rather than

philosophical. Three of these were recognized when the first incision was made and others have appeared as the limits of surgical endeavor have been widened. Perhaps the most immediate problem of the primitive surgeon was the control of hemorrhage. In the beginning there was no method of control of bleeding and prevention became the first concern of the surgeon. In the Papyrus Ebers (circa 1550 B.C.), the surgeon is adjured "to treat it with the knife, but look out that you avoid the blood vessels." Obviously, such necessity greatly restricted the scope of surgery and perhaps the outstanding qualifications of the surgeon of that day were familiarity with the anatomy of the superficial vascular system and caution and courage, in proper balance. Pressure was probably the first technique for the control of hemorrhage, and this was followed by actual cautery and use of styptics. Although the ligature was used as early as the thirteenth century, boiling oil as a hemostatic continued to be popular for more than 300 years thereafter and the absorbable ligature did not appear until the nineteenth century.

Ability to control hemorrhage markedly increased the scope of surgical practice. However, as soon as this danger was minimized, other problems became limiting factors which had not been very formidable within the restrictions imposed by uncontrollable hemorrhage. One of these was the distantly related pair of reactions, pain and surgical shock; the other was infection. It is moot as to which of these complications was the greater obstacle to further development of surgery. Since the latter continued to plague surgery long after the discovery of anesthesia and since anesthesia extended the limits of surgery into areas in which infection became a much more serious problem, relief from pain may be accepted as the triumph next in importance as well as next in time.

So long as surgical procedures were restricted to the extremities and the superficial layers of the head, neck and torso, the intensity and the duration of pain could be favorably influenced by speed of operation. So, quick decision and manual dexterity became important qualifications of a surgeon. In this era, except for the rarer massive amputations, surgical shock was not ordinarily so profound as to create serious problems. It was when the surgeon began to meddle with the contents of the peritoneal cavity that shock became a complication to be reckoned with. While anesthesia deadened

THE QUALIFICATIONS OF A SURGEON

By PAUL R. HAWLEY, M.D.

PAUL RAMSEY HAWLEY, the son of a country doctor in Indiana, practiced with his father and entered the regular army medical corps in World War I. Chief Surgeon of the European Theatre of Operations during World War II, he was responsible for the organization of the superior quality of care given to the wounded. He became Chief Medical Director of the Veterans Administration and initiated the participation of the members of medical school faculties in the treatment of veterans. In his present capacity as Director of the American College of Surgeons, Dr Hawley has made important contributions to the maintenance of the high ethical and professional standards of the surgical profession and to the education of the public.

Just as the qualifications of an aviator have changed with the development of aircraft and the qualifications of a sea captain with the transition from Roman galleys to luxury liners, so have the qualifications of the surgeon changed with the advances in surgery. Certain basic requirements for the surgeon, however, have persisted since the first incision was made for the alleviation of suffering and these will remain unchanged so long as surgery is done.

In part, these essential qualifications are those which apply to every practitioner of the healing arts—integrity, humanity, fidelity to responsibility and freedom from avarice. To these must be added one which applies particularly to the surgeon. This is intrepidity—the quality of calm judgment and decisive action in sudden crises. No one will practice surgery long before he is suddenly faced with a grave emergency in the course of an operation. To hesitate, to become

panicked is fatal. The surgeon must never become bewildered.

While centuries have not altered these basic qualifications of a surgeon, surgical progress has forced the addition of a number of other qualifications. For centuries surgery was the poor relation in the family of medical sciences. The surgeon had little formal education and he occupied a lowly social position. If these were handicaps, they were also advantages. They freed the surgeon from the rigid formalization of learning which impeded scientific progress for centuries. Unable to read Greek and Latin, he studied the patient. Susruta (fifth century, A.D.) called surgery "the first and best of the medical sciences, less liable than any other to the fallacy of conjecture and inferential practice, pure in itself, the worthy product of heaven."

In this praise of surgery are implied the obstacles which delayed advances in internal

ing tissue. Surgery is no longer a mechanical art, it is a coalition of several sciences, and those who contribute to its advancement in the future must be prepared accordingly.

Refinement of anesthesia has opened another field of surgery of vast and increasing importance. This is surgery within the chest. By overcoming Nature's intolerance of a vacuum, the anesthesiologist has made it possible for the surgeon to work leisurely upon the lungs, the great vessels and, within rapidly expanding limits, upon the heart itself. The end of restrictive limitations upon cardiac surgery is already in sight.

So much for the technical and scientific advances in surgery. Just as each technical advance introduced new problems or magnified existing ones, so have these great strides in surgical usefulness introduced new problems for the surgical profession. Only a few years ago surgery was a dangerous undertaking for the patient—so dangerous that it was considered only in urgent and critical situations in which death appeared to be the only alternative. Under such conditions, the reluctance of both the patient and the surgeon offered considerable protection against unjustified surgery.

Now that the danger of surgery has been considerably decreased—although not so greatly as some believe—two problems are increasing rapidly in importance. One of these is that too many physicians are attempting to do surgery without adequate preparation and training and the other is that too many of this group and too many adequately trained surgeons are performing operations which cannot be justified. One mark of a good surgeon is knowing when not to operate and an essential characteristic of an ethical surgeon is refraining from surgery unless there is definite indication for it.

In his presidential address at the 1953 Convocation of the American College of Surgeons, Doctor Fred W. Rankin said that "in many respects surgeons carry the heaviest responsibilities of all physicians, if only because of the harm they can do. For this reason it is essential that they never forget what they are undertaking when they lay hands upon the human body." This locates precisely the boundary of surgical endeavor across which no upright surgeon will step. During World War II a young military surgeon once boasted to Surgeon General Kirk that he had "taken a chance" in some surgery upon a patient and that he had "got away with it." "You took a chance!" replied General Kirk, "the surgeon never takes a

chance. It is the patient who takes the chance."

Many definitions have been offered to distinguish between major and minor surgery. None has been completely acceptable and there is the rapidly growing belief that almost all surgery is major in character. Diagnosis yet being an art subject to frequent inaccuracies, one who essays an exploration of the human body must be competent to deal with any situation he may encounter. The projected cholecystectomy may turn out to be an operation for carcinoma of the pancreas. To rule out all possible contingencies inherent in major surgery upon the assurance offered by preoperative diagnosis is no more defensible than venturing far to sea in a cockleshell upon the prediction of continued fair weather. Diagnosis is no more exact a science than meteorology and the granting of surgical privileges on the basis of specified operative procedures indicates total indifference to the safety of patients.

Furthermore, the surgeon is no mere technician, despite the growing tendency to so limit his function. He is a consultant to the point where he advises, and the patient agrees to, surgery. At this point, the surgeon becomes the physician in charge, responsible for all decisions in the care and treatment of the patient and this relationship is continued until it is terminated by the one or the other. The surgeon must arrive at his own diagnosis and must make his own decision as to what surgery, if any, is indicated. If his decision to operate is made solely upon the advice or request of another physician, he is in effect engaging in ghost surgery, regardless of the patient's awareness of his identity.

These requirements place the full responsibility for surgery upon the surgeon. So long as the surgical condition is paramount, the patient is a surgical patient and his care and treatment remain the obligation of the surgeon. The decisive influence of physiology upon surgical results makes it mandatory that, whenever possible, both preoperative and postoperative care be directed by one specially trained in this field, and that surgeon has shirked his duty who voluntarily relinquishes control of a surgical patient before all danger of postoperative complications has passed. In such a practice lies the chief iniquity of itinerant surgery.

One of the heaviest responsibilities of the family physician is in the choice of surgical consultants for his patients. There is only one defensible rule for him to follow and this is to make the same choice that he

the pain from rough handling of the abdominal viscera, it was less effective in preventing shock, and manual dexterity, applied particularly to gentleness in handling delicate structures, continues to be a qualification of a surgeon. While indecisive puttering is not acceptable technique, speed in recent years has been sacrificed in some degree for a more careful toilet of the operating field. Anesthesia opened the door of the abdomen to the surgeon, but he entered at rare intervals and only for urgent reasons until he learned to avoid soiling the carpet and the furniture.

While hemorrhage and shock were immediate dangers in surgical procedures, an even greater danger had almost always to be faced within a few hours after operation. Almost all wounds, whether accidental or purposeful, were infected, even though this was not always apparent to the naked eye. Healing by first intention was so rare as to cause suspicion in some surgeons. Pus was so often a concomitant of wound healing as to be regarded as possibly contributing to that process. The appearance of "laudable pus" was anxiously awaited. Since the character of the pus was some index of the pathogenicity of the invader and the amount some index of the resistance of the host, it is readily understandable that certain types of suppuration were regarded as laudable.

It is difficult to conceive of a phenomenon in medicine more baffling to the early surgeon than infection. The cause could not be detected by the unaided senses and the effects were so variable as to defy pure speculation. There is the legend that Ambrose Paré delivered the wife of a shepherd by cesarean section, using the shepherd's knife and operating in the shepherd's isolated cottage. The operation was successful and one can imagine Paré's wonder when an impressive series of his patients without exception died of peritonitis when he attempted the same procedure in a Paris hospital. So, to the special qualifications of surgeons was added a heart "of steel to bear the recurring discouragement of death and failure which followed in their wake."

The seizure of Lister upon the discoveries of Pasteur inaugurated a revolution in surgical technique. Never in history had surgery taken such a long step forward or added so much to the qualifications of a surgeon. Heretofore, largely interested in only the descriptive sciences, the surgeon suddenly found himself an experimental scientist. As Lord Moynihan said, "Every operation in

surgery [becomes] an experiment in bacteriology. . . . The success of the experiment . . . depends not only on the skill but also upon the care exercised by the surgeon in the ritual of the operation."

With hemorrhage, pain, shock and sepsis controllable if not entirely preventable, the area limits of surgery were almost removed. There remained only the obstacles to entering the thorax, which were overcome by advances in anesthesiology. Had surgeons remained primarily artists with shallow excursions into the sciences, these accomplishments might have been considered sufficient.

Fortunately, surgery has adopted no such complaisant attitude. With the technical improvements of the last decade or so now permitting operations of a magnitude not dreamed of a generation ago, it has become apparent that the ultimate limits of surgery are to be fixed not by the resources of the surgeon or by the accessibility or dispensability of the offending parts, but by the ability of the human body as a whole to withstand the onslaught made upon it and to readjust thereafter. It is in this respect that the animal organism differs most remarkably from the inanimate machine. The machine may be placed in a state of suspended animation while repairs are made, but life must be maintained in the animal organism during and after surgery. Life, insofar as can yet be demonstrated, is a continuous and complex physical chemical operation in rather delicate balance and the survival of a surgical patient often depends more upon the maintenance of this balance than upon the excellence of surgical technique.

For this reason, perhaps the most significant advances in surgery in the past few years have been in the fields of preoperative and postoperative care of the patient. Competence in these fields distinguishes the surgeon from the operator. Preoperative treatment is designed to fortify the physiology of the patient against the terrific insult to his metabolism which cannot be avoided in big surgery, postoperative treatment is directed toward the rapid re-establishment of normal physiologic processes and their maintenance thereafter. In researches seeking the solution of these problems, surgery has led the way. While it may continue to be possible for the practitioner of surgery to apply techniques of which he has little or no basic understanding, those who in the future will push back the limits of surgery must have a working knowledge of all the sciences involved in the mechanisms of liv-

SURGICAL JUDGMENT

By HAROLD LAUFMAN, M.D.

If surgery were an exact science in the strictest sense of the word, the concept of surgical judgment would never have come into being. Facts could be collated to list all possible deviations from the healthy human state and universally applicable formulas could be devised to describe accurately and unerringly the exact procedures for their correction. In such case, the student of surgery need but memorize a list of facts and develop through usage a high degree of mechanical skill to achieve pre-eminence in his field. He would never be faced with a host of conflicting variables requiring appraisal and interpretation; he would not need to make a separate decision in each case; he would not have to deal with his patients as people. He would be, in fact, no more than a superbly functioning machine.

Surgery is not, however, "exact" in that narrow sense. Insofar as the discipline of surgery is based on certain universally applicable principles of anatomy, bacteriology, physiology and related disciplines, it is a science. Insofar as it must apply these principles to the specific needs of an individual patient under particular circumstances at a given time, surgery is also an art.

Sound training in the fundamentals of surgery and a high degree of technical competence are the basic equipment of the surgeon, they are taken for granted. If he has nothing more, a surgeon may be adequate in ordinary situations. If, however, he is to translate his knowledge and apply his skills into their highest potential of healing for each individual, the surgeon must enter into the infinitely complex series of mental, moral

and physical acts which for working purposes is called *surgical judgment*.

Since it is so complex, both as a concept and as a working process, a completely adequate consideration of surgical judgment would have to deal with virtually every aspect of a surgeon's life and the whole of his psychologic structure. Yet surgical judgment is said to be something that a surgeon either has or does not have. It is perennially offered to medical students as a distinguishing excellence they may one day hope to achieve.

Because of the comprehensive nature of surgical judgment, authoritative criteria for it cannot be codified. On the other hand, since it does exist as a therapeutic tool or as a catalyst for all other therapeutic tools, it warrants a more orderly and systematic consideration than has so far been accorded it. It should not remain forever in the realm of a mystique, implicitly acknowledged but always undefined.

Judgment, in general, is not just a static condition or quality, though it is regarded as something one "has." It is actually a mental process in which man is always consciously or unconsciously engaged. Daily, a number of trivial or important decisions are made based on momentary or prior evaluations. Daily, evaluations of one sort or another are made, on which future decisions will be based. Most of the time this process is not recognized and requires little conscious attention. An effort to define it would necessitate looking back on the decisions made over a time. A certain pattern of choices would emerge, a pattern of a fairly consistent nature; the nature of this pattern

would make if he or one of his immediate family were in the position of the patient. This means that no inducement to refer a patient to a specialist should ever be considered other than the quality of patient care expected or desired.

Unethical inducements to refer patients are the product of growing competition and shrinking ideals. They are offered, and accepted, in many guises. The form best known, and probably most common, is the division of the fee collected by the specialist with the referring physician. This practice has long been outlawed by organized medicine, but despite such proscription it has increased in prevalence in many areas. Other forms of unethical inducement are practiced by some who hesitate to divide an individual fee. These are individual billing of alternate patients, wherein the specialist collects the entire fee from one patient and the referring physician from the next, the giving of lavish gifts to referring physicians, and subsidizing of young men starting practice with the understanding that they will refer their patients to the creditor. The betrayal of the trust of a patient for a few pieces of silver is on a par with the crime of Judas. Even if the choice of a consultant is not influenced by the commission received, the mere yielding to avarice in accepting it brands the physician as deficient in integrity.

Thus, the enormous increase in the capabilities of the surgeon has been accompanied by an equal increase in his responsibilities. His capabilities for good are matched by his capabilities for evil and his most important qualifications are the ability to distinguish between the two and the integrity to choose the right. In no other vocation are the words of Saint Paul more applicable: "they that will be rich fall into temptation. . . For the love of money is the root of all evil."

As often happens in other fields, efforts to codify medical ethics have confused rather than clarified these rules. Rules of etiquette among physicians have been interpolated between rules of morality and have become re-

spected as much as, if not more than, rules protecting the patient. Webster defines ethics simply as moral principles, quality or practice, the science of moral duty; and, more broadly, the science of the ideal human character and the ideal ends of human action. Medical ethics is merely the application of these principles to the practice of medicine. The Great Physician simplified medical ethics still more when He said, "Therefore all things whatsoever ye would that men should do unto you, do ye even so to them." This is all there is to medical ethics.

To summarize, the qualified surgeon must be first a physician; he must be observant, manually dexterous, both courageous and cautious, calm in the presence of disaster; he must acquire an adequate working knowledge of the basic sciences applicable in surgery and, above all, he must have integrity. Guy de Chauliac (1300-1370) wrote a prescription for a surgeon some 600 years ago to which the centuries have added little and from which they have detracted nothing. He said, "Let the surgeon be bold in all sure things, and fearful in dangerous things, let him avoid all faulty treatments and practices. He ought to be gracious to the sick, considerate to his associates, cautious in his prognostications. Let him be modest, dignified, gentle, pitiful and merciful; not covetous nor an extortionist of money, but rather let his reward be according to his work, to the means of the patient, to the quality of the issue, and to his own dignity."

tained by one surgeon do not necessarily reveal what another surgeon may expect. In order to make a cogent comparison one would need to presume approximate equality of experience, ability, facilities and judgment between the surgeons, as well as comparable lesions and risk components in the patients. A surgeon's use of the literature, therefore, must be discriminating and selective when he attempts to apply what he reads to his own practice. Although knowledge of current statistics may serve as a guiding factor to the surgeon's judgment, it cannot substitute for judgment nor even dominate it. The surgeon cannot operate on a statistical basis alone, for although it will certainly yield numbers, it cannot dependably yield meanings and interpretations.

RAPPORT IN SURGERY

Once these preparatory preoperative judgments have been made, at least tentatively, by the surgeon, he must inform and prepare the patient and responsible members of the family. A good personal rapport with them will depend on two cardinal qualities in the surgeon, which may at first seem to conflict: honesty and tact. A patient is entitled to know everything pertinent both to his condition and to the probable course of his treatment which he is capable of understanding intellectually and able to accept emotionally. His questions must be respected and answered fully but simply, without recourse to unnecessarily technical language. Professional jargon has no place with a patient; it is designed to impress rather than to inform. Oversimplification is equally out of taste, it is a condescension the patient is quick to sense and which he may justifiably resent. Needless to say, the abrupt dismissal, "Let me worry about that," to which an earlier generation of surgeons was prone, insults the patient and argues an insufficiency in the surgeon.

Even as a patient must be respected intellectually, respect must also be accorded his particular emotional system. His tensions and anxieties must be accepted as natural. It is particularly difficult to do so when they are exaggerated or "neurotic." A patient comes for help, not for censure, he needs assurance and perhaps the support of an authoritative figure, but the surgeon's "authority" must not be misused to reduce the patient's self-respect and dignity. The patient who is treated as an equal and co-operative adult will tend to be one.

STEREOTYPY AND ROUTINE

The dangers of stereotypy in general are among the most pervasive and pernicious of therapeutic fallacies. The organization of knowledge is part of the business of science; to define separate entities and classify them according to general type is a legitimate intellectual act. Except in rare instances, almost any condition in almost any patient can be placed, for the purposes of classification, into conformance with a familiar disease entity described previously in the literature or familiar to the physician. To establish this is only the first part of the surgeon's obligation. A second, sometimes larger, and equally cogent part is to know that there is no such thing as an "average" patient. Even the most "ordinary" patient with the "simplest" lesion has certain sensitivities, stresses, patterns peculiarly his own, requiring the surgeon's individual attention to his particular problem. A surgeon who works in the climate of this basic attitude will be swiftly and sensitively respondent to unexpected reactions and events for which surgeons who think in stereotypes may be unprepared.

Does a usual procedure need to be modified in its nature or degree for a particular patient? This question, again, must be answered by balancing the nature of the disease against a series of factors peculiar to a given patient. Among other things, these include: expected longevity in relation to existing pathology; the presence and severity of associated but not necessarily related infirmities; the degree of urgency deemed essential for preservation of health or life, the success of the physiologic preparation for surgery; an appraisal of the patient's tolerance for the several variations of the available procedural plans, and knowledge of the choice of goals to be sought.

Even as a patient must not be regarded as "average," so the tendency to regard procedures as "routine" must be avoided. The word is often used to indicate a tested and reliable method of approach or to describe a pattern of procedural steps which has proved dependable throughout the years in thousands of individual instances. The word "routine" is allowable, in this context, on practical and pragmatic grounds.

But when dealing, as here, with more precise meanings of concepts in terms of their ultimate implications for intellectual and clinical behavior, the word "routine" is best avoided. It suggests an unthinking, undiffer-

would serve to define the quality of judgment. Judgment can thus be defined as a series of mental acts involving an appraisal of factors leading to decision in the service of a goal.

Surgical judgment is a specialized application of this process requiring greater awareness and subject to more stringent criteria, since the attainment of such important goals depends on it. The goals of surgical judgment upon which all decisions are based and toward which all evaluations are oriented consist in the perennial aims of all therapy: *prolongation of life and alleviation of suffering*. The manner in which a surgeon employs his personal endowments, his training and his experience in the service of these ends will define him as a surgeon.

PREOPERATIVE JUDGMENT— MOTIVATIONS IN SURGERY

A patient comes to a surgeon because either he or his referring physician thinks he may need surgery. The referral, strictly speaking, is for purposes of a surgical opinion rather than for surgery *per se*. Even if a given pathologic state is ordinarily amenable to surgery, the decision for or against surgical intervention in a particular instance must be made. Such a decision involves first the accumulation of pertinent data through the indispensable classic sources: a careful history, a thorough physical examination, diagnostic laboratory findings and the surgeon's general or clinical impression of the case. Each factor in the data accruing from these sources must be assessed first individually for its own implications and then in relation to all other factors. This appraisal is made to answer three prime questions: (1) Is a surgical operation advisable at all? (2) If it is advisable, is it also feasible in terms of risk to the patient or anticipated result? (3) How might the operation have to be modified to fit a specific set of circumstances?

Often the highest product of seasoned and responsible surgical judgment is the decision not to operate. A number of influences irrelevant to the patient's welfare may be brought to bear upon the surgeon in the formation of this important decision. The surgeon may be eager for experience, he may be influenced consciously or unconsciously by his own psychologic or financial needs; the referring physician may indicate a subtle but influencing preference; the patient himself, for tangential reasons, may urge surgery.

Sometimes a patient has a vague disorder which he hopes may be magically defined and cured, sometimes he has lived with a fear of surgery long enough that he "wants to get it over with"; sometimes he is just surgery prone. Without playing psychiatrist, a surgeon must remain alert to such distortions if he is effectively to resist them.

The most dangerous artifacts introduced into the area of surgical motivation are, of course, those which may occasionally arise out of the surgeon's own distortions or out of his own self-interest. No matter how well it can be rationalized, any motive that is not based exclusively on a concern for the patient's welfare is an artifact which violates the basic principles of surgical judgment. It is in this area of mixed motive that we encounter such aberrations of surgical behavior as fee splitting, ghost surgery, irresponsible timing of operations and unjustified surgery.

If surgery is feasible at all, the only allowable motivation for it is a conclusion that it is necessary to the patient's welfare. There are, of course, different kinds and degrees of necessity. Surgery may be deemed necessary if (1) the available information indicates that the patient's condition cannot improve in a reasonable time without surgery, (2) the condition may lead to complications or death without surgery, (3) accurate diagnosis leading to more accurate therapy depends upon surgical intervention.

When, according to the valid criteria, it does seem advisable to operate, all factors must be weighed to estimate the extent and nature of risk for the particular patient involved, since the next complexus of decisions is made with a view of minimizing, insofar as possible, the attendant risks. This consideration will govern the selection of an optimal time, the most adequate available place, the course of preoperative care, the type of anesthesia, the best anatomic approach and the extent of permissible radicality. Estimation of risk will also involve some knowledge of the possible complications and a reasonably close prediction of probable outcome, based on the nature and urgency of the case in light of the best results to be hoped for. It requires knowledge of the current statistics on morbidity, complications and mortality, based not only upon the literature, but upon the surgeon's own experiences with comparable cases.

If his experience is sparse, a surgeon's use of the literature can help him in his estimates, but only up to a point. Results ob-

tained by one surgeon do not necessarily reveal what another surgeon may expect. In order to make a cogent comparison one would need to presume approximate equality of experience, ability, facilities and judgment between the surgeons, as well as comparable lesions and risk components in the patients. A surgeon's use of the literature, therefore, must be discriminating and selective when he attempts to apply what he reads to his own practice. Although knowledge of current statistics may serve as a guiding factor to the surgeon's judgment, it cannot substitute for judgment nor even dominate it. The surgeon cannot operate on a statistical basis alone, for although it will certainly yield numbers, it cannot dependably yield meanings and interpretations.

RAPPORT IN SURGERY

Once these preparatory preoperative judgments have been made, at least tentatively, by the surgeon, he must inform and prepare the patient and responsible members of the family. A good personal rapport with them will depend on two cardinal qualities in the surgeon, which may at first seem to conflict, honesty and tact. A patient is entitled to know everything pertinent both to his condition and to the probable course of his treatment which he is capable of understanding intellectually and able to accept emotionally. His questions must be respected and answered fully but simply, without recourse to unnecessarily technical language. Professional jargon has no place with a patient; it is designed to impress rather than to inform. Oversimplification is equally out of taste; it is a condescension the patient is quick to sense and which he may justifiably resent. Needless to say, the abrupt dismissal, "Let me worry about that," to which an earlier generation of surgeons was prone, insults the patient and argues an insufficiency in the surgeon.

Even as a patient must be respected intellectually, respect must also be accorded his particular emotional system. His tensions and anxieties must be accepted as natural. It is particularly difficult to do so when they are exaggerated or "neurotic." A patient comes for help, not for censure, he needs assurance and perhaps the support of an authoritative figure, but the surgeon's "authority" must not be misused to reduce the patient's self-respect and dignity. The patient who is treated as an equal and co-operative adult will tend to be one.

STEREOTYPY AND ROUTINE

The dangers of stereotypy in general are among the most pervasive and pernicious of therapeutic fallacies. The organization of knowledge is part of the business of science; to define separate entities and classify them according to general type is a legitimate intellectual act. Except in rare instances, almost any condition in almost any patient can be placed, for the purposes of classification, into conformance with a familiar disease entity described previously in the literature or familiar to the physician. To establish this is only the first part of the surgeon's obligation. A second, sometimes larger, and equally cogent part is to know that there is no such thing as an "average" patient. Even the most "ordinary" patient with the "simplest" lesion has certain sensitivities, stresses, patterns peculiarly his own, requiring the surgeon's individual attention to his particular problem. A surgeon who works in the climate of this basic attitude will be swiftly and sensitively responsive to unexpected reactions and events for which surgeons who think in stereotypes may be unprepared.

Does a usual procedure need to be modified in its nature or degree for a particular patient? This question, again, must be answered by balancing the nature of the disease against a series of factors peculiar to a given patient. Among other things, these include: expected longevity in relation to existing pathology; the presence and severity of associated but not necessarily related infirmities, the degree of urgency deemed essential for preservation of health or life, the success of the physiologic preparation for surgery, an appraisal of the patient's tolerance for the several variations of the available procedural plans, and knowledge of the choice of goals to be sought.

Even as a patient must not be regarded as "average," so the tendency to regard procedures as "routine" must be avoided. The word is often used to indicate a tested and reliable method of approach or to describe a pattern of procedural steps which has proved dependable throughout the years in thousands of individual instances. The word "routine" is allowable, in this context, on practical and pragmatic grounds.

But when dealing, as here, with more precise meanings of concepts in terms of their ultimate implications for intellectual and clinical behavior, the word "routine" is best avoided. It suggests an unthinking, undiffer-

entiating stereotypy in the surgeon's attitude which will, if adopted, obviate any real potential for what is called surgical judgment.

Flexibility must be preserved in even the most ordinary and familiar circumstance: new knowledges, insights and techniques must be correlated, unexpected variants of familiar surgical situations must be differentiated from their individual application.

In the well-disciplined surgeon who knows he will not violate basic surgical principles, and has no impulse to do so, there is no need for undeviating adherence to a rigid routine. Such a surgeon will, of course, make use of his experience, but he does not make a fetish of it. He will be able to respond to the specific needs of the moment, whether ordinary or deviant, within the principles of sound surgical practice.

FEAR AND SURGICAL JUDGMENT

There are, generally speaking, two kinds of fear common to the surgeon: rational fears which are a necessary tool of responsible surgery and irrational fears which are an unnecessary and sometimes dangerous burden.

Rational fear recognizes realistically all potential danger to the patient; it keeps the surgeon alert to physiologic changes before, during and after surgery; it makes him respectful of tissue, attentive to detail, swiftly responsive to subtle changes, careful to avoid complications. He uses rational fear to quicken his purposeful responses and sharpen his skills so that he may avoid catastrophe and meet new problems flexibly when they arise.

Irrational fears are those germane not to the patient, but to the surgeon. They may immobilize him into a repetition of familiar and "safe" routines insufficient to or irrelevant to the problem at hand. They may spur him to irresponsible innovations or deviations from sound surgical principles. The surgeon may suffer from fears based on an insufficient knowledge of the kind of problem he is dealing with or an insufficient experience of it. In such instance he would do well to obtain assistance from a surgeon better versed in the problem or to refer the patient.

There are a host of other fears arising out of threats to the surgeon's own professional or personal welfare, but having no real pertinence to the condition of the patient; fear of criticism, fear because the patient is "important," fear of extensive surgical procedures, fear conditioned by interpersonal

difficulties with colleagues. The presence of any such irrational fear may distort the surgeon's motives, presence of mind and coordination to such a degree that his best surgical judgment is impossible. When fear of this sort is a major motivating force, it threatens the logical performance of what otherwise might be acceptable surgery.

TECHNICAL SKILL AND SURGICAL JUDGMENT

A surgeon's confidence with tissue comes out of his basic physical coordination, his training and his experience. It is developed by work done in the experimental laboratory, at the autopsy table and in the operating room. Within the limits set by his manual dexterity, muscular coordination and total integration as an individual, each surgeon learns when to be gentle, how to be strong, he knows, or senses, the balance of strength and delicacy to be applied in a given instance. The sum of his relationship to tissue may be called a surgeon's technique. There are, of course, different technical styles having equal effectiveness and validity. It is interesting to observe two skilled surgeons, one with a slow, plodding manner, the other with spectacular rapidity of motion. Whatever their differences, they will have in common respect for tissue, meticulous attention to detail and a subordination of their physical procedures to the demands of their surgical judgment.

For although technique is of the greatest importance, it is so not as an end in itself, but only as a highly developed instrument of the surgeon's intention. During the war it became evident that technical skill at the operating table can be acquired rather easily by well-coordinated individuals. Often outstanding surgical assistance was rendered by medical technicians who had been stockbrokers, saloon keepers or salesmen in civilian life. But without a surgeon's education and experience, even these especially skilled people could not be expected to estimate operative risk, to prepare a patient physiologically or psychologically for surgery, to know when or when not to operate, to adapt their skills to unfamiliar situations or to carry a patient through a stormy post-operative course.

Recently, C. W. Mayo gave clear expression to the relationship between surgical skill and surgical judgment.

Surgical judgment differs from surgical skill which implies the quality of technique that, for the most part, is confined to the time a patient is un-

dergoing an operation. It is during this period that the quality of judgment should be most dominant over the best of technical skills. This statement is not made with any intent to belittle the value of dexterity but rather to place it in proper perspective.

One does not inherit either judgment or skill. They are attained in varying degrees by individual effort. Only in the "top flight" surgeon do they approach eventual perfection in balance. Good surgical judgment has its foundation in a knowledge not only of the basic sciences but also of the social sciences and the arts. The rocks on which to build are obtainable in premedical and medical schools. It is what one does with one's time after finishing medical school that determines one's rating in judgment. Some acquire good judgment the hard way, by trial and error, at particular expense, in all senses, to the patient, others acquire it by continuing study of the written word from reliable sources, by association with and observation of those of proved good surgical judgment, and by unending constructive criticism of their own work and experience. There is nothing that will limit one's surgical advancement more abruptly than will a closed mind. . . .

The surgeon whom I would select to tend my family or me must first know when not to cut, then when and where to cut, how to cut, and when to stop cutting.

JUDGMENT IN CERTAIN SPECIFICS OF SURGICAL MANAGEMENT

Experienced surgeons are aware of their responsibility in managing certain aspects of surgical care which may appear less consequential than in fact they are. Other aspects merge into related or allied disciplines and are therefore often left to the responsibility of colleagues or house staff. Whatever the necessary and desirable collaboration with such colleagues as the anesthetist, the internist or members of the house staff, the surgeon must regard himself as the fulcrum of responsibility to the patient in a surgical situation.

Decisions about mode and type of anesthesia, for example, cannot be left entirely to the anesthetist, ultimately the surgeon must decide. Unusual reactions to the induction of anesthesia demand the surgeon's decision whether to proceed or to send the patient back to his bed without surgery. Certainly many types of surgery can be postponed advantageously under these conditions.

Problems in judgment associated with so-called standard operative procedures are not necessarily inherent in application of the procedure, but in encountering, recognizing and acting upon unexpected findings necessitating change from the planned attack.

Such postoperative measures as bandaging, splinting and grading of motion may make the difference between success and

failure. In many instances, the most trying days for both the patient and the surgeon only begin with the day of surgery. It is in the postoperative period that some of the most perplexing problems in judgment arise. Since the surgeon assumes the responsibility for the patient's welfare by subjecting him to surgery, he must, by the same token, see the patient through the subsequent period. Nor should discharge from the hospital necessarily be the end of patient-surgeon relations.

In the immediate postoperative period the surgeon must cope with the intricacies of fluid and electrolyte balance; precautions against complications arising either from surgery or from unrelated infirmities by keeping in constant touch with the status of all the vital functions of the body through appropriate physical and laboratory examination, the judicious employment of medications; the timing and grading of alimentation and ambulation, and not least, the encouragement of the patient to cooperate properly. All require judgment.

In the late postoperative period, it is the surgeon's obligation to the patient, to himself and to his profession to obtain follow-up information, especially for types of surgery in which such information is not well known or in which it may possibly alter his future surgical approach to comparable problems. Much of the present-day knowledge of what to expect from surgery has come from careful judgment exercised in appraisal of results. In turn, such information is bound to affect the judgment of other surgeons.

NEWNESS IN SURGERY

The concept of newness often is confused with one of unfamiliarity. One need only reflect on how often rediscoveries are made. Yet the rediscovery is new to the rediscoverer. Familiarity by association constitutes a foundation of experience each surgeon must acquire for himself. Every skill grasped by the young surgeon in his graded program of training is, in a sense, a rediscovery. For the young man it is a discovery for himself, a realization that he is capable of doing something he was not sure he could do the day before.

One type of newness has to do with novel situations confronting a surgeon, perhaps unexpectedly, which may require a novel approach to be accomplished by variations of old and established techniques. Occasionally, discoveries are made by chance rather than by sagacity, but such advances

ordinarily require a background of experience, ability to recognize and utilize a new turn and the skill to employ the discovery to advantage. Chance discovery and pragmatism have their place in surgery as they do in other fields, but they merely complement and do not replace sound judgment.

Most surgical advances employ standard techniques with some variations but are made possible by advances in sister fields of physiologic knowledge. Surgeons readily acknowledge the debt owed to other sciences for surgical advances. The gamut spans scientific fields from physiology to physics, from immunology to electronics, from chemistry to metallurgy.

A second variety of newness is seen in certain procedures which have proved satisfactory in the originator's hands but nonetheless require a fresh experimental and experiential background by every new team of surgeons, no matter how experienced they may be in other types of surgery. Such is the case, for example, in the use of oxygenators in open heart surgery.

Experimental types of surgery undertaken under carefully controlled conditions are often reported from large university centers. The surgeon who reads reports of this kind of work can easily become overstimulated and overenthused. Despite warnings by the reporting surgeons on the experimental nature of the work, the reader may tend to accept the new procedure too readily.

It is often difficult to distinguish newness, bigness or firstness from betterness. Also, it is important to realize that certain types of surgery cannot easily be done except within certain well-controlled surroundings. To proceed with new surgery on the basis of the printed word alone is *injudicious*. One cannot expect to acquire from the printed word every detail of technical know-how and every nuance of each phase of judgment. Only by a sensible use of skepticism and by his own observations, experimental work and experience with problems and pitfalls can the surgeon arrive at a surgical philosophy acceptable to himself. Nor is experience with numbers alone a guarantee of correctness. A numerically large experience will have been qualitatively small unless it yields changes for the better by the incorporation of changing concepts, aims toward simplification, safety precautions and advancement of knowledge.

A third type of newness involves the planned employment of an operative procedure for which there is no precedent. It

is assumed that any planned operation which is to be undertaken as an experimental procedure upon a human being is preceded by its performance over and over again in animals or at the autopsy table. To undertake a life-endangering new procedure without a background of experimental work could be considered an unprincipled act. But once all phases of the technique, timing, use of special equipment and teamwork are mastered in experimental trials, and once "dry-runs" in the operating room run smoothly, a new procedure may be considered for application to a human being. It goes without saying that the patient or legal guardian must be apprised of the experimental nature of the procedure and must agree to its performance.

The odds for success based on the life-improving prospects of the proposed surgery, the surgeon's confidence in himself, his team, and his equipment, an estimate of the patient's chances of withstanding the surgery and the physiologic soundness of the procedure must all be assured within reasonable limits of expectancy. Even after successful performance, new procedures must be considered experimental until long-term follow-up studies have proved their value.

CONFLICTING GOALS

But though there are rewarding advances, some defeating or essentially insoluble problems must be faced. Ordinarily, therapeutic goals such as the prolongation of life and the alleviation of suffering are adequate criteria and we need only concern ourselves with how best to meet them. However, it is often necessary in surgery to make decisions when these two goals are not confluent at all, but *antithetical*, when the goals conflict with each other.

If the only known method of alleviating pain involves a radical alteration or destruction of the personality, is it justifiable to act to alleviate it?

If it is known that death can only be postponed in the face of unalterable, intractable pain, is it justifiable to act only to postpone it?

These are among the gravest decisions surgeons are called upon to make. They are not properly matters for surgical judgment so much as they are matters for the judgment of the surgeon. Such problems will remain in the province of philosophy until better tools are developed—mechanical, chemical or intellectual—with which to solve them. Until then surgeons can only *cope* for a

leavening of human wisdom with which to season their surgical judgment.

Surgical judgment is a distillate of physical, emotional, intellectual and moral capacities, of the training and experience which informed and disciplined them, of an individual's potential to grow, learn and create; of the capacity to apply known principles to new specific situations, and of dedication to the welfare of the patient.

No one can lay claim to superlatives in these things: one may hope to have some of each and to maintain an effectively pro-

ductive balance among them. If one recognizes with rigorous honesty his own special abilities and limitations, if he remains sensitive to the needs of patients and the demands of the profession, he may lay some claim to participation in the development and understanding of his own surgical judgment.
